1. Bing Liu Lexicon of Negative and positive words (Hu and Liu, 2004).
2. MPQA Subjectivity Lexicon, it is a Multi-Perspective Question Answering Subjectivity Lexicon (Wilson et al., 2005).

And the below automatic constructed sentiment lexicons:

3. Sentiment140 corpora containing tweets with positive or negative emoticons (Go et al., 2009).
4. NRC Hashtag Sentiment Lexicon (Mohammad and Turney, 2013).

5. SentiWordNet <sup>2</sup> (Baccianella et al., 2010), it is the result of automatically annotating all WordNet synsets according to their degrees of positivity, negativity, and neutrality.
6. Sentiment words from the MPQA word list (Riloff et al., 2003; Wilson et al., 2005). We used the positive, negative words only.
7. And we also use the test file's data of SemEval-2013 Task2 (subtaskA) <sup>3</sup> with positive and negative annotated tweets.

And based on the test results, we used the sentiment lexicons 1,3,4,5 and 7 of the ones previously mentioned, which gave the best results.

For the Arabic language, we are using the below manual constructed sentiment lexicons:

1. Arabic Sentiment Tweets Dataset<sup>4</sup>, a set of Arabic tweets containing over 10,000 entries.
2. Twitter data-set for Arabic Sentiment Analysis<sup>5</sup>, 1000 positive tweets and 1000 negative ones on various topics such as: politics and arts.
3. LABR Lexicons<sup>6</sup>.
4. NRC Hashtag Sentiment Lexicon in many languages (Mohammad and Turney, 2013).

The sentiment lexicons and labeled tweets we are taking as a base for our method do not include all the needed phrases and words. For example: the hashtag phrases (e.g. #live\_love\_laugh), the phrases with no space between the words (e.g. goodvibes), and in Arabic language the English words written in Arabic characters (e.g. cute written as كيوت).

To solve that issue, we use the web search engines to calculate the probability of using the phrase in a positive context, since the orientation of a phrase is negative if that phrase is more associated with the word "poor" and positive if it is more associated with the word "excellent". For that purpose we apply the Equation 3 for the sentiment orientation (SO) (Turney, 2002):

$$SO(p) = \log_2 \frac{hits(pNEAR"excellent") \cdot hits("poor")}{hits(pNEAR"poor") \cdot hits("excellent")} \quad (3)$$

---

<sup>2</sup>File:subjclueslen1-HLTEMNLP05.tff  
(<http://www.cs.pitt.edu/mpqa/>)

<sup>3</sup><https://www.cs.york.ac.uk/semeval-2013/task2/index.html>

<sup>4</sup><http://www.mohamedaly.info/datasets/asfd>

<sup>5</sup><https://archive.ics.uci.edu>

<sup>6</sup><http://www.mohamedaly.info/datasets/labr>

Where  $hits(x)$  is the number of pages returned from a search engine for a query based on the phrase used. For example,  $hits('poor')$  represents the number of pages returned for the query 'poor'. When there are a phrase  $p$  and 'excellent' (or 'poor') connected by  $NEAR$  operator, it is the co-occurrences of the phrase and 'excellent' (or 'poor') in same pages on a specified range of words (we choose the range of 10 words (Turney, 2002)). The SO values of the extracted phrase is considered as its sentiment intensity.

Since the main goal of SemEval2016 Task7 evaluation is the ranking of phrases provided according to their sentiment intensity, we are able to simplify the Equation 3 by removing the part shown in Equation 4, which is constant and will not effect the ranking. The final equation we use is Equation 5.

$$hits("poor")/hits("excellent") = 0.637 \quad (4)$$

$$SO(p) = \log_2 \frac{hits(pNEAR"excellent")}{hits(pNEAR"poor")} \quad (5)$$

For the Arabic language, we apply the same concept and equation, but we have to specify the words which once associated to a phrase, they make it more negative or more positive. We have done some tests, on a sample of 40 phrases from development data provided by SemEval-2016 Task7, using the translation of "poor" and "excellent" in Arabic (فقر, ممتاز). We had for many phrases the value of  $hits(p NEAR$  فقر) and  $hits(p NEAR$  ممتاز) equals to zero. Thus, we decided to choose a group of words that we find most sentimentally expressive:

1. Arabic Positive words:

رائع جميل أحسن أفضل فرح حيد ذكي

2. Arabic Negative words:

خيف قبيح أسوأ غلط حزين سيئ غبي

We first tested our method using Bing Search Engine API<sup>78</sup>. But the use of the "near:" operator, to restrict the distance between search phrases, did not work as expected. For example when we search

---

<sup>7</sup><http://www.bing.com/toolbox/bingsearchapi>

<sup>8</sup>Bing gives till 5,000 Transactions/month, set at 50 results per query, for free

| Method                 | Kendall | Spearman |
|------------------------|---------|----------|
| Google_Search_API      | 0.287   | 0.412    |
| PMI_Sentiment_Lexicons | 0.207   | 0.305    |

**Table 1:** Sample Eng. Test: Google Search API and Unsupervised PMI Sentiment Lexicons.

for the word "awesome" near the word "poor", at "near:5" we get 21360 results, and the same search with "near:10", although it should give larger number than the previous since we search in a wider range, it returns 21332 results. And we assume it is caused by the use limitation of Bing Search API, which as consequences gives bad results for the sentiment intensity prediction. Once applied on the test data provided by SemEval-2015 Task10 SubtaskE<sup>9</sup>, it gives the below results reflecting the lack of correlation:

Kendall rank correlation coefficient: 0.029

Spearman rank correlation coefficient: 0.039

Then we applied our method using Google Search API<sup>10</sup>. We use it to return the number of documents containing the phrase of the query, within ten words of 'excellent' (or 'poor') in either order.

And as text prepossessing, we removed the hashtags (#) from the phrases, and we replaced the underscores (\_) by spaces.

## 5 Experiments and Evaluations

We test our "English language system" using English test data provided by SemEval-2015 Task10 SubtaskE<sup>11</sup> (1315 of general English phrases). And since the use of Google Search API is limited by a number of queries by day, we tested Google Search API by a sample of 40 sentences from the test data file. As shown in Table 1, the Google Search API gives better results than the unsupervised PMI Sentiment Lexicons method alone.

In the Table 2 we have the results of the methods: PMI\_Sentiment\_Lexicons, PMI\_Sentiment\_Lexicons + Google\_Search\_API and Bing\_Search\_API, using English test data provided by SemEval-2015 Task10 SubtaskE. The best results are for "PMI\_Sentiment\_Lexicons + Google\_Search\_API" although the use of Google

| Method                           | Kendall | Spr.  |
|----------------------------------|---------|-------|
| PMI_Sentiment_Lexicons           | 0.443   | 0.620 |
| PMI_Sent.Lex + Google_Search_API | 0.452   | 0.631 |
| Bing_Search_API                  | 0.029   | 0.039 |

**Table 2:** Eng. Test: Bing Search API, Google Search API and PMI Sentiment Lexicons (Spr. as Spearman).

| Method                           | Kendall | Spr.  |
|----------------------------------|---------|-------|
| PMI_Sentiment_Lexicons           | 0.417   | 0.584 |
| PMI_Sent.Lex + Google_Search_API | 0.402   | 0.561 |

**Table 3:** Arabic Test: Google Search API and PMI Sentiment Lexicons (Spr. as Spearman).

Search API is applied on 5% only of the file's phrases (since those 5% were the only phrases not found in our data-set). And in case of no results returned from Google Search API, the phrase is classified Neutral and the value 0.5 is given as its sentiment intensity.

We test our "Arabic language system" using Arabic development data provided by SemEval-2016 Task7 (200 of Arabic phrases), where we used Google Search API on 20% of the phrases (since those 20% were not found in our data-set). The results are in Table 3. We can notice that the use of Google Search API did not increase the values and that would be due to our choice in Arabic positive and negative words included in the SO equation.

We apply the method with the higher score on the testing data provided by SemEval2016 task7<sup>12</sup>. A data-set was provided for each sub-task: the first sub-task's data-set contains 2799 single words and phrases of general English. The second sub-task's data-set contains 1069 English phrases of mixed polarity words (e.g. lazy Weekend). And the third data-set contains 1166 of single words and phrases commonly found in Arabic tweets. The results of the SemEval2016 Task7 are in Tables 4, 5 and 6. Compared to others teams' systems, which are based on supervised methods with extremely large training corporas (1.6M) or Deep-learning approaches, we can say that our system give good results for the mixed polarity English sub-task (since it has the second best result). Also in the Arabic phrases sub-task, we have interesting results since we applied the unsupervised PMI Sentiment Lexicons method only.

## 6 Conclusion

In this paper, we present our contribution in SemEval2016 task7: Determining Sentiment Intensity of English and Arabic Phrases, where we use web search engines for English and Arabic unsupervised sentiment intensity prediction. Applying our system to the 3 sub-tasks, faced to other teams' systems based on supervised approaches with much higher costs than ours:

- For the General English sub-task, our system have modest but interesting results.
- For the Mixed Polarity English sub-task, our system results achieve the second place.
- For the Arabic phrases sub-task, our system have very interesting results since we applied the unsupervised method only.

Although the results are encouraging, further investigation is required, in both languages, concerning the choice of positive and negative words which once associated to a phrase, they make it more negative or more positive.

## Abstract

This paper describes the iLab-Edinburgh Sentiment Analysis system, winner of the Arabic Twitter Task 7 in SemEval-2016. The system employs a hybrid approach of supervised learning and rule-based methods to predict a sentiment intensity (SI) score for a given Arabic Twitter phrase. First, the supervised method uses an ensemble of trained linear regression models to produce an initial SI score for each given text instance. Second, the resulting SI score is adjusted using a set of rules that exploit a number of publicly available sentiment lexica. The system demonstrates strong results of 0.536 Kendall score, ranking top in this task.

## 1 Introduction

Sentiment Analysis (SA) concerns the automatic extraction and classification of sentiment-related information from a given text instance (Thelwall et al., 2012). This is the first time SA on Arabic text is considered in an international competition, like SemEval. Most of previous work on SA is in English, but there have been recent attempts to address SA for Arabic, e.g. (Abdul-Mageed et al., 2012; Mourad and Darwish, 2013; Refae and Rieser, 2014c; Refae and Rieser, 2014b). Previous work in this area has mainly focused on identifying the sentiment polarity in a given tweet/phrase, whereas within SemEval-2016 Task 7, the task is to predict the Sentiment Intensity (SI) in Arabic tweets. That is, in addition to their prior association to a sentiment class, i.e. positive or negative, each text instance has an SI score that indicates the strength of its assigned sentiment on a scale from 0 to 1.

In this work, we use a combination of supervised learning and rule-based approaches, exploiting a number of publicly available sentiment lexica. We find that the quality (rather than quantity) of these lexica influence system performance for the supervised part of the system. Our best performing system demonstrates strong results of 0.536 Kendall score, ranking top in SemEval-2016 Task 7. This type of hybrid approach between rule-based and statistical methods has been demonstrated to be successful in other shared tasks, such as dialogue state tracking (Wang and Lemon, 2013).

## 2 Related Work

Research on predicting Sentiment Intensity in Arabic is still limited. For example, El-Beltagy and Ali (2013) built a sentiment lexicon in which each entry is manually assigned an SI score. Using this lexicon, they calculated the overall Sentiment Orientation for a set of Egyptian tweets by adding up the score of extracted positive/negative words. The authors observed a significant improvement of up to 20.6% in accuracy when exploiting the SI scores, as compared to results using a uniform weighting scheme, i.e. positive word= +1 and negative word= -1.

A recent effort by Eskander and Rambow (2015) presents a large-scale sentiment lexicon for Arabic called SLSA wherein each entry is associated with an SI score. The scores are assigned using a linking algorithm that links the English gloss of each Arabic entry to a synset from SentiWordNet (Esuli and Sebastiani, 2006), which is a large-scale sentiment lexicon for English with SI scores. SLSA

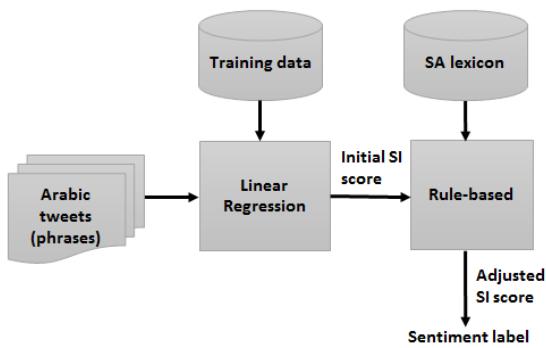

is publicly available, and contains up-to-date coverage with nearly 35k lemma. However, SLSA covers only Modern Standard Arabic (MSA), which differs substantially from Dialectal Arabic (DA) typically used in social media platforms (Habash et al., 2013).

Other work that built sentiment lexica for Arabic either includes SA labels without SI scores, e.g. (Abdul-Mageed et al., 2011), or suffers from having duplicated and inflected (surface form) entries, e.g. (Abdul-Mageed and Diab, 2014). Others have not been made publicly available yet, e.g. (Mahyoub et al., 2014).

In this work, we make use of publicly available SI lexica and also contribute to ongoing efforts in automatically creating SI lexica for Arabic.

### 3 Approach

The proposed system uses a hybrid approach of supervised learning and rules for determining the sentiment orientation and assigning an SI score for a given Arabic phrase (see Figure 1). The assigned scores are real-valued ranging from 0 to 1, with the interval  $[0, 0.5]$  associated with negative sentiment and the interval  $[0.5, 1]$  associated with positive sentiment.

**Figure 1:** Hybrid system architecture.

#### 3.1 Supervised Learning Component: Training LR models

The supervised part of the system uses Linear Regression (LR),<sup>1</sup> following Amir et al. (2015). To train the LR model, we use training data comprising publicly available sentiment lexica of posi-

<sup>1</sup>We use WEKA’s implementation of the LR scheme (Witten et al., 2013) with the default parameters configuration.

tive/negative words along with their SI scores (training data-sets are described in section 4.1). We use word-lemma unigrams as features for training the LR models. The trained LR model is used to predict an initial SI score for each given text instance.

Training an LR model on thousands of data instances, such as those we used in our system to train the LR models (see section 4.1), can result in a significant increase in training time. For instance, we recorded a training time of more than 48 hours on a training-set of 10k instances (using a 64-bit operating system with 3.20 GHz, 48 core, 512GB RAM). Therefore, we experimented with several alternative settings. In our experiments, the best results (in terms of speed) are reached using a *bagging* method that generates multiple versions of a predictor, each of which is trained on a different sub-set of the learning data (Breiman, 1996). Each predictor produces a numerical value representing its prediction on a given test instance. The predictors are combined by averaging the output. In our experiments, we used an ensemble of 10 predictors, following (Banko and Brill, 2001), which produced a considerable reduction in training time (12.6 minutes to train an LR model using 10k instances).

#### 3.2 Rule-based Component

In the second part of the system, the initial SI scores are passed to a rule-based component wherein a set of hand-crafted rules are applied to adjust the SI scores. The rules we use are inspired by those proposed by Taboada et al. (2011) and Thelwall et al. (2012) for lexicon-based SA. In particular, we use a combination of three publicly available sentiment lexica (see Section 4.2)<sup>2</sup> together with the following rules:

- Whenever a negative word from the combined lexicon (section 4.2) is detected, the SI score will be scaled towards negative  $[0, 0.5]$ .
- Same for positive words, except that the SI score will be scaled towards positive  $[0.5, 1]$ .
- If a negator is detected, the score will be shifted by a fixed amount, i.e.  $+0.4 / - 0.4$ . The

<sup>2</sup>Note that the sentiment lexica used in the 2nd phase are only associated with their sentiment labels, i.e. positive and negative, and are different from sentiment lexica used in the 1st phase of the system to train LR models.

only exception is when the SI score is between [0.45, 0.55]; then it will be considered neutral and will not be affected by negation.

- Finally, if no entries are found in the combined lexicon, then the final score will be the SI score initially assigned by the LR ensemble.

## 4 Data and Sentiment Lexica

### 4.1 Resources Used in the 1st Phase of the System: Training the LR Models

For the supervised LR models, we train with the following publicly available sentiment lexica that include SI scores. Note that the system that entered the competition only uses the labMT1.0 Sentiment Lexicon (see Section 6).

**labMT1.0 Sentiment Lexicon:** This is a compiled list of the most frequently-used 10k Arabic words from several resources including Twitter by Dodds et al. (2015). Each entry was manually annotated by 50 native speakers via Amazon MTurk using a nine-point-scale (1 very-negative/ 5 neutral/ 9 very-positive). We re-scale the manually assigned SI values to [0,1].

**9k manually annotated Arabic Twitter data-set (Ar-tweet):** This is a manually annotated and publicly available multi-dialect data-set of 9k Arabic tweets (Refaee and Rieser, 2014a). A feature vector representation of these tweets is created forming a list/lexicon of word-based unigrams. We add SI scores to this lexicon using an SVM classifier, following (Guyon et al., 2002). The classifier ranks the words according to how informative/useful they are for predicting the positive/negative label, see Table 1. Excluding words with a weight=0, the current list includes 9,785 words/features along with their weights/coefficients as assigned by the SVM classifier. Again, the SVM coefficients are re-scaled to [0,1].

**SLSA v1.0 lexicon:** This is a freely available sentiment lexicon for MSA (Eskander and Rambow, 2015). The lexicon is composed of nearly 35k entries annotated with their SI scores using a linking algorithm, as described in Section 2.

### 4.2 Resources Used in the 2nd Phase of the System: Rule-based Method

For the rule-based part of the system, the entries of the sentiment lexica do not need to be associated with SI scores. We therefore use a combination of the following resources:

**ArabSenti sentiment lexicon:** This is a freely available and manually annotated sentiment lexicon of 1,492 words that was created by Abdul-Mageed et al. (2011). Each entry is associated with a positive/negative sentiment label.

**MPQA English sentiment lexicon:** This is a manually annotated English lexicon that is created and made publicly available by Wilson et al. (2005). We automatically translate the lexicon (using Google Translate) and then manually filter it to remove irrelevant or no-sentiment-bearing words. The resultant lexicon includes 2,627 entries.

**A manually annotated dialectal sentiment lexicon:** This is a publicly available sentiment lexicon of 489 dialectal Arabic words. The lexicon is manually annotated by native speakers of Arabic (Refaee and Rieser, 2014a).<sup>3</sup>

### 4.3 Data Used for Developing and Evaluating the System

We use the data sets provided by SemEval Task 7.

**SemEval’16 gold-standard development-set:** This is a list of 200 instances (words/phrases taken from Arabic tweets) with their SI scores manually assigned. The entries can include negations. This set is used to evaluate different versions of the system.

**SemEval’16 gold-standard test-set:** This is a list of 1,166 instances (words/phrases taken from Arabic tweets) with their SI scores manually assigned. This data-set is used to evaluate the final system.

## 5 Data Pre-processing

We adopt a number of pre-processing techniques to tackle informality and alleviate the noise typically encountered in social media, following previous work, e.g. (Go et al., 2009; Bifet and Frank,

<sup>3</sup>The latter two lexica are available at: <http://goo.gl/qNLIZZ>

| ID | Positive |                 |            | Negative |             |            |
|----|----------|-----------------|------------|----------|-------------|------------|
|    | Arabic   | English         | SVM-weight | Arabic   | English     | SVM-weight |
| 1  | مبروك    | congratulations | 0.7378     | ابليس    | devil       | -0.0327    |
| 2  | جميل     | beautiful       | 0.6337     | ارهاب    | terrorism   | -0.5145    |
| 3  | حلو      | nice            | 0.5178     | دمار     | destruction | -0.3653    |
| 4  | ابداع    | creative        | 0.4878     | حقد      | hatred      | -0.3474    |
| 5  | ابطال    | heros           | 0.0653     | جحيم     | hell        | -0.3345    |

**Table 1:** Examples of the most predictive word uni-grams in the Ar-tweet data-set as evaluated by an SVM.

2010; Kouloumpis et al., 2011; Agarwal et al., 2011; Ahmed et al., 2013; Balahur et al., 2014; Rosenthal et al., 2014). The following procedures are applied to Ar-tweet (section 4.1) and SemEval’s data-sets (section 4.3). Text lemmatisation is applied to all data described in section 4.

- **Normalising conventional symbols of Twitter:** this involves detecting entities like: #hashtags, @user-names, RT, and URLs; and replacing them by place-holders.
- **Normalising exchangeable Arabic letters:** mapping letters with various forms (i.e. alef and yaa) to their representative character.
- **Removing punctuations and normalising digits.**
- **Reducing emphasised words/expressive lengthening:** this involves normalising word-lengthening effects. In particular, a word that has a letter repeated subsequently more than 2 times will be reduced to 2 (e.g. *sadddd* is reduced to *sadd*).
- **Text lemmatisation:** we use lemmatised word-form to maximise coverage of the combined sentiment lexicon, following Taboada et al. (2011).<sup>4</sup>

## 6 Experiments and Results

We experimented using different combinations of lexical features (word-lemma unigrams) to train the LR models used in the 1st part of the system. The 2nd part is fixed throughout. Results are summarised in Table 2. The reported results are the final outcomes for the entire system, i.e. after adjusting IS

<sup>4</sup>For lemmatisation, we use a stat-of-the-art Arabic morphological analyser, namely MADAMIRA v1.0 (Pasha et al., 2014).

scores in phase 2. Overall, we recorded an average improvement of 14% for applying the 2nd phase of the system. We report on Kendall’s rank correlation coefficient ( $\tau$ ) and Spearman’s coefficient ( $\rho$ ) to account for SI ordering. Further details of the task, data and competing systems can be found in the task description paper (Kiritchenko et al., 2016).

### System 1: (official submission to SemEval-16)

This version of the system attained the best performance at a Kendall score of 0.5362 using lexical features based on the LabMT lexicon. This version has entered the competition and won Task 7.

**System 2:** This version uses features based on the Ar-tweet lexicon, which have resulted in a significantly ( $p < 0.05$ ) lower performance as compared to LabMT at 0.0243  $\tau$ . A possible explanation for the performance variation is that the Ar-tweet lexicon is an auto-generated one. This auto-generation makes it prone to the inclusion of ‘indirect’ sentiment indicators (i.e. indicators which are merely inferred by the SVM model), because, for example, they are likely to appear in a negative political context. For instance, the SVM model assigned a strong negative weight of  $-0.78$  for the feature *Bashar Al-Asad*, which is currently occurring in the context of the Syrian civil war. Thelwall et al. (2012) argue that such a feature can become outdated/irrelevant at a different point in time. Furthermore, human annotators, such as those recruited to annotate SemEval’s test-set, are more likely to assign a neutral SI score to a feature like *Bashar Al-Asad*. In future, we will explore setting threshold values to filter features with lower SVM-weights as a mechanism to avoid the presence of indirect sentiment-bearing features.

**System 3:** Using SLSA, this version of the system is able to attain a comparable score to that recorded

| System | Features            | Kendall’s $\tau$ coefficient | Spearman’s $\rho$ coefficient |
|--------|---------------------|------------------------------|-------------------------------|
| 1*     | <i>labMT1.0</i>     | <b>0.5362</b>                | <b>0.67997</b>                |
| 2      | Ar-tweet SVM-coeff. | 0.0243                       | 0.04329                       |
| 3      | SLSA                | 0.5244                       | 0.65647                       |
| 4      | 1 + 2               | 0.5261                       | 0.66825                       |
| 5      | 1 + 3               | 0.5256                       | 0.67461                       |
| 6      | 1 + 2 + 3           | 0.5141                       | 0.66450                       |

**Table 2:** Results on SemEval’16 gold-standard test-set using different lexical features for LR models. \*System 1 entered the competition.

with LabMT. Although auto-generated (see section 4.1), SLSA is able to attain a Kendall score of up to 0.5244. SLSA has the advantage of being more than 3 times larger in size than LabMT (System 1) and Ar-tweet (System 2). In addition, the auto-generated SI scores in SLSA differs from the ones generated with SVM in Ar-tweet (System 2), as the former relies on linking Arabic entries to their corresponding English synset in SentiWordNet (Esuli and Sebastiani, 2006). Furthermore, being only based on MSA, SLSA can be assumed to be less noisy, especially when mapped to lemma-form, compared to slang and spelling variation in DA.

**System 4:** Combining LabMT and Ar-tweet has resulted in a comparable performance to System 3 at a Kendall score of 0.5261. However, this system is still not able to outperform that using LabMT on its own (see System 1). A possible explanation is that the presence of Ar-tweet results in introducing more noise than improving coverage of features (see System 2), resulting in slight degrading below the score attained by LabMT on its own (System 1).

**System 5:** Combining LabMT and SLSA has resulted in a slight improvement over using SLSA on its own, but still not competing with the performance of LabMT. However, when only considering phase 1 on its own, LabMT+SLSA performs best at a Kendall score of 0.377. In future work, we plan to investigate possible interactions between SLSA and the lexica used in phase 2.

**System 6:** Finally, combining all the training data still cannot reach the performance of LabMT on its own. It is also interesting to note that adding the auto-generated Ar-tweet caused a slight drop in Kendal score, compared to only using LabMT+SLSA (System 5).

## 7 Conclusion

This paper describes the iLab-Edinburgh Sentiment Analysis system, which is the top performing system of Arabic Twitter subtask for SemEval-2016 Task 7 (Kiritchenko et al., 2016). The aim of the task is to determine Sentiment Intensity for phrases taken from Arabic tweets. The proposed system consists of two phases: First, an ensemble of linear regression models are trained on lexicon-based word-lemma unigrams. Second, the SI scores are adjusted using a set of rules, leveraging pre-existing sentiment lexica. We experiment with different lexica for training the LR models. We find that the best results are attained using a manually annotated lexicon, labMT1.0 Sentiment Lexicon (Dodds et al., 2015). We also observe a drop in performance when adding features based on an auto-generated lexicon, which we attribute to noise. This highlights the need for high quality sentiment lexica for this task.

## **Abstract**

We present a novel method for determining sentiment intensity. The main goal is to assign a phrase a score from 0 to 1 which indicates the strength of its association with positive sentiment. The proposed model uses a rich set of features with Gaussian processes regression model that computes the final score. The system was evaluated on the data from 7th task of SemEval 2016. Our regression model trained on the development data reached Kendall rank correlation of 0.659 on general English phrases and 0.414 on English Twitter test data.

## **1 Introduction**

A great part of today's communication takes place on the Internet. Many companies make their business on the Web, it is possible to read newspapers through this media, etc. All these topics are tightly connected with forums, reviews and comments where users express their opinions and feelings. This great amount of short messages is a very rich source of information. For example companies can survey how people appreciate their goods or services. Social media such as Twitter or Facebook can also provide large amount of data for opinion and sentiment analysis.

Sentiment analysis can be seen as a part of opinion mining that gives the affective part of an opinion (Kim and Hovy, 2004). The short texts are usually assigned either positive or negative sentiment (i.e. sentiment polarity). It can be done for example by text categorization techniques. The minimum

cuts are used for this task in (Pang and Lee, 2004). Another sentiment analysis approach based on Latent Dirichlet Allocation (LDA) is proposed in (Li et al., 2010).

Many researchers evaluate their approaches on movie or product reviews. Lately, with the boom of social networks, there are also applications that analyze sentiment on Twitter (Wang et al., 2011).

An important progress was made thanks to the SemEval workshop (Rosenthal et al., 2015) in a sentiment analysis task. The task of determining sentiment intensity was introduced as a part of SemEval 2015 task 10. The goal of this task is to associate a word (or a short phrase) with a score that indicates its sentiment level. A score of 1 means that the phrase is fully positive whereas 0 is assigned to negative ones. This approach allows much more fine-grained sentiment evaluation. This year, sentiment intensity determination is the objective of the task 7 (Kiritchenko et al., 2016) and aims at three separate datasets: General English phrases, English Twitter and Arabic Twitter.

An interesting method that uses no linguistic resources and is based on word embeddings was proposed in (Astudillo et al., 2015). The system reached Kendall rank correlation of 0.625 on the SemEval 2015 test data. Another successful system (Zhang et al., 2015) used sentiment lexicons and a regression model to determine the sentiment intensity.

The proposed system computes a rich set of features which are further used to train a regression model that computes the final sentiment intensity score. Four different types of features are proposed:

- lexicon based features;

| List  | hp  | p   | n   | hn  | int | inv | dim |
|-------|-----|-----|-----|-----|-----|-----|-----|
| Words | 171 | 772 | 782 | 554 | 83  | 15  | 31  |

**Table 1:** Numbers of words in the JRC sentiment lexicon

- word2vec embeddings (Mikolov et al., 2013) based features;
- classifier based features;
- other features.

The paper is organized as follows. Section 2 describes the proposed system. Section 3 summarizes the experiments conducted with individual features and presents further the final results on the test data. Section 4 then concludes the paper and lists some perspectives for the future research.

## 2 Proposed System

The first part of this section is focused on the proposed features while the second one deals with the regression model.

The first group of the features used in the proposed system is built upon the sentiment lexicons.

### 2.1 Sentiment Lexicons

#### 2.1.1 AFINN

AFINN 111 (Nielsen, 2011) contains 2,477 English words or 2-word phrases. All entries are associated with an integer value in the interval from -5 to 5.

Therefore, we have normalized these numbers to the interval [0; 1].

#### 2.1.2 JRC

This lexicon was created by using the approach proposed in (Steinberger et al., 2012). It contains four lists of words grouped according to their sentiment (*hp* - highly positive, *p* = positive, *n* = negative, *hn* = highly negative) and additional lists of intensifiers (*int*), inverters (*inv*) and diminishers (*dim*). Table 1 summarizes the numbers of words in these lists.

We have joined the four lists and associated all entries with values 0, 0.25, 0.75 or 1 corresponding to its presence in the *hn*, *n*, *p* or *hp* list respectively.

#### 2.1.3 SentiWordNet

SentiWordNet (SWN) is a large lexicon for sentiment analysis and opinion mining applica-

tions (Esuli and Sebastiani, 2006). We used the version 3.0 (Baccianella et al., 2010) which contains the results of automatic annotation of synsets from the WordNet dictionary. Each synset is annotated with three scores: *positivity*, *negativity* and *objectivity*. The sum of these three values is always equal to 1. Each word can have several entries for different meanings and for different Parts Of Speech (POS) tags.

To obtain one sentiment intensity value, we compute a score according to the Equation 1.

$$\frac{1}{P} \sum_{p=1}^P \sum_{m=1}^M \frac{1}{m} (Pos_{p,m} - Neg_{p,m}) \quad (1)$$

where  $P$  is the number of POS tags that the word has entries for and  $M$  is the number of meanings that the word can have.  $Pos_{p,m}$  and  $Neg_{p,m}$  are the positivity and negativity word values with the given POS  $p$  and meaning  $m$ . The *objectivity* value was not used in this computation.

### 2.2 Features

We list below the features that we used to build our regression model. The features that are built upon the dictionaries (i.e. Direct search, W2V search and Rule based W2V search) are computed for each of the above described dictionaries.

1. **Direct search:** We search an intensity value of a particular word in the dictionary (if present, the result is its value, if not, the result is the neutral value 0.5). For multi-word phrases, we compute the arithmetic mean of all word values in the phrase.
2. **W2V search:** This approach is motivated by the assumption that semantically close words have often also similar sentiment (e.g. “nice” and “fine”). Of course, some exceptions can occur (e.g. “good” and “bad”), however we would like to minimize their impact by averaging a significant number of other close words.

Word2vec is used to identify  $N$  semantically closest words from the dictionary for a word given. The resulting value is computed accord-

ing to the Equation 2.

$$score = \frac{1}{KN} \sum_{k=1}^K \sum_{n=1}^N int(word_{k,n}) \quad (2)$$

where  $K$  is the number of words in the analyzed phrase,  $N$  is the number of most similar words identified by word2vec and  $int(word_{k,n})$  denotes the intensity value of  $n$ -th most similar word to the  $k$ -th. The intensity value is provided by a particular dictionary (described above).

3. **Rule based (rb) W2V search:** This feature computing approach is an extension of the previous one with two significant differences:

- It first searches each word in the lists of diminishers, inverters and intensifiers. If the target word is not contained in these lists, we use word2vec and the dictionaries to compute the intensity (similarly as in the previous case).
- The obtained value is further fine-tuned using three rules:
  - If the phrase contains a diminisher and is positive (intensity  $> 0.5$ ), it is multiplied by a constant lesser than 1 (if negative, by a constant greater than 1)<sup>1</sup>.
  - If the phrase contains an intensifier and is positive, it is multiplied by a constant greater than 1 (if negative by constant lesser than 1)<sup>1</sup>.
  - If the phrase contains an inverter, its value is subtracted from 1.

4. **Classifier output:** We use the 5-level Stanford sentiment classifier proposed by Socher in (Socher et al., 2013). The classifier returns the probabilities of five labels. We compute the final sentiment intensity using a weighted sum of the probabilities with the following weights: -1,-0.5, 0, 0.5, 1 (1 for very positive phrases). This approach gives a value from the interval from -1 to 1 and it is thus normalized to the interval from 0 to 1.

---

<sup>1</sup>Constant values were set experimentally on the development data to 0.85 and 1.15 respectively.

## 5. Other (simple) features

- **Word count:** number of words in a phrase
- **Diminisher:** binary feature, 1 represents a presence of a diminisher (e.g. word “less”)
- **Inverter:** binary feature, 1 represents a presence of an inverter (e.g. word “not”)
- **Intensifier:** binary feature, 1 represents a presence of an intensifier (e.g. word “more”)<sup>2</sup>

### 2.3 Regression Model

To combine the above described features and to obtain the final result we use a regression model. Because of our experience with the Weka package (Hall et al., 2009) we chose this tool for implementation. We did a comparison of several regression models that are implemented in this package and based on the experiments performed on the SemEval development data we chose Gaussian processes (Rasmussen, 2006) as a good candidate for creating the regression model.

## 3 Experimental Results

First, the development data containing 200 annotated words and phrases were provided for each subtask. The general English test dataset contains 2,799 words and phrases and the English Twitter dataset contains 1,069 phrases. All of the presented experiments are done on the general English test dataset. The testing gold data were not provided. Therefore, we have tuned our system on the development data as briefly presented below.

### 3.1 Results on General English Test Dataset

#### 3.1.1 Performance of the Individual Features

We first use all proposed features (excluding binary and word count features) separately to check their individual performance. Table 2 shows the results of this experiment.

We have set the parameter  $N = 16$  in the W2V search feature computing approach because this value gave the best results on the development data.

---

<sup>2</sup>The three last features are based on the lists provided by the JRC lexicon with a few words that were present in the development data and not in these lists.

| Feature             | Kendall | Spearman |
|---------------------|---------|----------|
| AFINN direct search | 0.435   | 0.560    |
| JRC direct search   | 0.467   | 0.603    |
| SWN direct search   | 0.438   | 0.617    |
| AFINN W2V search    | 0.510   | 0.698    |
| JRC W2V search      | 0.527   | 0.720    |
| SWN W2V search      | 0.458   | 0.639    |
| AFINN rb W2V        | 0.557   | 0.753    |
| JRC rb W2V          | 0.541   | 0.726    |
| SWN rb W2V          | 0.464   | 0.650    |
| Classifier output   | 0.423   | 0.591    |

**Table 2:** Performance of the individual features on general English test dataset

| Feature set    | Kendall      | Spearman     |
|----------------|--------------|--------------|
| without SWN    | <b>0.659</b> | <b>0.854</b> |
| without binary | 0.630        | 0.831        |
| all features   | 0.632        | 0.834        |

**Table 3:** Results of the regression model with the different feature sets on general English test dataset

We can conclude that the superior feature is *AFINN rb W2V* followed by *JRC rb W2V* and *JRC W2V search*. The other features have somewhat worse results but still might be usable in the final system.

### 3.1.2 Results of the Regression Model

Table 3 presents the results of the final regression model on general English test dataset. This model was trained on the development data. The bold-faced numbers indicate the results submitted to the SemEval. *Without SWN* means that we have used all the features except the three features based on the SWN dictionary. *Without binary* means that we have used all the features except the three binary features and the *word count* feature. Based on this experiment, we have decided not to use the SWN features in the submission because of its slightly lower performance on the development data. We have measured the performance on the development data using a ten fold cross-validation.

### 3.1.3 Comparison with the Top Three Teams

Table 4 shows the final results of the top three teams for the SemEval 2016 task 7 (general English subtask). This table shows that the performance of our system is close to the first one particularly when measured by Spearman correlation.

| Team            | Kendall | Spearman |
|-----------------|---------|----------|
| ECNU            | 0.704   | 0.863    |
| UWB (presented) | 0.659   | 0.854    |
| LSIS            | 0.350   | 0.508    |

**Table 4:** Comparison of the top three teams competing in SemEval 2016 task 7 general English subtask

| Team            | Kendall | Spearman |
|-----------------|---------|----------|
| ECNU            | 0.523   | 0.674    |
| LSIS            | 0.422   | 0.591    |
| UWB (presented) | 0.414   | 0.578    |

**Table 5:** Comparison of the top three teams competing in SemEval 2016 task 7 English Twitter subtask

## 3.2 Results on English Twitter

To show the robustness of our approach, we have evaluated the proposed model also on the English Twitter test data from the SemEval task 7. We did not use any tuning of the method for the rather specific data from Twitter. We just trained the model on the English Twitter development data and tested it on the test data. Table 5 shows the results of three best performing systems submitted to SemEval 2016 task 7, English Twitter subtask. The comparison shows that the performance is not far away from the two better systems.

## 4 Conclusion and Perspectives

We proposed a novel method for sentiment intensity determination. The method uses a rich set of features based on three sentiment lexicons, output of a sentiment classifier and binary features based on lists of modifiers. We first evaluated the features separately on the test data. Then we utilized a Gaussian processes regression model which combines the proposed features and computes the final sentiment intensity. The final system was submitted to the task 7 of the SemEval 2016 competition. The regression model trained on the SemEval development data reached Kendall rank correlation of 0.659 on general English phrases and 0.414 on English Twitter test data.

One perspective is using more sophisticated phrase parametrization. Another one is to prepare word embedding algorithm that groups together words with similar sentiment.

# NileTMRG at SemEval-2016 Task 7: Deriving Prior Polarities for Arabic Sentiment Terms

Samhaa R. El-Beltagy

Center for Informatics Sciences

Nile University, Juhayna Square, Sheikh Zayed City

Giza, Egypt

samhaa@computer.org

## Abstract

This paper presents a model that was developed to address SemEval Task 7: “Determining Sentiment Intensity of English and Arabic Phrases”, with focus on ‘Arabic Phrases’. The goal of this task is to determine the degree to which some given term is associated with positive sentiment. The underlying premise behind the model that we have adopted is that determining the context (positive or negative) in which a term usually occurs can determine its strength. Since the focus is on Twitter terms, Twitter was used to collect tweets for each term for which a strength value was to be derived. An Arabic sentiment analyzer, was then used to assign a polarity to each of these tweets, thus defining their context. We then experimented with normalized point wise mutual information with and without linear regression to assign intensity scores to input terms. The output of the model that we’ve adopted ranked at two out of the three presented systems for this task with a Kendall score of 0.475.

## 1 Introduction

During the past few years, interest in sentiment analysis has surged. Sentiment lexicons are often an essential component for building sentiment analysis systems. Entries in sentiment lexicons can vary significantly in terms of how strongly they re-

flect positive or negative sentiment. For example, while both the terms “good” and “amazing” reflect a positive sentiment, the term “amazing” is stronger and more positive than “good”. In this paper, we address early work that has been conducted to determine the intensity of Arabic twitter sentiment terms with respect to positive sentiment. Since the desired task is to determine the “positive strength” of a word, the results can be interpreted as follows: the closer the term score is to 1, the stronger it is as a positive indicator; the closer it is to 0, the stronger it is as a negative indicator. Terms that can be used in both positive and negative contexts will usually fall somewhere in the middle.

While this task was introduced in SemEval--2015 as Task 10- sub-task E (Rosenthal et al. 2015) for English terms, this is the first time that it has been introduced for Arabic terms. Addressing this task for Arabic has to take place in the absence of many resources that are available for English. In this work we make of use an Arabic sentiment analyzer (El-Beltagy et al. 2016) that was developed by our team as well as of a sentiment lexicon that was also developed within by same team and which is publicly available for research purposes (El-Beltagy 2016).

The main idea behind this work is to try to collect a representative number of tweets for each term for which a strength value is to be derived and to then classify those tweets in terms of polarity. This

classification would then be used for calculating the co-relation between positive sentiments and the original terms using normalized point wise mutual information (nPMI) (Bouma 2009). However, as will be detailed in section 3.1, there were cases when tweets were not available for input terms, or when they were too few. A small sample of development data was also supplied with the task. We have basically used this data set to test the developed model and to make adjustments when needed.

The rest of this paper is organized as follows: section 2 briefly outlines related work; section 3 provides an overview of the developed model, section 4 presents the evaluation results and future directions, while section 5 concludes this paper.

## 2 Related Work

Because sentiment lexicons are an integral part of many sentiment analysis systems, many such lexicons have been developed for the English language. The most commonly used English lexicons include: SentiWordNet (Baccianella et al. 2010), Bing Liu’s opinion lexicon (Liu 2010), and the MPQA subjectivity lexicon (Wilson et al. 2005). Recently, Twitter specific lexicons have also come into existence and are increasing being used. These include the Hashtag Sentiment Lexicon and the Sentiment140 Lexicon (Mohammad et al. 2013) (Kiritchenko et al. 2014). However despite the availability of many English lexicons, only a few include a sentiment score, with work on automatically assigning such a score only recently starting to attract attention. This particular research area was introduced as a subtask in SemEval-2015- task10. The top performing team for this sub-task, employed word embeddings to train a logistic regression model for assigning scores to sentiment terms (Astudillo et al. 2015). The second best performing team, used 6 different sentiment lexicons to score input terms (2 manually created, and 4 automatically created). Basically, input terms were compared against entries in the lexicons. If a term was found in a manually constructed lexicon, it was assigned a value of 1 or -1, depending on its polarity. If it was found in any of the automatically created lexicons, it was assigned the score found in those lexicons. If it was not found in any of the used lexicons, it was assigned a default value (Hamdan et al. 2015).

Arabic lexicons are much more scarce than their English counterparts, and are often translated versions of an existing English lexicon. An example of this is the Arabic translated version of the NRC word emotion association lexicon (EmoLex) (Mohammad & Turney 2013).

There have been some attempts to assign scores to Arabic lexicon terms. (El-Beltagy & Ali 2013) presented a method for semi-automatically building a sentiment lexicon as well as two different approaches for assigning scores to sentiment terms. The authors also demonstrated that the introduction of sentiment scores can increase the accuracy of sentiment analysis. (Eskander & Rambow 2015) constructed a sentiment lexicon by devising a matching algorithm that tries to match entries in the lexicon of an Arabic morphological analyzer to entries in SentiWordNet (Baccianella et al. 2010). When a match is found, a link is created between the lexicon entry and the matching entry in SentiWordNet and the scores of the matching term in SentiWordNet are assigned to that entry.

## 3 Model Overview

In order to assign strength scores to a given list of terms (input terms), a number of steps are carried out. These steps can be summarized as follows:

1. Collect tweets for input terms
2. Classify and index collected tweets
3. Calculate a score for each term

Each of the above steps is explained in the following subsections.

### 3.1 Data Collection

Since the goal of our work was to try to determine the correlation between a given term and positive or negative sentiments, we had to obtain a representative set of tweets for each term. We have chosen to retrieve 500 tweets for each term using Twitter’s search API (Twitter 2016). There were cases however, when the search API was unable to retrieve this number of tweets and cases where no tweets were retrieved at all. It must also be noted that even though the flag that prevents retweets from being retrieved was set when invoking Twitter search, many tweets were in fact identical to other tweets in the tweet set. To eliminate those

from the dataset, they were filtered out using the Jaccard similarity measure (Leskovec et al. 2014).

For cases when only very few tweets ( less than 15) could be retrieved or when no tweets could be retrieved, an extra processing step was performed. In this step, a check was used to determine if the term in question was a hashtag. If it was, the hash symbol was removed from the term and so were any underscores. The resulting phrase was then used to query Twitter. If the term was not a hashtag or if the step just described also resulted in the retrieval of very few or no tweets, then the term was stemmed using a simple stemmer (El-Beltagy & Rafea 2011) and re-sent to Twitter as a query.

For the supplied 1166 test phrases in the Arabic set, 141 had to undergo these extra processing steps and 15 failed to return any tweets.

In total, approximately 249 K tweets were collected for deriving scores for the 1166 test phrases. This collection of tweets will henceforth be referred to as the twitter corpus.

### 3.2 Data Classification and Indexing

After carrying out the data collection step described in the previous section, each of the collected tweets was classified using the sentiment analyzer described in (El-Beltagy et al. 2016). The analyzer was built using a Complement Naïve Bayes classifier (Rennie et al. 2003) with a smoothing parameter of 1 and trained using 11,242 Arabic tweets of which 3759 were negative, 3725 were positive and 3758 were neutral. The prediction accuracy using 10 fold cross validation on this dataset was 79.4%. Complement Naïve Bayes was selected as a classifier based on the work presented in (Khalil et al. 2015).

Features related to the occurrence of positive and negative terms, were part of the feature-set used by the classifier. These features were determined using the NileULex sentiment lexicon (El-Beltagy 2016) which consists of 5953 single and compound MSA and Egyptian Arabic terms. The overlap between the input SemEval test set and NileULex was as follows: Out of the 1166 supplied test terms, 162 (13.8%) existed in the used lexicon, while 148(12.6%) hash-tagged terms, existed in the lexicon, but without the hashtag.

Some of the terms in both the development set and the test set, were negated. This was not really

an issue when automatically assigning polarity labels, as the obtained label is one that it is relative to the entire phrase. What had to be handled however, were cases when the retrieved tweets included the negated form of a non-negated term. For example, when trying to assign a score to term “حلو”, a tweet with the following text:

امسيي كلامك عن علاقه مع احمد مش حلو  
ها حكي في حقها

would be classified as negative. In cases like this, negative labels were converted to positive ones and vice versa.

Each polarity classified tweet was then indexed using the Lucene(Apache 2011) search engine. The index was used to store the body of the tweet, the polarity class of the tweet, and the search term that was used to retrieve the tweet.

### 3.3 Term Scoring

Following the indexing and classification step, it was easy to retrieve information needed to calculate the *normalized pmi* (*npmi*) scores for each term relative the positive class. So for each term  $term_i$  in the list for which strength values are to be derived, equation 1 was applied to calculate its *npmi* value relative to positive (pos) sentiment.

$$npmi(term_i, pos) = \frac{pmi(term_i, pos)}{-\log p(term_i, pos)} \quad (1)$$

where

$$pmi(term_i, pos) = \log \frac{p(term_i, pos)}{p(term_i)p(pos)} \quad (2)$$

$$p(term_i) = \frac{\# \text{ of } term_i \text{ in twitter corpus}}{\text{size of twitter corpus}} \quad (3)$$

$$p(pos) = \frac{\text{total number of positive tweets}}{\text{size of twitter corpus}} \quad (4)$$

$$p(term_i, pos) = \frac{\# \text{ of pos } term_i \text{ tweets}}{\text{size of twitter corpus}} \quad (5)$$

To calculate the probability of the occurrence of the  $i^{th}$  term in the test set ( $p(term_i)$ ) in the twitter corpus, the number of tweets classified as neutral for this term ( $term_i$ ) are subtracted from the total count of  $term_i$  before applying equation 3. The total count of neutral tweets in the entire cor-

pus is also subtracted from the size of the twitter corpus before applying equations 3 through 5.

Normalized point wise mutual information returns values in the range of [-1,1] where -1 indicates that a term would never occur with the positive class and 1, indicates that it always will. In our model, terms for which no tweets were retrieved received a *npmi* score of 0. The *npmi* scores of terms that had to undergo extra processing as described in section 3.1 were penalized by multiplying their scores by a penalty factor <1. We have experimented with various factors using the development dataset, and ended up with 0.75 as a penalty factor.

We also experimented with two methods for rescaling the *npmi* scores to values from 0 to 1. In the first model, we used the development dataset, which consisted of 200 terms, and then applied linear regression to map *npmi* scores to the gold standard scores. This linear regression model, was then applied on the scores of the supplied test set. In the second method, we applied simple re-scaling so that the scores would range from 0 to 1. When we experimented with both methods on the development dataset, simple re-scaling yielded slightly better results despite the fact that the regression model was built using that same set. Accordingly, the results that we've submitted, were the results obtained using simple rescaling rather than by applying linear regression.

## 4 Results and Discussion

Based on the results supplied by the organizers of the task, the presented approach ranked at number 2 as shown in **Table 1**.

| Rank | Team name      | (official metric) |          |
|------|----------------|-------------------|----------|
|      |                | Kendall           | Spearman |
| 1    | iLab-Edinburgh | 0.5362            | 0.67997  |
| 2    | NileTMRG       | 0.47515           | 0.65763  |
| 3    | LSIS           | 0.42431           | 0.58299  |

**Table 1:** Official results

We also ran the scoring script provided by the organizers on the results that were obtained using linear regression using the post submission test data with the gold labels. The results were as follows: **Kendall**: 0.47524, **Spearman**: 0.65756. The

variation between these results and the submitted results are very minor.

By examining the results, it can be seen that the difference between our score and that achieved by the number 1 performer with respect to the Kendall metric is about 0.06. The difference in the Spearman metric is not quite as large. This difference as well as the score itself, suggests that there is still a need for improving this model.

The following points summarize some of the ideas that we plan on pursuing for improving this model:

1. Investigate alternative ways for handling the assignment of a score to terms for which no tweets were found.
2. Some terms had a higher percentage of duplicates than other in their tweet sets. Duplicate removal in cases like that resulted in those terms being under-represented. In the future, we intend to make sure that we get a pre-defined number of tweets for each term whenever possible.
3. We would like to repeat the experiment presented in this paper using tweets collected over a reasonable period of time, rather than in one go as we have done here. This should counter-act any time sensitivity issues for any given term.
4. We would like to examine the effect of replacing the sentiment analyzer for tweet labeling, with a method based on simple counting between the co-occurrence of the term for which we need to calculate a score, and known positive and negative terms.
5. Make better use of the existing lexicon as well as other available lexicons by experimenting with a similar approach to that presented in (Hamdan et al. 2015).

## 5 Conclusion

This paper presented the approach followed by NileTMRG for addressing Sem-Eval task 7, with respect to Arabic phrases. While the presented work shows promising results, further work is needed to improve its performance. In the previous section, we discussed several ideas that we believe might have a positive impact on the overall performance of the system.

## Abstract

This paper describes our system submissions to task 7 in SemEval 2016, i.e., Determining Sentiment Intensity. We participated the first two subtasks in English, which are to predict the sentiment intensity of a word or a phrase in English Twitter and General English domains. To address this task, we present a supervised learning-to-rank system to predict the relevant scores, i.e., the strength associated with positive sentiment, for English words or phrases. Multiple linguistic and sentiment features are adopted, e.g., *Sentiment Lexicons*, *Sentiment Word Vectors*, *Word Vectors*, *Linguistic Features*, etc. Officially released results showed that our systems rank the 1st among all submissions in English, which proves the effectiveness of the proposed method.

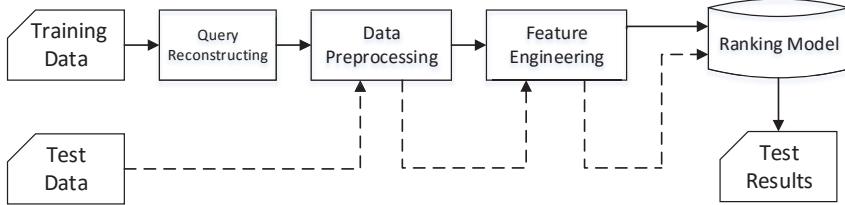

## 1 Introduction

The study of sentiment analysis is increasingly drawing attention of Natural Language Processing (NLP). Many of the top performing sentiment analysis systems rely on sentiment lexicon (Tan et al., 2008; Na et al., 2009; Mohammad et al., 2013). A sentiment lexicon is a list of words and phrases, such as “*excellent*”, “*awful*” and “*not bad*”, each of them is assigned with a positive or negative score reflecting its sentiment polarity and strength (Tang et al., 2014a). Higher scores indicate stronger sentiment strength. However, many existing manually generated sentiment lexicons consist of lexicons with only sentiment orientation rather than sentiment strength. For example, the words in *BL* (Ding et al., 2008) are generally divided to two classes, i.e.,

positive and negative. Although several sentiment lexicons have assigned discrete labels for terms, i.e., *strong* and *weak*, for example, MPQA (Wiebe et al., 2005), there is no continuous real-valued scores to indicate the intensity of sentiment so far.

The task of Determining Sentiment Intensity of English and Arabic Phrases intends to automatically create a sentiment lexicon with real-valued scores indicating the intensity of sentiment. The purpose of this task is to test the ability of an automatic system to predict a sentiment intensity score for a word or a phrase. Phrases include negators, modals, intensifiers, and diminishers. Given a list of terms, the participants are required to assign appropriate scores between 0 and 1, to indicate their strength of association with positive sentiment. The task contains three subtasks (the first two are in English and the third is in Arabic) and we participated the first two subtasks in English. The first General English Sentiment Modifiers Set contains phrases formed by a word and a modifier, where a modifier can be a negator, an auxiliary verb, a degree adverb, or even a combination of those above modifiers, e.g., “*would be very easy*”, “*did not harm*”, and “*would have been nice*”. The second English Twitter Mixed Polarity Set contains phrases made up of opposite polarity terms, such as “*lazy sundays*”, “*best winter break*”, “*couldn’t stop smiling*”, etc. The official evaluation measure is Kendall correlation coefficient (Lindskog et al., 2003).

In previous work, the task was treated as a regression problem, the word embedding is used as a feature (Amir et al., 2015). In addition, (Hamdan et al., 2015) adopted unsupervised approach by using

**Figure 1:** The framework of our proposed system.

several sentiment lexicons for computing the score for each twitter term and ranked them. In this paper, we treated this task as a ranking problem, and used pair-wise strategy to train the model.

The rest of the paper is organized as follows. Section 2 elaborates the procedure of query reconstruction, data preprocessing, feature engineering and the learning-to-rank model built in our systems. Section 3 describes the data sets and experiments. Finally, Section 4 concludes this work.

## 2 System Description

The purpose of this task is to predict the sentiment strength of given words or phrases, it is reasonable to regard the value of strength as the relevant score refer to positive polarity. Thus, to address the sentiment strength prediction task, we presented a supervised learning-to-rank system to predict the relevant score which interprets the strength associated with positive sentiment. Figure 1 depicts the architecture of our system, which contains four main modules, i.e., *Query Reconstruction*, *Data Preprocessing*, *Feature Engineering*, and *Ranking Model*. The diversity of methods for General English and English Twitter domains is located in the different training data.

### 2.1 Query Reconstruction

Since the sentiment strength task was treated as a ranking problem, we converted the provided training data into appropriate forms as the input of our ranking system in the first stage. In general, several queries were fed into the ranking system served as training data. In consideration of the provided training data is a word list ordered by the strength score associated with positive sentiment, we manually divided the word list into several “queries” and the words in each query were sorted by their corresponding scores. Specifically, the test data would

not be processed into *Query Reconstruction* module, because we considered all records in the test set as a unique query and the *Ranking Model* was used to predict their relevant scores.

### 2.2 Data Preprocessing

Due to the characteristic of training data in English Twitter domain, which consists of many informal words, such as “waiiiit”, “#happytweet”, etc., we converted the irregular forms to normal forms. For example, the elongated word “waiiiit” was transformed into “wait”, the hashtag “#happytweet” was converted into “happy tweet”. Then, we used the processed data to perform lemmatization and stemming to extract the further information with the aid of *NLTK tool*<sup>1</sup>.

### 2.3 Feature Engineering

To address the sentiment strength task, we extracted features summarized as follows: *Sentiment Lexicon Features*, *Sentiment Word Vectors*, *Word Vectors*, and *Linguistic Features*.

#### 2.3.1 Sentiment Lexicon Features

We employed the following seven sentiment lexicons to extract *Sentiment Lexicon Features*: *Bing Liu lexicon*<sup>2</sup>, *General Inquirer lexicon*<sup>3</sup>, *IMDB*<sup>4</sup>, *MPQA*<sup>5</sup>, *AFINN*<sup>6</sup>, *NRC Hashtag Sentiment Lexicon*<sup>7</sup>, and *NRC Sentiment140 Lexicon*<sup>8</sup>. Generally, we

<sup>1</sup><http://www.nltk.org/>

<sup>2</sup><http://www.cs.uic.edu/liub/FBS/sentiment-analysis.html#lexicon>

<sup>3</sup><http://www.wjh.harvard.edu/inquirer/homecat.htm>

<sup>4</sup><http://anthology.aclweb.org//S/S13/S13-2.pdf#page=444>

<sup>5</sup><http://mpqa.cs.pitt.edu/>

<sup>6</sup>[http://www2.imm.dtu.dk/pubdb/views/publication\\_details.php?id=6010](http://www2.imm.dtu.dk/pubdb/views/publication_details.php?id=6010)

<sup>7</sup><http://www.umiacs.umd.edu/saif/WebDocs/NRC-Hashtag-Sentiment-Lexicon-v0.1.zip>

<sup>8</sup><http://help.sentiment140.com/for-students/>

transformed the sentiment orientation of all words in all sentiment lexicons into the range of  $-1$  to  $1$ , where the minus sign denotes negative sentiment and the positive number indicates positive sentiment.

We considered each term (consisting of phrases and words) in the provided data as a tuple. If one term contains a single word, the size of this tuple is  $1$ . If one term is a phrase, e.g., “*happy accident*”, the tuple size is the count of words in the phrase (for “*happy accident*”, it is  $2$ ). Then, for each tuple, we concatenated the following sentimental scores extracted from each sentiment lexicon: (1) the maximum sentiment score of words, (2) the minimum sentiment score of words, (3) the sum of sentiment scores of all words. If one word does not exist in a sentiment lexicon, its corresponding score is set to  $0$ . Specifically, if any negator, e.g., “*not*”, exists in a tuple, we reverse its sentiment orientation.

Considering the diversity of word forms, we also extracted additional sentiment lexicon features about their lemmatization and stemming forms. The final sentiment lexicon representation of the  $i$ -th record  $l_i \in \mathbb{R}^{n_l * n_s * t}$ , where  $n_l$  is the number of sentiment lexicons (i.e.,  $7$ ),  $n_s$  is set as  $3$  representing the three scores calculated according to the above rules,  $t$  is also set as  $3$  representing the three forms (i.e., original, lemmatization and stemming forms) of the word in the record.

### 2.3.2 Word Vectors

Word vector is a continuous-valued representation of the word which carries syntactic and semantic information. In this task, we adopted various *Word Vectors* as features. Since the task data contains phrases made up of more than one word, it is necessary to convert these word vectors into a phrase vector. Unlike previous work which summed up all words vectors to represent the phrase, we first check whether the phrase is present in training data or not. If a phrase is present in training data, we actually treat it as a single token and learn its vector based on the given word vector learning model. If it is a new phrase not existing in training data, we follow previous work and sum up all vectors of words in this phrase as a phrase vector.

In this part, we introduce two types of word vector which are adopted in our method, i.e., Traditional

Word Vector and Sentiment Word Vector, which are described as follows:

#### Traditional Word Vectors:

- *GoogleW2V*: We used the publicly available *word2vec* tool<sup>9</sup> to get word vectors with dimensionality of  $300$ , which were trained on  $100$  billion words from Google News as *GoogleW2V* feature.
- *GloveW2V*: The Glove(Pennington et al., 2014) rely on different assumptions about the relations between words within a context window. We used the available pre-trained word vector with dimensionality of  $100$  and trained on  $2$  billion tweets, which were supplied in *GloVe*<sup>10</sup> as *GloveW2V* feature.
- *NormalW2V*: We fed *NRC140 tweet corpus* into *word2vec tool* to build *NormalW2V* with dimensionality of  $100$ .
- *NormalW2V\_Multi*: To train specific word vectors (i.e., words and phrases) for this task, we preprocessed the *NRC140 corpus* by connecting words in the phrase appeared in training data to obtain a single token. The processed data were fed into word vector model to train *NormalW2V\_Multi* with dimensionality of  $100$ .

**Sentiment Word Vectors:** Since the above word vectors are trained based on the context, they are supposed to contain semantic and syntactic information. However, due to lack of sentiment information, these traditional word vectors may not be quite effective for sentiment analysis tasks. To address this issue, our previous work and other researchers have proposed methods to learn sentiment word vectors.

- *SWV*: In (Zhang and Lan, 2015) we proposed the *Combined-Sentiment Word Embedding Model* (i.e., *SWV-C*) to learn sentiment word vectors, which are confirmed to be helpful to settle sentiment analysis task. In this work, we used this model to train the *SWV* with the aid of *NRC140 tweet corpus* (Go et al., 2009), where the corpus is made up of  $1.6$  million positive tweets and  $1.6$  million negative tweets. The vector size is set as  $100$ .

<sup>9</sup><https://code.google.com/archive/p/word2vec>

<sup>10</sup><http://nlp.stanford.edu/projects/glove/>

- *SWV\_Multi*: Similar with *NormalW2V\_Multi*, we used the *NRC140 corpus* as training corpus and reconstructed it to the task specific form. The processed corpus was employed as input of *SWV-C* model to generate *SWV\_Multi* with dimensionality of 100.
- *SSWE*: The sentiment-specific word embeddings (*SSWE*) were proposed by (Tang et al., 2014b), which is quite similar to our idea in (Zhang and Lan, 2015) but differs in proposed models. This *SSWE* sentiment word embeddings were trained by using multi-hidden-layers neural network with vector size of 50.

### 2.3.3 Linguistic Features

- Negation: The sentiment polarity of word or phrase can be reversed by a modification of negation. Therefore, we collected 29 negations from Internet and we sign 1 or 0 to this binary feature if corresponding negation is present or absent in the pending word or phrase.
- Elongated: This feature represents if word or phrase with one character repeated more than twice, e.g., “*lottttt*”.

### 2.4 Ranking Model

Different from the classification or regression methods, which focus on labeling the single record, the ranking method takes the relation between two arbitrary records associated with a query into consideration.

In this module, we used a supervised learning-to-rank approach to perform ranking. Generally, the mentioned approach can be divided into three groups: point-wise, pair-wise, and list-wise. We adopted the second strategy, i.e., pair-wise for our work. In pair-wise strategy, several record1-record2 pairs were constructed with a query and some records which were provided in advance. If record1 is more relevant than record2 in terms of the given query, this pair label will be set as 1, otherwise 0.

## 3 Experiments and Results

### 3.1 Datasets

This sentiment strength prediction task was severed as the subtask E of Sentiment Analysis on Tweet in

SemEval 2015. Thus, the trial (i.e., *15trial*) and test (i.e., *15test*) data in SemEval 2015, which contained 200 and 1,315 records separately, are integrated as training data for this task. The organizer provided 200 records as development data set for each domain (i.e., *16trial\_Twitter* and *16trial\_General*) and the labels are the same as before, where each record is labeled with a decimal in the range of 0 to 1 and the score is the strength associated with positive sentiment.

In consideration of the lack of training data, we expanded it with the Language Assessment by Mechanical Turk lexicon (i.e., *LabMT*) which automatically labeled by (Dodds et al., 2011). It contains 10,222 words rated on a scale of 1(sad) to 9(happy). Note that the labels in the *LabMT* are different from the standard data, we converted the score to the scale of 0 to 1 by min-max normalization, i.e.,  $\frac{x-\min}{\max-\min}$ .

### 3.2 Evaluation Metrics

For this task, Kendall rank correlation coefficient (usually measures the association between two measured quantities) is used as the metric to compare the ranked lists. Besides, the scores for Spearman’s Rank Correlation(a nonparametric measure of statistical dependence between two variables) is provided as well. The Kendall rank correlation coefficient is severed as the final official evaluation criteria.

### 3.3 Experiment on training data

As we described in 2.1, several operations should be conducted to transform the raw data form to accommodate the ranking system. Considering that the *LabMT* is a term list that has been automatically labeled, while the provided standard data is more precise, so we constructed each query in *LabMT* with 200 records. With regard to the provided standard data (i.e., *15trial*, *15test*), each query was made up of 20 records.

To construct training data for English Twitter domain, the *LabMT*, *15train* and *15test* were utilized, whereas the *16trial\_Twitter* was utilized as development data. Several types of features have been proposed in 2.3, in order to conduct feature selection, we adopted *hill climbing* which is described as: keeping adding one type of feature at a time until no further improvement can be achieved.

The system’s diversity of two domains lies on

| Feature                              |                 | English Twitter      | General English      |
|--------------------------------------|-----------------|----------------------|----------------------|
| Traditional W2V                      | GoogleW2V       | ✓                    |                      |
|                                      | NormalW2V       | ✓                    | ✓                    |
|                                      | NormalW2V_Multi |                      |                      |
|                                      | GloveW2V        |                      | ✓                    |
| Sentimental W2V                      | SWV             | ✓                    | ✓                    |
|                                      | SWV_Multi       |                      | ✓                    |
|                                      | SSWE            | ✓                    | ✓                    |
| Sentiment Lexicon                    | SentiLexi       | ✓                    | ✓                    |
| Linguistic                           | Negation        | ✓                    | ✓                    |
|                                      | Emphasize       | ✓                    | —                    |
| Ranking Results (Kendall/Sperman)    |                 | <b>59.83%/75.38%</b> | <b>71.67%/86.83%</b> |
| Regression Results (Kendall/Sperman) |                 | 57.80%/73.01%        | 70.50%/85.26%        |

**Table 1:** Results of feature selection experiments for Twitter English and General English domains.

the different training data we utilized: all tweet-related data were adopted in English Twitter, while the words and phrases with *hashtag*(#) or informal forms were removed for General English. Thus, the filtered data of *LabMT, 15trial* and *15test* were severed as training data and the *16trial\_General* were utilized as development data. The process of feature selection was similar with English Twitter domain except that the *Emphasize* feature was not used.

Table 1 shows the results of feature selection experiments on the development data, which lists the optimal feature sets of two domains.

From Table 1, it is interesting to find: (1) The *Sentiment Lexicon* features make a considerable contribution, because that the used sentiment lexicons contain sentiment information to some extent and its sentiment scores in lexicons are closely related to the strength associated with positive sentiment. For example, in *BL*, the scores of positive words are 1 and the negative words are represented as -1. (2) The *Linguistic* features (i.e., *Negation* and *Emphasize*) also contribute to performance. As for *Negation*, the possible reason may be that there are plentiful negators existed in training and development data and the emphatic words have similar situation. (3) The *NormalW2V* and *SWV* are both effective features for this task. In our further experiments which test the *SWV* and *NormalW2V* respectively, we found that *SWV* performs much better than *NormalW2V*, which showed that the *Combined Sentiment Word Vector Model* indeed captured sentiment information from abundant auto-labeled tweets. (4) The ranking based system outperforms the regression method, which indicates that it is convincing to regard this labeling

task as a ranking problem. (5) Compared with the results on English Twitter domain, we notice that the performance is much better. Based on the observation on development data of two domains, we found that the phrases on English Twitter domain are made up of opposite polarity terms, e.g., “*happy accident*”, “*couldn’t stop smiling*”, while the records in General English domain are much more ordinary. The diversity of data distribution results in the above mentioned gap.

### 3.4 System Configuration

We built two systems for the two subtasks. In our preliminary experiments, we examined several algorithms with different parameters implemented in *RankLib tool*<sup>11</sup>, e.g., *Random Forest*, *RankNet*, *RankBoost*, and *ListNet*. According to the best performance in our experiments, we adopted *Random Forest* algorithm with parameters *tree* = 5, *bag* = 100 for English Twitter domain and *tree* = 1, *bag* = 300 for General English domain for our final submitted systems.

### 3.5 Results and Analysis

Table 2 lists the performances of our system and the top ranked system provided by organizer on test data.

The results in the Table 2 show that our system indeed performed well on sentiment strength prediction task regardless of domains, where the proposed system ranks 1st above both domains among all submissions. The results of test data are consistent with our experiment on training data, the performance on

<sup>11</sup><https://people.cs.umass.edu/vdang/ranklib.html>

English Twitter domain is worse than that on General English domain due to the data distribution.

| Domain  | Rank | TeamID | Kendall(%)   | Sperman(%)   |
|---------|------|--------|--------------|--------------|
| General | 1    | ECNU   | <b>70.42</b> | <b>86.27</b> |
|         | 2    | UWB    | 65.91        | 85.36        |
|         | 3    | LSIS   | 34.97        | 50.75        |
| Twitter | 1    | ECNU   | <b>52.31</b> | <b>67.40</b> |
|         | 2    | LSIS   | 42.16        | 59.06        |
|         | 3    | UWB    | 41.38        | 57.82        |

**Table 2:** Performances of our systems and the top-ranked system for two domains. *General* and *Twitter* stand for *General English domain* and *English Twitter domain* respectively.

## 4 Conclusion

In this paper, we presented a supervised learning-to-rank system to predict the strength of positive sentiment associated with words and phrases. Multiple features, e.g., *Sentiment Lexicon*, *Sentiment Word Vectors*, *Word Vectors*, and *Linguistic Features*, were presented. We find that the *Sentiment Lexicon Features* and the *Sentiment Word Vectors* make contributions to performance improvement. However the phrase vector is not effective as expected and in future work it is interesting to explore more ways to represent phrase.

montse.maritxalar@ehu.eus

## Abstract

The final goal of Interpretable Semantic Textual Similarity (iSTS) is to build systems that explain which are the differences and commonalities between two sentences. The task adds an explanatory level on top of STS, formalized as an alignment between the chunks in the two input sentences, indicating the relation and similarity score of each alignment. The task provides train and test data on three datasets: news headlines, image captions and student answers. It attracted nine teams, totaling 20 runs. All datasets and the annotation guideline are freely available<sup>1</sup>

## 1 Introduction

Semantic Textual Similarity (STS) (Agirre et al., 2015) measures the degree of equivalence in the underlying semantics of paired snippets of text. The idea of Interpretable STS (iSTS) is to explain *why* two sentences may be related/unrelated, by supplementing the STS similarity score with an explanatory layer.

Our final goal would be to enable interpretable systems, that is, systems that are able to explain which are the differences and commonalities between two sentences. For instance, let's assume the following two sentences drawn from a corpus of news headlines:

12 killed in bus accident in Pakistan  
10 killed in road accident in NW Pakistan

The output of such a system would be something like the following:

The two sentences talk about accidents with casualties in Pakistan, but they differ in the number of people killed (12 vs. 10) and level of detail: the first one specifies that it is a *bus* accident, and the second one specifies that the location is *NW Pakistan*.

While giving such explanations comes naturally to people, constructing algorithms and computational models that mimic human level performance represents a difficult Natural Language Understanding (NLU) problem, with applications in dialogue systems, interactive systems and educational systems.

In the iSTS 2015 pilot task (Agirre et al., 2015), we defined a first step of such an ambitious system, which we follow in 2016. Given the input (a pair of sentences), participant systems need first to identify the chunks in each sentence, and then, align chunks across the two sentences, indicating the relation and similarity score of each alignment. The relation can be one of equivalence, opposition, specificity, similarity or relatedness, and the similarity score can range from 1 to 5. Unrelated chunks are left unaligned. An optional tag can be added to alignments for the cases where there is a difference in factuality or polarity. See Figure 1 for the manual alignment of the two sample sentences. The alignments between chunks in Figure 1 can be used to produce the kind of explanations shown in the previous example.

In previous work, Brockett (2007) and Rus et al. (2012) produced a dataset where corresponding

\* Authors listed in alphabetical order

[in Pakistan] <=> [in NW Pakistan] : (MORE-GENERAL 4)
```

**Figure 1:** Example of a manual alignment of two sentences: “12 killed in bus accident in Pakistan” and “10 killed in road accident in NW Pakistan”. Each aligned pair of chunks included information on the type of alignment, and the score of alignment.

words (including some multiword expressions like named-entities) were aligned. Although this alignment is useful, we wanted to move forward to the alignment of segments, and decided to align chunks (Abney, 1991). Brockett (2007) did not provide any label to alignments, while Rus et al. (2012) defined a basic typology. In our task, we provided a more detailed typology for the aligned chunks as well as a similarity/relatedness score for each alignment. Contrary to the mentioned works, we first identified the segments (chunks in our case) in each sentence separately, and then aligned them.

In a different strand of work, Nielsen et al. (2009) defined a textual entailment model where the “facets” (words under some syntactic/semantic relation) in the response of a student were linked to the concepts in the reference answer. The link would signal whether each facet in the response was entailed by the reference answer or not, but would not explicitly mark which parts of the reference answer caused the entailment. This model was later followed by Levy et al. (2013). Our task was different in that we identified the corresponding chunks in both sentences. We think that, in the future, the aligned facets could provide complementary information to chunks.

The SemEval Semantic Textual Similarity (STS) task in 2015 contained a subtask on Interpretable STS (Agirre et al., 2015), showing that the task is feasible, with high inter-annotator agreement and system scores well above baselines. The datasets comprised news headlines and image captions.

For 2016, the pilot subtask has been updated into a standalone task. The restriction from the iSTS 2015 task to allow only one-to-one alignments has been now lifted, and we thus allow any number of chunks to be aligned to any number of chunks. Annotation guidelines have been revised accordingly, including an updated chunking criterium for subordinate clauses and a better explanation of the instruc-

tions.

The 2015 datasets were re-annotated and released as training data. New pairs from news headlines and image captions have been annotated and used for test. In addition, a new dataset of sentence pairs from the education domain has been produced, including train and test data.

The paper is organized as follows. We first provide the description of the task, followed by the evaluation metrics and the baseline system. Section 5 describes the participation, Section 6 the results, and Section 7 comments on the systems, tools and resources used.

## 2 Task Description

The dataset was produced using sentence pairs from news headlines, image captions and answers from students. Headlines have been mined from several news sources by European Media Monitor, and collected by us using their RSS feed<sup>2</sup>. We saw a pair of headlines from this corpus in the introduction.

The Image descriptions dataset is a subset of the Flickr dataset presented in (Rashtchian et al., 2010), which consisted of 8108 hand-selected images from Flickr, depicting actions and events of people or animals, with five captions per image. The image captions of the dataset are released under a Creative Commons Attribution-Share Alike license. This is a sample pair from this dataset:

A man sleeps with a baby in his lap  
A man asleep in a chair holding a baby

The Answer-Students corpus consists of the interactions between students and the BEETLE II tutorial dialogue system. The BEETLE II system is an intelligent tutoring engine that teaches students in basic electricity and electronics. At first, students

| Student test  | 344   | student answers | 2015 |

**Table 1:** Details of the datasets, including number of pairs, source, and relation to STS datasets. HDL stands for Headlines, and Student to Student-Answers.

spend from three to five hours reading the material, building and observing circuits in the simulator and interacting with a dialogue-based tutor. They used the keyboard to interact with the system, and the computer tutor asked them questions and provided feedback via a text-based chat interface. The data from 73 undergraduate volunteer participants at south-eastern US university were recorded and annotated to form the BEETLE human-computer dialogue corpus (Dzikovska et al., 2010; Dzikovska et al., 2012), and later used in a SemEval 2015 task (Dzikovska et al., 2013). In the present corpus, we include sentence pairs composed of a student answer and the reference answer of a teacher. We have rejected those answers containing pronouns whose antecedent is not in the sentence (pronominal coreference), as the question is not included in the train data and, therefore, it is not possible to deduce which is the antecedent. There are also some dataset-specific details that are mentioned in the same section. The next pair sentences are an example of the Answer-Students corpus.

because switch z is in bulb c's closed path  
there is a path containing both Z and C

All datasets have been previously used in STS tasks. Table 1 shows details of the datasets, including train-test splits. The Headlines and Images datasets are tokenized, as in the STS release. The Answer-Students dataset was not tokenized, and was used as in the STS release.

## 2.1 Annotation

The manual annotation has been performed following the annotation guidelines<sup>3</sup>. Please refer to those

<sup>3</sup><http://alt.qcri.org/semeval2016/task2/data/uploads/>

guidelines for further details. The general annotation procedure is as follows:

1. First identify the chunks in each sentence separately.
2. Align chunks in order, from the clearest and strongest correspondences to the most unclear or weakest ones.
3. For each alignment, provide a similarity/relatedness score.
4. For each alignment, choose one (or more) alignment label.

Chunk annotation was based on those used in the CoNLL 2000 chunking task (Tjong Kim Sang and Buchholz, 2000). The annotators were provided with the output of an automatic chunker<sup>4</sup> trained on the CoNLL corpora<sup>5</sup>, which they corrected manually.

Independently of the labels, and before assigning any label, the annotators need to provide a similarity/relatedness score for each alignment from 5 (maximum similarity/relatedness) to 0 (no relation at all), as follows:

- 5 if the meaning of both chunks is equivalent
- [4,3] if the meaning of both chunks is very similar or closely related
- [2,1] if the meaning of both chunks is slightly similar or somehow related
- 0 (represented as NIL) if the meaning of the chunk is completely unrelated.

Note that 0 is not possible for an aligned pair, as that would mean that the two chunks would be left unaligned. Note also that if the score is 5, then the label assigned later should be equivalence (EQUI, see below). After assigning the label, the annotator should check for the following: if a chunk is not aligned it should have NIL score, equivalent chunks

annotationguidelinesinterpretablests2016v2.2.pdf

<sup>4</sup><https://github.com/ixa-ehu/ixa-pipe-chunk>

<sup>5</sup><http://www.clips.ua.ac.be/conll2000/chunking/>

(EQUI) should have a 5 score. The rest of the labels should have a score larger than 0 but lower than 5.

We will now describe the alignment types, but first note that the interpretation of the whole sentence, including common sense inference, has to be taken into account. This means that we need to take into account the context in order to know whether the aligned chunks refer to the same instance (or set of instances) or not. Instances may refer to physical or abstract object instances (for NPs) or real world event instances (for verb chains):

- EQUI: both chunks have the same meaning, they are semantically equivalent in this context.
- OPPO: the meanings of the chunks are in opposition to each other, lying in an inherently incompatible binary relationship.
- SPE1: both chunks have similar meanings, but chunk in sentence 1 is more specific.
- SPE2: like SPE1, but it is the chunk in sentence 2 which is more specific.

In addition, the meaning of the chunks can be very close, either because they have a similar meaning, or because their meanings have some other relation. In those cases, we use SIMI or REL as follows:

- SIMI: both chunks have similar meanings, they share similar attributes and there is no EQUI, OPPO, SPE1 or SPE2 relation.
- REL: both chunks are not considered similar but they are closely related by some relation not mentioned above (i.e. no EQUI, OPPO, SPE1, SPE2, or SIMI relation).
- NOALI: this chunk has not any corresponding chunk in the other sentence. Therefore, it is left unaligned.

The above seven labels are exclusive, and each alignment should have one such label.

In addition to one of the labels above, there are two labels which can be used either in isolation or together, that is, you can use none, one or both:

- FACT: the factuality in the aligned chunks (i.e. whether the statement is or is not a fact or a speculation) is different.
- POL: the polarity in the aligned chunks (i.e. the expressed opinion, which can be positive, negative, or neutral) is different.

Note that NOALI can also be FACT or POL, meaning that the respective chunk adds a factuality or polarity nuance to the sentence.

Listing 1 shows the annotation format for a given sentence pair from the training set (note that each alignment is reported in one line as follows: token-id-sent1 <==> token-id-sent2 // label // score // comment).

Finally, there are some specific criteria related to the Answer-Students corpus that have been followed during the annotation process. For instance, in the Answer-Students example in the previous section, *switch z* (first sentence) and *Z* (second sentence) are considered equivalent as, in this dataset, *X*, *Y*, and *Z* always refer to switches *X*, *Y*, and *Z*. The same criteria is followed when annotating *bulb c* and *C* as equivalent, as *A*, *B* and *C* are always used to refer to bulb *A*, *B* and *C*. In the same way *closed path* and *a path* are equivalent, as paths are always considered to be closed. For further details related to such a corpus specific criteria refer to the annotation guidelines.

### 3 Evaluation Metrics

The official evaluation is based on (Melamed, 1998), which uses the F1 of precision and recall of token alignments (in the context of alignment for Machine Translation). Fraser and Marcu (2007) argue that F1 is a better measure than other alternatives such as the Alignment Error Rate. The idea is that, for each pair of chunks that are aligned, we consider that any pairs of tokens in the chunks are also aligned with some weight. The weight of each token-token alignment is the inverse of the number of alignments of each token (so-called fan out factor, Melamed, 1998). Precision is measured as the ratio of token-token alignments that exist in both system and gold standard files, divided by the number of alignments in the system. Recall is measured similarly, as the ratio of token-token alignments that exist in both system and gold-standard, divided by the number of alignments in the gold standard. Precision and recall are evaluated separately for all alignments of all pairs.

Participating runs were evaluated using four different metrics: F1 where alignment type and score are ignored (alignment F1, F for short); F1 where alignment types need to match, but scores are ignored (type F1, +T for short); F1 where alignment type is ignored, but each alignment is penalized

**Listing 1:** Annotation format

```

<sentence id="6" status="">
  12 killed in bus accident in Pakistan
  10 killed in road accident in NW Pakistan
  ...
<alignment>
  1 <==> 1 // SIMI // 4 // 12 <==> 10
  2 <==> 2 // EQUI // 5 // killed <==> killed
  3 4 5 <==> 3 4 5 // SPE1 // 4 // in bus accident <==> in road accident
  6 7 <==> 6 7 8 // SPE2 // 4 // in Pakistan <==> in NW Pakistan
</alignment>
</sentence>

```

when scores do not match<sup>6</sup> (score F1, +S for short); and, F1 where alignment types need to match, and each alignment is penalized when scores do not match (type and score F1, +TS for short). The type and score F1 is the main overall metric.

Note that our evaluation procedure does not explicitly evaluate the chunking results. The method implicitly penalizes chunking errors via the induced token-token alignments, using a soft penalty.

## 4 Baseline System

The baseline system consists of a cascade concatenation of several procedures. First, input sentences are tokenized using simple regular expressions. Additionally, we collect chunks coming either from the gold standard or from the chunking done by *ixa-pipes-chunk* (Agerri et al., 2014). This is followed by a lower-cased token aligning phase, which consists of aligning (or linking) identical tokens across the input sentences. Then we use chunk boundaries as token regions to group individual tokens into groups, and compute all links across groups. The weight of the link across groups is proportional to the number of links counted between within-group tokens. The next phase consists of an optimization step in which groups x,y that have the highest link weight are identified, as well as the chunks that are linked to either x or y but not with a maximum alignment weight (thus enabling us to know which chunks were left unaligned). Finally, in the

<sup>6</sup>The penalization is the difference between the scores divided by five.

last phase, the baseline system uses a rule-based algorithm to directly assign labels and scores: to chunks with the highest link weight assign label = “EQUI” and score = 5, to the rest of aligned chunks (with lower weights) assign label = “NOALI” and score = NIL, and, to unaligned chunks assign label = “NOALI” and score = NIL.

## 5 Participation

The pilot task presented two scenarios: raw text and gold standard chunks. In the first scenario, given a pair of sentences, participants had to identify the composing chunks, and then align them; after that they would assign a relatedness tag and a similarity score to each alignment. In the gold standard scenario, participants were provided with the gold standard chunks.

In both scenarios the datasets were provided with tokenized text, with exception of Answer-Students, which was not tokenized<sup>7</sup>.

The task allowed up to a total of three submissions for each team on each of the evaluation scenarios. The organizers provided a script to check if the run files are well formed.

Nine teams participated on the gold chunks scenario, and out of them six teams also participated in the system chunks scenario. Regarding the datasets, all the teams gave their results for the three datasets,

<sup>7</sup>In fact The Answer-Students dataset was only partially tokenized. In order to be consistent with the gold standard, participants had to follow the partial tokenization, separating tokens at blanks alone.

except *Venseeval* who sent results only for Headlines and Images.

The iUBC team includes some of the organizers of the interpretable STS task. It is marked by the symbol \* in the result tables, and it is not taken into account in the rankings. The organizers took measures to prevent developers of that team to access the test data or any other information, so the team participated in identical conditions to the rest of participants.

## 6 Results

Table 2 provides the overall type and score (+TS) performance per dataset, and the mean across the three datasets. Results for Headlines, Images and Answer-Students datasets are shown in the Appendix, tables 3, 4 and 5, respectively. Each row of the tables corresponds to a run configuration named *TeamID\_RunID*. Note that task results are separately written with respect to the scenario. A unique baseline was used for both evaluation scenarios and its performance is jointly presented with the scores obtained by participants.

The results of the present edition corroborate last years' results regarding the difficulty of the system chunks scenario. Indeed, it is considerably more challenging than the gold chunks scenario.

With regard to the datasets, the Answer-Students ended up being more challenging than the other datasets for five out of eight teams, but FBK-HLT-NLP, IISCNLP and iUBC teams give their best results for such a scenario.

Compared to last year, the best results for Images and Headlines in the +TS metric have improved in both SYS and GS scenarios: 4 and 6 points for Headlines (in SYS and GS, respectively), and 5 and 7 points for Images (in SYS and GS, respectively). In order to check whether the datasets were easier this year, we checked the performance of the baseline. The differences are small: this year the Images dataset seems slightly easier (3 and 4 point difference for SYS and GS scenarios), and the Headlines dataset is only slightly more difficult (1 point difference for SYS and GS scenarios). The improvement in results for this year seems to be due to better system performance.

The complexity of the evaluation (cf. tables 3, 4

and 5) was incremental for the four available metrics, which obviously, were lower for the system chunks. Both type and score are bounded by the alignment results and it is thus natural that alignment results are higher. Comparing type and score results, the type results are generally lower, possibly due to the harder task of guessing the correct label. The final results are bounded by both type and score, and the systems doing best in type are the ones doing best overall. From the results we can see that labeling the type was the most challenging.

Regarding the overall test results for type and score (+TS) across datasets, UWB (Konopík et al., 2016) and DTsim (Banjade et al., 2016) obtained the best results for the gold chunks scenario, and DTsim and FBK-HLT-NLP (Magnolini et al., 2016) for the system chunks scenario. In addition, DTsim obtained the best overall results even though they have not good results for the Answer-Students dataset.

## 7 Systems, tools and resources

Most of the teams reported input text processing such as lemmatization and part of speech tagging, and in some cases named-entity recognition and syntactic parsing. Additional resources such as WordNet, distributional embeddings, paraphrases from PPDB and global STS sentence scores were also used. Participants also revealed that most of their systems were built using some kind of distributional or knowledge-based similarity metrics. We noticed, for instance, that WordNet or word embeddings were used by several teams to compute word similarity.

Looking at the learning approaches, both supervised and unsupervised approaches have been applied, as well as mainly manual rule-based combinations.

Next, we briefly introduce the participant teams, with slightly more details for the top performing systems.

- UWB (Konopík et al., 2016): UWB used three separate supervised classifiers to perform alignment, scoring and typing. They defined a similarity function based on a distribution similarity paradigm: vector composition, lexical semantic vectors and iDF weighting. They introduced a modified method to create word vectors, and

|                |                      |          |           |             |          | Inspire_r3     | .487                  | .579     | .386      | .484        | 19       |
|                |                      |          |           |             |          | Vensemseval_r1 | .574                  | .573     | -         | -           |          |
|                |                      |          |           |             |          | *iUBC_r2       | .612                  | .587     | .644      | .614        |          |
|                |                      |          |           |             |          | *iUBC_r3       | .578                  | .592     | .644      | .604        |          |
|                |                      |          |           |             |          | *iUBC_r1       | .513                  | .505     | .499      | .506        |          |
|                |                      |          |           |             |          | AVG            | .570                  | .598     | .549      | .573        |          |
|                |                      |          |           |             |          | MAX            | .671                  | .696     | .639      | .638        |          |

**Table 2:** Overall test results for type and score (+TS) across datasets. Each row correspond to a system run, and each column to a dataset: (**I**) for Images, (**H**) for Headlines, (**AS**) for Answer-Students, **Mean** for the mean across the three datasets, and **R** for the rank. The “\*” symbol denotes runs that include task organizers. Additionally, the table shows results for the baseline, average of participants (**AVG**) and maximum score of participants (**MAX**).

combine unique words from the chunks of both sentences into one single vocabulary which is then used to produce similarity measures. They claim that the following three differences have significant influence on the final results: modified lexical semantic vectors (+3% of the mean of T+S F1 scores), shared words (+2%) and POS tags difference (+2%).

- DTSim (Banjade et al., 2016): This team builds on the NeroSim system (Banjade et al., 2015), which participated in the 2015 task with good results using a system based on manual rules blended semantic similarity features. The team explored several chunking algorithms and in-

cluded new rules. Concretely, they expanded the rules for SIMI and EQUI. They mainly improved the chunker and concluded that a Conditional Random Fields (CRFs) based chunking tool is the best approach for chunking. The input sequence to their chunking model are POS tags, and the chunker yielded the highest average accuracies on both the training and test datasets.

- FBK-HLT-NLP (Magnolini et al., 2016): This teams built a multi-layer perceptron to solve alignment, scoring and typing. The perceptron shares some layers for the three tasks, and other layers are separate. They use a variety of

features, including WordNet and word embeddings. The system performs better in the system chunks scenario than in the gold chunks one. Therefore, there is no specific advantage of using chunked sentence pairs and their system is very powerful. The Answer-Students dataset has better performance than Headlines and Images. They obtain better results training a single system for the three datasets (compared to training a classifier separately for each dataset).

- Inspire (Kazmi and Schüller, 2016): The authors propose a system based on logic programming which extends the basic ideas of NeroSim (Banjade et al., 2015). The rule based system makes use of several resources to prepare the input and uses Answer Set Programming to determine chunk boundaries.
- IISCNLP (Tekumalla and Sharmistha, 2016): The system uses an algorithm, iMATCH, for the alignment of multiple non-contiguous chunks based on Integer Linear Programming (ILP). Similarity type and score assignment for pairs of chunks is done using a supervised multiclass classification technique based on Random Forest Classifier.
- Vrep (Henry and Sands, 2016): features are extracted to create a learned rule-based classifier to assign a label. It uses semantic and syntactic (form of the chunks) relationship features.
- Rev (Ping Ping et al., 2016): The system consists of rules based on the analysis of the Headlines dataset considering lexical overlapping, part of speech tags and synonymy.
- VensemEval: This system is an adaptation of a pre-existing textual entailment system, VENSES, which first performs a semantic analysis of the text including argument structure and then looks for bridging information between chunks using several knowledge resources.
- iUBC (Lopez-Gazpio et al., 2016): A two layer architecture is used to produce the similarity type and score of pairs of chunks. The top layer consists of two models: a classifier and a regressor. The bottom layer consists of a recurrent neural network that processes input and feeds composed semantic feature vectors to the

top layer. Both layers are trained at the same time by propagating gradients.

## 8 Conclusions

Last year, the Interpretable STS task was introduced as a pilot subtask of the STS task. At the present edition, it has been presented as an independent task that has attracted nine teams. In addition to the image caption and news headlines datasets, this year participants were challenged with a new dataset from the Educational area. Concretely, the Answer-Students corpus, which consists of the interactions between students of electronics and the BEETLE II tutorial dialogue system.

Compared to the results last year (Agirre et al., 2015), the results have improved in the two datasets that happened both years, Images and Headlines. The Answer-Students dataset is the most challenging, and among the three subtasks (alignment, type and score) guessing the correct type of the aligned chunks is the most difficult one. Teams that did best on type get the best overall score.

All datasets and the annotation guideline are available in <http://alt.qcri.org/semeval2016/task2/>.

**Table 3:** Test results in Headlines for both scenarios. Each row correspond to a system run, and each column to one evaluation metric: F alignment (**F**), F alignment with type penalty (**+T**), F alignment with score penalty (**+S**) and F alignment with type and score penalty (**+TS**), and **R** for the rank. The “\*” symbol denotes runs that include task organizers. Additionally, the table shows results for the baseline, average of participants (**AVG**) and maximum score of participants (**MAX**).

## Abstract

This paper describes the SemEval–2016 Task 3 on Community Question Answering, which we offered in English and Arabic. For English, we had three subtasks: *Question–Comment Similarity* (subtask A), *Question–Question Similarity* (B), and *Question–External Comment Similarity* (C). For Arabic, we had another subtask: *Rerank the correct answers for a new question* (D). Eighteen teams participated in the task, submitting a total of 95 runs (38 primary and 57 contrastive) for the four subtasks. A variety of approaches and features were used by the participating systems to address the different subtasks, which are summarized in this paper. The best systems achieved an official score (MAP) of 79.19, 76.70, 55.41, and 45.83 in subtasks A, B, C, and D, respectively. These scores are significantly better than those for the baselines that we provided. For subtask A, the best system improved over the 2015 winner by 3 points absolute in terms of Accuracy.

## 1 Introduction

Building on the success of SemEval–2015 Task 3 “Answer Selection in Community Question Answering”<sup>1</sup> (Nakov et al., 2015), we run an extension in 2016, which covers a full task on *Community Question Answering* (CQA) and which is, therefore, closer to the real application needs. All the information related to the task, data, participants, results and publications can be found on the SemEval–2016 Task 3 website.<sup>2</sup>

<sup>1</sup><http://alt.qcri.org/semeval2015/task3>

<sup>2</sup><http://alt.qcri.org/semeval2016/task3>

CQA forums such as Stack Overflow<sup>3</sup> and Qatar Living<sup>4</sup>, are gaining popularity online. These forums are seldom moderated, quite open, and thus they typically have little restrictions, if any, on who can post and who can answer a question. On the positive side, this means that one can freely ask any question and can then expect some good, honest answers. On the negative side, it takes effort to go through all possible answers and to make sense of them. For example, it is not unusual for a question to have hundreds of answers, which makes it very time-consuming for the user to inspect and to winnow through them all. The present task could help to automate the process of finding good answers to new questions in a community-created discussion forum, e.g., by retrieving similar questions in the forum and by identifying the posts in the comment threads of those similar questions that answer the original question well.

In essence, the main CQA task can be defined as follows: “given (i) a new question and (ii) a large collection of question-comment threads created by a user community, rank the comments that are most useful for answering the new question”.

The test question is new with respect to the collection, but it is expected to be related to one or several questions in the collection. The best answers can come from different question-comment threads. In the collection, the threads are independent of each other and the lists of comments are chronologically sorted and contain some meta information, e.g., date, user, topic, etc.

<sup>3</sup><http://stackoverflow.com/>

<sup>4</sup><http://www.qatarliving.com/forum>

The comments in a particular thread are intended to answer the question initiating that thread, but since this is a resource created by a community of casual users, there is a lot of noise and irrelevant material, apart from informal language usage and lots of typos and grammatical mistakes. Interestingly, the questions in the collection can be semantically related to each other, although not explicitly.

Our intention was not to run just another regular Question Answering task. Similarly to the 2015 edition, we had three objectives: (*i*) to focus on semantic-based solutions beyond simple “bag-of-words” representations and “word matching” techniques; (*ii*) to study the new natural language processing (NLP) phenomena arising in the community question answering scenario, e.g., relations between the comments in a thread, relations between different threads and question-to-question similarity; and (*iii*) to facilitate the participation of non IR/QA experts to our challenge. The third point was achieved by explicitly providing the set of potential answers—the search engine step was carried out by us—to be (re)ranked and by defining two optional subtasks apart from the main CQA task. Subtask A (*Question-Comment Similarity*): given a question from a question-comment thread, rank the comments according to their relevance (similarity) with respect to the question; Subtask B (*Question-Question Similarity*): given the new question, rerank all similar questions retrieved by a search engine, assuming that the answers to the similar questions should be answering the new question too.

Subtasks A and B should give participants enough tools to create a CQA system to solve the main task. Nonetheless, one can approach CQA without necessarily solving the two tasks above. Participants were free to use whatever approach they wanted, and the participation in the main task and/or the two subtasks was optional. A more precise definition of all subtasks can be found in Section 3.

Keeping the multilinguality from 2015, we provided data for two languages: English and Arabic. For English, we used real data from the community-created Qatar Living forum. The Arabic data was collected from medical forums, with a slightly different procedure. We only proposed the main ranking CQA task on this data, i.e., finding good answers for a given new question.

Finally, we provided training data for all languages and subtasks with human supervision. All examples were manually labeled by a community of annotators in a crowdsourcing platform. The datasets and the annotation procedure are described in Section 4, and some examples can be found in Figures 3 and 4.

The rest of the paper is organized as follows: Section 2 introduces some related work. Section 3 gives a more detailed definition of the task. Section 4 describes the datasets and the process of their creation. Section 5 explains the evaluation measures. Section 6 presents the results for all subtasks and for all participating systems. Section 7 summarizes the main approaches and features used by these systems. Finally, Section 8 offers some further discussion and presents the main conclusions.

## 2 Related Work

Our task goes in the direction of passage reranking, where automatic classifiers are normally applied to pairs of questions and answer passages to derive a relative order between passages, e.g., see (Radlinski and Joachims, 2005; Jeon et al., 2005; Shen and Lapata, 2007; Moschitti et al., 2007; Severyn and Moschitti, 2015; Moschitti, 2008; Tymoshenko and Moschitti, 2015; Tymoshenko et al., 2016; Surdeanu et al., 2008). In recent years, many advanced models have been developed for automating answer selection, producing a large body of work. For instance, Wang et al. (2007) proposed a probabilistic quasi-synchronous grammar to learn syntactic transformations from the question to the candidate answers; Heilman and Smith (2010) used an algorithm based on Tree Edit Distance (TED) to learn tree transformations in pairs; Wang and Manning (2010) developed a probabilistic model to learn tree-edit operations on dependency parse trees; and Yao et al. (2013) applied linear chain CRFs with features derived from TED to automatically learn associations between questions and candidate answers. One interesting aspect of the above research is the need for syntactic structures; this is also corroborated in (Severyn and Moschitti, 2012; Severyn and Moschitti, 2013). Note that answer selection can use models for textual entailment, semantic similarity, and for natural language inference in general.

Using information about the thread is another important direction. In the 2015 edition of the task, the top participating systems used thread-level features, in addition to the usual local features that only look at the question–answer pair. For example, the second-best team, HITSZ-ICRC, used as a feature the position of the comment in the thread, whether the answer is first, whether the answer is last (Hou et al., 2015). Similarly, the third-best team, QCRI, used features that model a comment in the context of the entire comment thread, focusing on user interaction (Nicosia et al., 2015). Finally, the fifth-best team, ICRC-HIT, treated the answer selection task as a sequence labeling problem and proposed recurrent convolution neural networks to recognize good comments (Zhou et al., 2015b).

In a follow-up work, Zhou et al. (2015a) included long-short term memory (LSTM) units in their convolutional neural network to learn the classification sequence for the thread. In parallel, Barrón-Cedeño et al. (2015) exploited the dependencies between the thread comments to tackle the same task. This was done by designing features that look globally at the thread and by applying structured prediction models, such as Conditional Random Fields (Lafferty et al., 2001).

This research direction was further extended by Joty et al. (2015), who used the output structure at the thread level in order to make more consistent global decisions. For this purpose, they modeled the relations between pairs of comments at any distance in the thread, and they combined the predictions of local classifiers in a graph-cut and in an ILP frameworks.

Finally, Joty et al. (2016) proposed two novel joint learning models that are on-line and integrate inference within the learning process. The first one jointly learns two node- and edge-level MaxEnt classifiers with stochastic gradient descent and integrates the inference step with loopy belief propagation. The second model is an instance of fully connected pairwise CRFs (FCCRF). The FCCRF model significantly outperforms all other approaches and yields the best results on the task (SemEval-2015 Task 3) to date. Crucial elements for its success are the global normalization and an Ising-like edge potential.

### 3 Definition of the Subtasks

The challenge was structured as a set of four different and independent subtasks. Three of them (A, B and C) were offered for English, while the fourth one (D) was offered for Arabic. We describe them below in detail. In order to make the subtask definitions more clear, we also provide some high-level information about the datasets we used (they will be described in more detail later in Section 4).

The English data comes from the Qatar Living forum, which is organized as a set of seemingly independent question–comment threads. In short, for subtask A we annotated the comments in a question-thread as “Good”, “PotentiallyUseful” or “Bad” with respect to the question that started the thread. Additionally, given original questions we retrieved related question–comment threads and we annotated the related questions as “PerfectMatch”, “Relevant”, or “Irrelevant” with respect to the original question (subtask B). We then annotated the comments in the threads of related questions as “Good”, “PotentiallyUseful” or “Bad” with respect to the original question (subtask C).

For Arabic, the data was extracted from medical forums and has a different format. Given an original question, we retrieved pairs of the form (related\_question, answer\_to\_the\_related\_question). These pairs were annotated as “Direct” answer, “Relevant” and “Irrelevant” with respect to the original question.

**English subtask A Question-Comment Similarity.** Given a question  $Q$  and its first ten comments<sup>5</sup> in the question thread  $(c_1, \dots, c_{10})$ , the goal is to rank these ten comments according to their relevance with respect to the question.

Note that this is a ranking task, not a classification task; we use mean average precision (MAP) as an official evaluation measure. This setting was adopted as it is closer to the application scenario than pure comment classification. For a perfect ranking, a system has to place all “Good” comments above the “PotentiallyUseful” and “Bad” comments; the latter two are not actually distinguished and are considered “Bad” in terms of evaluation.

---

<sup>5</sup>We limit the number of comments we consider to the first ten only in order to spare some annotation efforts.

Note also that subtask A this year is the same as subtask A at SemEval-2015 Task 3, but with slightly different annotation and evaluation measure.

**English subtask B** *Question-Question Similarity.* Given a new question  $Q$  (aka original question) and the set of the first ten related questions from the forum ( $Q_1, \dots, Q_{10}$ ) retrieved by a search engine, the goal is to rank the related questions according to their similarity with respect to the original question.

In this case, we consider the “PerfectMatch” and “Relevant” questions both as good (i.e., we do not distinguish between them and we will consider them both “Relevant”), and they should be ranked above the “Irrelevant” questions. As in subtask A, we use MAP as the official evaluation measure. To produce the ranking of related questions, participants have access to the corresponding related question-thread.<sup>6</sup> Thus, being more precise, this subtask could have been named *Question — Question+Thread Similarity*.

**English subtask C** *Question-External Comment Similarity.* Given a new question  $Q$  (aka the original question), and the set of the first ten related questions ( $Q_1, \dots, Q_{10}$ ) from the forum retrieved by a search engine, each associated with its first ten comments appearing in its thread ( $c_1^1, \dots, c_1^{10}, \dots, c_{10}^1, \dots, c_{10}^{10}$ ), the goal is to rank the 100 comments  $\{c_i^j\}_{i,j=1}^{10}$  according to their relevance with respect to the original question  $Q$ .

This is the main English subtask. As in subtask A, we want the “Good” comments to be ranked above the “PotentiallyUseful” and “Bad” comments, which will be considered just bad in terms of evaluation. Although, the systems are supposed to work on 100 comments, we take an application-oriented view in the evaluation, assuming that users would like to have good comments concentrated in the first ten positions. We believe users care much less about what happens in lower positions (e.g., after the 10th) in the rank, as they typically do not ask for the next page of results in a search engine such as Google or Bing. This is reflected in our primary evaluation score, MAP, which we restrict to consider only the top ten results in subtask C.

<sup>6</sup>Note that the search engine indexes entire Web pages, and thus, the search engine has compared the original question to the related questions together with their comment threads.

**Arabic subtask D** *Rank the correct answers for a new question.* Given a new question  $Q$  (aka the original question), the set of the first 30 related questions retrieved by a search engine, each associated with one correct answer  $((Q_1, c_1) \dots, (Q_{30}, c_{30}))$ , the goal is to rank the 30 question-answer pairs according to their relevance with respect to the original question. We want the “Direct” and the “Relevant” answers to be ranked above the “Irrelevant” answers; the former two are considered “Relevant” in terms of evaluation. We evaluate the position of “Relevant” answers in the rank, therefore, this is again a ranking task.

Unlike the English subtasks, here we use 30 answers since the retrieval task is much more difficult, leading to low recall, and the number of correct answers is much lower. Again, systems were evaluated using MAP, restricted to the top-10 results.

## 4 Datasets

As we mentioned above, the task is offered for two languages, English and Arabic. Below we describe the data for each language.

### 4.1 English Dataset

We refer to the English data as the CQA-QL corpus; it is based on data from the Qatar Living forum.

The English data is organized with focus on the main task, which is subtask C, but it contains annotations for all three subtasks. It consists of a list of original questions, where for each original question there are ten related questions from Qatar Living, together with the first ten comments from their threads. The data is annotated with the relevance of each related question with respect to the original question (subtask B), as well as with the relevance of each comment with respect to the related (subtask A) and also with respect to the original question (subtask C).

To build the dataset, we first selected a set of questions to serve as original questions. In a real-world scenario those would be questions that were never asked before; however, here we used existing questions from Qatar Living. For the training and for the development datasets, we used questions from SemEval-2015 Task 3 (Nakov et al., 2015), while we used new Qatar Living questions for testing.

From each original question, we generated a query, using the question’s subject (after some word removal if the subject was too long). Then, we executed the query in Google, limiting the search to the Qatar Living forum, and we collected up to 200 resulting question-comment threads as related questions. Afterwards, we filtered out threads with less than ten comments as well as those for which the question was more than 2,000 characters long. Finally, we kept the top-10 surviving threads, keeping just the first 10 comments in each thread.

We formatted the results in XML with UTF-8 encoding, adding metadata for the related questions and for their comments; however, we did not provide any meta information about the original question, in order to emulate a scenario where it is a new question, never asked before in the forum. In order to have a valid XML, we had to do some cleansing and normalization of the data. We added an XML format definition at the beginning of the XML file and made sure it validates.

We provided a split of the data into three datasets: training, development, and testing. A dataset file is a sequence of original questions (OrgQuestion), where each question has a subject, a body (text), and a unique question identifier (ORGQ\_ID). Each such original question is followed by ten threads, where each thread has a related question (according to the search engine results) and its first ten comments.

Each related question (RelQuestion) has a subject and a body (text), as well as the following attributes:

- RELQ\_ID: question identifier;
- RELQ\_RANKING\_ORDER: the rank of the related question in the list of results returned by the search engine for the original question;<sup>7</sup>
- RELQ\_CATEGORY: the question category, according to the Qatar Living taxonomy;<sup>8</sup>

---

<sup>7</sup>This is the rank of the thread in the original list of Google results, before the thread filtering; see above.

<sup>8</sup>Here are some examples of Qatar Living categories: Advice and Help, Beauty and Style, Cars and driving, Computers and Internet, Doha Shopping, Education, Environment, Family Life in Qatar, Funnies, Health and Fitness, Investment and Finance, Language, Moving to Qatar, Opportunities, Pets and Animals, Politics, Qatar Living Lounge, Qatari Culture, Salary and Allowances, Sightseeing and Tourist attractions, Socialising, Sports in Qatar, Visas and Permits, Welcome to Qatar, Working in Qatar.

- RELQ\_DATE: date of posting;
- RELQ\_USERID: identifier of the user asking the question;
- RELQ\_USERNAME: name of the user asking the question;
- RELQ\_RELEVANCE2ORGQ: human assessment on the relevance this RelQuestion thread with respect to OrgQuestion. This label can take one of the following values:

- *PerfectMatch*: RelQuestion matches OrgQuestion (almost) perfectly; at test time, this label is to be merged with Relevant;
- *Relevant*: RelQuestion covers some aspects of OrgQuestion;
- *Irrelevant*: RelQuestion covers no aspects of OrgQuestion.

Each comment has a body text,<sup>9</sup> as well as the following attributes:

- RELC\_ID: comment identifier;
- RELC\_USERID: identifier of the user posting the comment;
- RELC\_USERNAME: name of the user posting the comment;
- RELC\_RELEVANCE2ORGQ: human assessment about whether the comment is Good, Bad, or Potentially Useful with respect to the original question, OrgQuestion. This label can take one of the following values:

- *Good*: at least one subquestion is directly answered by a portion of the comment;
- *PotentiallyUseful*: no subquestion is directly answered, but the comment gives potentially useful information about one or more subquestions (at test time, this class will be merged with Bad);
- *Bad*: no subquestion is answered and no useful information is provided (e.g., the answer is another question, a thanks, dialog with another user, a joke, irony, attack of other users, or is not in English, etc.).

---

<sup>9</sup>As most of the time the comment’s subject is just “RE:<question subject>”, we decided to drop it from the dataset.

Question: Good Bank // Which is a good bank as per your experience in Doha [Q2633]

**Thread Topic:** What is the best bank to open an account? // Seems like all the banks need the salary to be credited to their accounts [where I came from that was not a necessity]. So it sort of limits my choices. Can anyone recommend me a bank that has good interest rates on loans and credit cards? So far I'm considering Doha Bank because of the Lulu card. Is it worth it? :)

[Q2633\_5][23258796]

Is this thread relevant to the question?

- Perfect match
- Relevant
- Irrelevant

Thread Comments:

Question: Good Bank // Which is a good bank as per your experience in Doha

Comment 1: IBQ... if your salary is 25k above you will have a banking officer that will take care of your needs... [6164531]

Is this comment a good answer to the question?

- Good
- Bad
- Potentially useful

Question: Good Bank // Which is a good bank as per your experience in Doha

Comment 2: West bank ??? [6164536]

Is this comment a good answer to the question?

- Good
- Bad
- Potentially useful

Figure 1: Screenshot for the first English annotation job, collecting labels for subtasks B and C.

Question and Comments:

Question: massage oil // is there any place i can find scented massage oils in qatar? [Q1\_1][20501150]

Comment 1: Yes. It is right behind Kahrama in the National area. [5444863]

Is this comment a good answer to the question?

- Good
- Bad
- Potentially useful

Question: massage oil // is there any place i can find scented massage oils in qatar? [Q1\_1][20501150]

Comment 2: whats the name of the shop? [5444866]

Is this comment a good answer to the question?

- Good
- Bad
- Potentially useful

Figure 2: Screenshot of the second English annotation job, collecting labels for subtask A.

- RELC\\_RELEVANCE2RELQ: human assessment about whether the comment is Good, Bad, or PotentiallyUseful (again, the latter two are merged under Bad at test time) with respect to the related question, RelQuestion.

We used the CrowdFlower<sup>10</sup> crowdsourcing platform to annotate the gold labels for the three sub-tasks, namely RELC\\_RELEVANCE2RELQ for subtask A, RELQ\\_RELEVANCE2ORGQ for subtask B, and RELC\\_RELEVANCE2ORGQ for subtask C. We collected several annotations for each decision (there were at least three human annotators per example) and we resolved the discrepancies using the default mechanisms of CrowdFlower, which take into account the general quality of annotation for each annotator (based on the hidden tests).

<sup>10</sup><http://www.crowdflower.com>

Unlike SemEval-2015 Task 3 (Nakov et al., 2015), where we excluded comments for which there was a lot of disagreement about the labels between the human annotators, this time we did not eliminate any comments (but we controlled the annotation quality with hidden tests), and thus we guarantee that for each question thread, we have the first ten comments without any comment being skipped.

To gather gold annotation labels, we created two annotation jobs on CrowdFlower, screenshots of which are shown in Figures 1 and 2.

The first annotation job aims to collect labels for subtasks B and C. We show a screenshot in Figure 1. An annotation example consists of an original question, a related question, and the first ten comments for that related question.

      <RelCText>whats the name of the shop?</RelCText>
    </RelComment>

```

Figure 3: Annotated English question from the CQA-QL corpus. Shown are the first two comments only.

We asked the annotators to judge the relevance of the thread with respect to the original question (RELQ\\_RELEVANCE2ORGQ, for subtask B), as well as the relevance of each comment with respect to the original question (RELC\\_RELEVANCE2ORGQ, for subtask C). Each example is judged by three annotators who must maintain 70% accuracy throughout the job, measured on a hidden set of 121 examples.<sup>11</sup> The average inter-annotator agreement on the training, development, and testing datasets is 80%, 74%, and 87% for RELQ\\_RELEVANCE2ORGQ, and 83%, 74%, and 88% for RELC\\_RELEVANCE2ORGQ.

The second CrowdFlower job collects labels for subtask A; a screenshot is shown in Figure 2. An annotation example consists of a question-comments thread, with ten comments, and we ask annotators to judge the relevance of each comment with respect to the thread question (RELC\\_RELEVANCE2RELQ). Again, each example is judged by three annotators who must maintain 70% accuracy throughout the job, measured on a hidden set of 150 examples. The average inter-annotator agreement on the training, development, and testing datasets is 82%, 89%, and 79% for RELC\\_RELEVANCE2RELQ.

<sup>11</sup>The hidden tests for all subtasks were generated gradually. We started with a small number of initial tests, verified by two task coorganizers, and we gradually added more, choosing from those for which we had highest annotation agreement.

A fully annotated example is shown in Figure 3. Statistics about the datasets are shown in Table 1.

Note that the training data is split into two parts, where part2 is noisier than part1. For part2, a different annotation setup was used,<sup>12</sup> which confused the annotators, and they often provided annotation for RELC\\_RELEVANCE2ORGQ while wrongly thinking that they were actually annotating RELC\\_RELEVANCE2RELQ. Note that the development data was annotated with the same setup as training part2; however, we manually double-checked and corrected it. Instead, the training part1 and testing datasets used the less confusing, and thus higher-quality annotation setup described above.

Note also that in addition to the above-described canonical XML format, we further released the data in an alternative uncleansed<sup>13</sup> multi-line format. We further released a simplified file format containing only the relevant information for subtask A, where duplicated related questions are removed.<sup>14</sup> Finally, we reformatted the training, development, and test data from SemEval-2015 Task 3 (Nakov et al., 2015), to match the subtask A format for this year.

<sup>12</sup>Here are the annotation instructions we used for part2: [http://alt.qcri.org/semeval2016/task3/data/uploads/annotation\\_instructions\\_for\\_part2.pdf](http://alt.qcri.org/semeval2016/task3/data/uploads/annotation_instructions_for_part2.pdf)

<sup>13</sup>In fact, minimally cleansed, so that the XML file is valid.

<sup>14</sup>The same question can be retrieved as related for different original questions. These are not repetitions for subtasks B and C, but they are such for subtask A.

| – <i>Bad</i>  | 6,362               | 1,777               | -                                     | 1,209        | 3,090        | 12,438        |
| – <i>Potentially Useful</i>                                     | 2,461               | 649                 | -                                     | 413          | 1,143        | 4,666         |

Table 1: Main statistics about the English CQA-QL corpus.

We released this reformatted SemEval-2015 Task 3, subtask A data as additional training data. We further released a large unannotated dataset from Qatar Living with 189,941 questions and 1,894,456 comments, which is useful for unsupervised learning or for training domain-specific word embeddings.

## 4.2 Arabic Dataset

While at SemEval-2015 (Nakov et al., 2015) we used a dataset from the Fatwa website, this year we changed the domain to medical, which is largely ignored for Arabic. We will refer to the Arabic corpus as CQA-MD. We extracted data from three popular Arabic medical websites that allow visitors to post questions related to health and medical conditions, and to get answers by professional doctors. We collected 1,531 question-answer (QA) pairs from WebTeb,<sup>15</sup> 69,582 pairs from Al-Tibbi,<sup>16</sup> and 31,714 pairs from the medical corner of Islamweb.<sup>17</sup>

We used the 1,531 questions from WebTeb as our original questions, and we looked to find related QA pairs from the other two websites. We collected over 100,000 QA pairs in total from the other two websites, we indexed them in Solr, and we searched them trying to find answers to the WebTeb questions.

We used several different query/document formulations to perform 21 retrieval runs, and we merged the retrieved results, ranking them according to the reciprocal rank fusion algorithm (Cormack et al., 2009). Finally, we truncated the result list to the 30 top-ranked QA pairs, ending up with 45,164 QA pairs<sup>18</sup> for the 1,531 original questions. Next, we used CrowdFlower to obtain judgments about the relevance of these QA pairs with respect to the original question using the following labels:

- “**D**” (Direct): The QA pair contains a direct answer to the original question such that if the user is searching for an answer to the original question, the proposed QA pair would be satisfactory and there would be no need to search any further.
- “**R**” (Related): The QA pair contains an answer to the original question that covers some of the aspects raised in the original question, but this is not sufficient to answer it directly. With this QA pair, it would be expected that the user will continue the search to find a direct answer or more information.
- “**I**” (Irrelevant): The QA pair contains an answer that is irrelevant to the original question.

<sup>15</sup><http://www.webteb.com/>

<sup>16</sup><http://www.altibbi.com/>

<sup>17</sup><http://consult.islamweb.net/>

<sup>18</sup>We had less than 30 answers for some questions.

Figure 4: Annotated question from the Arabic CQA-MD corpus.

We controlled the quality of annotation using a hidden set of 50 test questions. We had three judgments per example, which we combined using the CrowdFlower mechanism. The average inter-annotator agreement was 81%.

Finally, we divided the data into training, development and testing datasets, based on confidence, where the examples in the test dataset were those with the highest annotation confidence. We further double-checked and manually corrected some of the annotations for the development and the testing datasets whenever necessary.

Figure 4 shows part of the XML file we generated. We can see that, unlike the English data, there are no threads here, just a set of question-answer pairs; moreover, we do not provide much meta data, but we give information about the confidence of annotation (for the training and development datasets only, but not for the test dataset).

Table 2 shows some statistics about the dataset size and the distribution of the three classes in the CQA-MD corpus.

| Category     | Train  | Dev   | Test  | Total  |
|--------------|--------|-------|-------|--------|
| Questions    | 1,031  | 250   | 250   | 1,531  |
| QA Pairs     | 30,411 | 7,384 | 7,369 | 45,164 |
| – Direct     | 917    | 70    | 65    | 1,052  |
| – Related    | 17,412 | 1,446 | 1,353 | 20,211 |
| – Irrelevant | 12,082 | 5,868 | 5,951 | 23,901 |

Table 2: Main statistics about the CQA-MD corpus.

## 5 Scoring

The official evaluation measure we used to rank the participating systems is Mean Average Precision (MAP) calculated for the ten comments a participating system has ranked highest. It is a well-established in Information Retrieval. We further report the results for two unofficial ranking measures, which we also calculate for the top-10 results only: Mean Reciprocal Rank (MRR) and Average Recall (AvgRec). Additionally, we report the results for four standard classification measures, which we calculate over the full list of results: Precision, Recall, F<sub>1</sub> (with respect to the Good/Relevant class) and Accuracy.

We released a specialized scorer that calculates and reports all above-mentioned seven scores.

## 6 Participants and Results

The list of all participating teams can be found in Table 7. The results for subtasks A, B, C, and D are shown in Tables 3, 4, 5, and 6, respectively. In all tables, the systems are ranked by the official MAP scores for their primary runs<sup>19</sup> (shown in the third column). The following columns show the scores based on the other six unofficial measures; the ranking with respect to these additional measures are marked with a subindex (for the primary runs).

<sup>19</sup>Participants could submit one primary run, to be used for the official ranking, and up to two contrastive runs, which are scored but have unofficial status.

Eighteen teams participated in the challenge presenting a variety of approaches and features to address the different subtasks. They submitted a total of 95 runs (38 primary and 57 contrastive), which are broken down by subtasks in the following way: The English subtasks A, B and C attracted 12, 11, and 10 systems and 29, 25 and 28 runs, respectively. The Arabic subtask D got 5 systems and 13 runs. The best MAP scores varied from 45.83 to 79.19, depending on the subtask. The best systems in each subtask were able to beat the baselines we provided by sizeable margins.

### 6.1 Subtask A, English (Question-Comment Similarity)

Table 3 shows the results for subtask A, English, which attracted 12 teams, which submitted 29 runs: 12 primary and 17 contrastive. The last four rows of the table show the performance of four baselines. The first one is the chronological ranking, where the comments are ordered by their time of posting; we can see that all submissions outperform this baseline on all three ranking measures. The second baseline is a random baseline, which outperforms some systems in terms of  $F_1$ , primarily because of having very high Recall. Baseline 3 classifies all comments as Good, and it outperforms four of the primary systems in terms of  $F_1$ . Finally, baseline 4 classifies all comments as Bad; it outperforms one of the primary systems in terms of Accuracy.

The winning team is that of KeLP (Filice et al., 2016), which achieved the highest MAP of 79.19, outperforming the second best by a margin; they are also first on AvgRec and MRR, and second on Accuracy. They learn semantic relations between questions and answers using kernels and previously-proposed features from (Barrón-Cedeño et al., 2015). Their system is based on the KeLP machine learning platform (Filice et al., 2015), and thus the name of the team.

The second best system is that of ConvKN (Barrón-Cedeño et al., 2016) with MAP of 77.66; it is also first on Accuracy, second on  $F_1$ , and third on AvgRec. The system combines convolutional tree kernels and convolutional neural networks, together with text similarity and thread-specific features. Their contrastive1 run achieved even better results: MAP of 78.71.

The third best system is SemanticZ (Mihaylov and Nakov, 2016b) with MAP of 77.58. They use semantic similarity based on word embeddings and topics; they are second on AvgRec and MRR.

Note also the cluster of systems of very close MAP: ConvKN (Barrón-Cedeño et al., 2016) with 77.66, SemanticZ (Mihaylov and Nakov, 2016b) with 77.58, ECNU (Wu and Lan, 2016) with 77.28, and SUper\_team (Mihaylova et al., 2016) with 77.16. The latter also has a contrastive run with MAP of 77.68, which would have ranked second.

### 6.2 Subtask B, English (Question-Question Similarity)

Table 4 shows the results for subtask B, English, which attracted 11 teams and 25 runs: 11 primary and 14 contrastive. This turns out to be a hard task. For example, the IR baseline (i.e., ordering the related questions in the order provided by the search engine) outperforms 5 of the 11 systems in terms of MAP; it also outperforms several systems in terms of MRR and AvgRec. The random baseline outperforms one system in terms of  $F_1$  and Accuracy, again due to high recall. The all-Good baseline outperforms two systems on  $F_1$ , while the all-Bad baseline outperforms two systems on Accuracy.

The winning team is that of UH-PRHLT (Franco-Salvador et al., 2016), which achieved MAP of 76.70 (just 2 MAP points over the IR baseline). They use distributed representations of words, knowledge graphs generated with BabelNet, and frames from FrameNet. Their contrastive2 run is even better, with MAP of 77.33.

The second best system is that of ConvKN (Barrón-Cedeño et al., 2016) with MAP of 76.02; they are also first on MRR, second on AvgRec and  $F_1$ , and third on Accuracy.

The third best system is KeLP (Filice et al., 2016) with MAP of 75.83; they are also first on AvgRec,  $F_1$ , and Accuracy. They have a contrastive run with MAP of 76.28, which would have ranked second.

The fourth best, SLS (Mohtarami et al., 2016) is very close, with MAP of 75.55; it is also first on MRR and Accuracy, and third on AvgRec. It uses a bag-of-vectors approach with various vector- and text-based features, and different neural network approaches including CNNs and LSTMs to capture the semantic similarity between questions and answers.

### 6.3 Subtask C, English (Question-External Comment Similarity)

The results for subtask C, English are shown in Table 5. This subtask attracted 10 teams, and 28 runs: 10 primary and 18 contrastive. Here the teams performed much better than they did for subtask B. The first three baselines were all outperformed by all participating systems. However, due to severe class imbalance, the all-Bad baseline outperformed 9 out of the 10 participating teams in terms of Accuracy.

The best system in this subtask is that of the SUper\_team (Mihaylova et al., 2016), which achieved MAP of 55.41; the system is also first on AvgRec and MRR. It used a rich set of features, grouped into three categories: question-specific features, answer-specific features, and question-answer similarity features. This includes more or less standard metadata, lexical, semantic, and user-related features, as well as some exotic ones such as features related to readability, credibility, as well as goodness polarity lexicons.<sup>20</sup> It is important to note that this system did not try to solve subtask C directly, but rather just multiplied their predicted score for subtask A by the reciprocal rank of the related question in the list of related questions (as returned by the search engine, and as readily provided by the organizers as an attribute in the XML file) for the original question. In fact, this is not an isolated case, but an approach taken by several participants in subtask C.

The second best system is that of KeLP (Filice et al., 2016), with MAP of 52.95; they are also first on  $F_1$ , and second on AvgRec and MRR. KeLP also has a contrastive run with a MAP of 55.58, which would have made them first. This team really tried to solve the actual subtask C by means of stacking classifiers: they used their subtask A classifier to judge how good the answer is with respect to the original and with respect to the related question. Moreover, they used their subtask B classifier to judge the relatedness of the related question with respect to the original question. Finally, they used these three scores, together with some features based on them, to train a classifier that solves subtask C.

<sup>20</sup>These goodness polarity lexicons were at the core of another system, PMI-cool (Balchev et al., 2016), which did not perform very well as it limited itself to lexicons and ignored other important features.

In fact, we anticipated solutions like this when we designed the task, i.e., that participants would solve subtasks A and B, and use them as auxiliary tasks to attack the main task, namely subtask C. Unfortunately, subtask B turned out to be too hard, and thus many participants decided to skip it and just to use the search engine’s reciprocal rank.

The third best system is SemanticZ (Mihaylov and Nakov, 2016b), with MAP of 51.68. Similarly to SUper\_team, they simply multiply their predicted score for subtask A by the reciprocal rank of the related question in the list of related questions for the original question.

### 6.4 Subtask D, Arabic (Reranking the correct answers for a new question)

Finally, the results for subtask D, Arabic are shown in Table 6. It attracted 5 teams, which submitted 13 runs: 5 primary and 8 contrastive. As the class imbalance here is even more severe than for subtask C, the all-Bad baseline outperforms all participating systems in terms of Accuracy. In contrast, the all-Good baseline only outperforms one system in terms of  $F_1$ . Here the teams perform much better than for subtask B. The random baseline outperforms one system in terms of both MAP and AvgRec.

The clear winner here is SLS (Mohtarami et al., 2016), which is ranked first on all measures: MAP, AvgRec, MRR,  $F_1$ , and Accuracy. Yet, their MAP of 45.83 is only slightly better than that of ConvKN, 45.50, which ranks second on MAP, AvgRec, MRR and  $F_1$ , and third on Accuracy.

The third system is RDI (Magooda et al., 2016) with MAP of 43.80, which is ranked third also on AvgRec and MRR. The system combines a TF.IDF module with a recurrent language model and information from Wikipedia.

## 7 Features and Techniques

The systems that participated in several subtasks typically re-used some features for all subtasks, whenever possible and suitable. Such features include the following: (i) *similarity features* between questions and comments from their threads or between original questions and related questions, e.g., cosine similarity applied to lexical, syntactic and semantic representations or distributed representa-

tions, often derived using neural networks, (ii) *content features*, which are special signals that can clearly indicate a bad answer, e.g., when a comment contains “thanks”, (iii) *thread level/meta features*, e.g., user ID, comment rank in the thread, and (iv) *automatically generated features* from syntactic structures using tree kernels.

Overall, most of the top positions are occupied by systems that used tree kernels, combined with similarity features. Regarding the machine learning approaches used, most systems chose SVM classifiers (often these were ranking versions such as SVM-Rank), or different kinds of neural networks. Below we look in more detail in the features and the used learning methods.

## 7.1 Feature Types

Participants preferred different kinds of features for different subtasks:

**Subtask A.** Similarities between question subject vs. comment, question body vs. comment, and question subject+body vs. comment.

**Subtask B.** Similarities between the original and the related question at different levels: subject vs. subject, body vs. body, and subject+body vs. subject+body.

**Subtask C.** The same from above, plus the similarities of the original question subject, body, and full levels with the comments from the thread of the related question.

The similarity scores to be used as features were computed in various ways, e.g., the majority of teams used dot product calculated over word  $n$ -grams ( $n=1,2,3$ ), character 3-grams, or with TF-IDF weighting. Or simply using word overlap, i.e., the number of common words between two texts, often normalized, e.g., by question/comment length. Or overlap in terms of nouns or named entities.

Several systems, e.g., UH-PRHLT, KeLP, SLS, SemanticZ, ECNU, used additional similarities based on distributed representations. For example, using the continuous skip-gram model of word2vec or Glove, trained on Google News, on the English Wikipedia, or on the unannotated Qatar Living dataset.

In particular, UH-PRHLT used word alignments and distributed representations to align the words of the question with the words of the comment.

On the alignment topic, it is worth mentioned that MTE-NN applied a model originally defined for machine translation evaluation (Guzmán et al., 2015), e.g., based on features computed with BLEU, TER, NIST, and Meteor (Guzmán et al., 2016a). Similarly, ECNU used Spearman, Pearson, and Kendall Ranking Coefficients as similarity scores for question similarity estimation, whereas ICL00 used word-to-word translation probabilities, and UniMelb used convolutional neural networks (CNNs) fed with word embeddings and machine translation evaluation scores as input.

ConvKN used a CNN that also encodes relational links between the involved pieces of texts (Severyn and Moschitti, 2015). MTE-NN applied a simple neural network, ECNU and SLS used LSTM networks, and Overfitting applied Feedforward Neural Net Language Model (FNNLM).

It should be noted that ConvKN and KeLP used tree kernels with relational links (Tymoshenko and Moschitti, 2015; Tymoshenko et al., 2016), i.e., the questions are aligned with the comments (or with the other questions) by means of a special REL tag, directly annotated in the parse trees.

Regarding text structures, UH-PRHLT used Knowledge Graph Analysis, which consists in labeling, weighting, and expanding concepts in the text using a directed graph. They also used frames from FrameNet to generate semantic features.

Several teams, e.g., ConvKN, KeLP and SUper Team, used meta-features, such as the user ID. In particular, the SUper Team collected statistics about the users, e.g., the comments/questions they produced, time since their last activity, the number of good and bad comments in the training data, etc.

Other important features, which were used by most systems, are related to rank, e.g., rank of the comment in the question thread, or rank of the related question in the list of questions retrieved by the search engine for the original question.

Some exotic features by the SUper Team modeled readability, credibility, sentiment analysis, trollness (Mihaylov et al., 2015a; Mihaylov et al., 2015b; Mihaylov and Nakov, 2016a), and goodness polarity, e.g., based on PMI lexicons as for PMI-Cool.

Regarding Arabic, QU-IR and SLS used word2vec, whereas RDI-Team relied on language models. In particular, the winning SLS team used simple text- and vector-based features, where the text similarities are computed at the word- and the sentence-level. Most importantly, they computed two sets of features: one between the original and the related questions, and one between the original question and the related answer, which are then concatenated in one feature vector.

The ConvKN team combined some basic SLS features with tree kernels applied to syntactic trees, obtaining a result that is very close to that of the winning SLS team.

QU-IR used a standard Average Word Embedding and also a new method, Covariance Word Embedding, which computes a covariance matrix between each pair of dimensions of the embedding, thus considering vector components as random variables.

Finally, RDI used Arabic-Wikipedia to boost the weights of medical terms, which improved their ranking function.

## 7.2 Learning Methods

The most popular machine learning approach was to use Support Vector Machines (SVM) on the features described in the previous section. SVMs were used in three different learning tasks: classification, regression, and ranking. Note that SVMs allow the use of complex convolutional kernels such as tree kernels, which were used by two systems (which in fact combined kernels with other features).

Neural networks were also widely used, e.g., in word2vec to train word embeddings. As previously mentioned, there were also systems using CNNs, LSTMs and FNNLM. Overfitting also used Random Forests.

Comparing tree kernels vs. neural networks: approaches based on the former were ranked first and second in Subtask A, second and third in Subtask B, and second in Subtasks C and D, while neural network-based systems did not win any subtask, but neural networks contributed to the best systems in all subtasks, e.g., with word2vec. Yet, post-competition improvements have shown that NN-based systems can perform on par with the best (Guzman et al., 2016a).

## 8 Conclusion

We have described SemEval-2016 Task 3 on Community Question Answering, which extended SemEval-2015 Task 3 (Nakov et al., 2015) with new subtasks (Question–Question similarity, Question–External Comment Similarity, and Reranking the correct answers for a new question), new evaluation metrics (based on ranking), new datasets, and new domains (biomedical for Arabic). The overall focus was on answering new questions that were not already answered in the target community forum.

The task attracted 18 teams, which submitted 95 runs; this is good growth compared to 2015, when 13 teams submitted 61 runs. The participants built on the lessons learned from the 2015 edition of the task, and further experimented with new features and learning frameworks. It was interesting to see that the top systems used both word embeddings trained using neural networks and syntactic kernels, which shows the importance of both distributed representations and linguistic analysis. It was also nice to see some new features being tried.

Apart from the new lessons learned from this year’s edition, we believe that the task has another important contribution: the datasets we have created as part of the task (with over 7,000 questions and over 57,000 annotated comments), and which we have released for use to the research community, should be useful for follow up research beyond SemEval.

Finally, given the growth in the interest for the task, we plan a rerun at SemEval-2017 with data from a new domain.

## Acknowledgements

This research was performed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation. It is part of the Interactive sYstems for Answer Search (Iyas) project, which is developed in collaboration with MIT-CSAIL.

We would like to thank the anonymous reviewers for their constructive comments, which have helped us improve the paper.

Table 3: **Subtask A, English (Question-Comment Similarity):** results for all submissions. The first column shows the rank of the primary runs with respect to the official MAP score. The second column contains the team’s name and its submission type (primary vs. contrastive). The following columns show the results for the primary, and then for other, unofficial evaluation measures. The subindices show the rank of the primary runs with respect to the evaluation measure in the respective column.

Table 4: **Subtask B, English (Question-Question Similarity):** results for all submissions. The first column shows the rank of the primary runs with respect to the official MAP score. The second column contains the team’s name and its submission type (primary vs. contrastive). The following columns show the results for the primary, and then for other, unofficial evaluation measures. The subindices show the rank of the primary runs with respect to the evaluation measure in the respective column.

## Abstract

This task combines the labeling of multiword expressions and supersenses (coarse-grained classes) in an explicit, yet broad-coverage paradigm for lexical semantics. Nine systems participated; the best scored 57.7%  $F_1$  in a multi-domain evaluation setting, indicating that the task remains largely unresolved. An error analysis reveals that a large number of instances in the data set are either hard cases, which no systems get right, or easy cases, which all systems correctly solve.

## 1 Introduction

Grammatical analysis tasks, e.g., part-of-speech tagging, are rather successful applications of natural language processing (NLP). They are *comprehensive*, i.e., they operate under the assumption that all grammatically-relevant parts of a sentence will be analyzed: We do not expect a POS tagger to only know a subset of the tags in the language. Most POS tags accommodate unseen words and adapt readily to new text genres. Together, these factors indicate a representation which achieves *broad coverage*.

Explicit analysis of lexical semantics, by contrast, has been more difficult to scale to broad coverage owing to limited comprehensiveness and extensibility. The dominant paradigm of fine-grained word sense disambiguation, WordNet (Fellbaum, 1998), is difficult to annotate in corpora, results in considerable data sparseness, and does not readily generalize to out-of-vocabulary words. While the main corpus with WordNet senses, SemCor (Miller et al., 1993), does reflect several text genres, it is hard to expand SemCor-style annotations to new genres, such as social web text or transcribed speech. This severely limits the applicability of SemCor-based NLP tools and restricts opportunities for linguistic studies of lexical semantics in corpora.

To address this limitation, in the DiMSUM 2016 shared task,<sup>1</sup> we challenged participants to analyze the lexical semantics of English sentences with a tagset integrating **multiword expressions** and **noun and verb supersenses** (following Schneider and Smith, 2015), on multiple nontraditional genres of text. By moving away from fine-grained sense inventories and lexicalized, language-specific<sup>2</sup> annotation, we take a step in the direction of broad-coverage, coarse-grained lexical semantic analysis. We believe this departure from the classical lexical semantics paradigm will ultimately prove fruitful for a variety of NLP applications in a variety of genres.

The integrated lexical semantic representation (§2, §3) has been annotated in an extensive benchmark data set comprising several nontraditional domains (§4). Objective, controlled evaluation procedures (§5) facilitate a comparison of the 9 systems submitted as part of the official task (§6). While the systems range in performance, all are below 60% in our composite evaluation, suggesting that further work is needed to make progress on this difficult task.

## 2 Background

**Multiword expressions.** Most contemporary approaches to English syntactic and semantic analysis treat space-separated words as the basic units of structure. However, this fails to reflect the basic units of meaning for sentences with non-compositional or idiosyncratic expressions, such as:

- (1) The staff **leaves a lot to be desired** .
- (2) I googled restaurants in the area and **Fuji Sushi** **came up** and reviews were great so I made a **carry out** order of : L 17 .

<sup>1</sup><http://dimsum16.github.io/>

<sup>2</sup>Though our data set is limited to English, the representation is applicable to other languages: see §2.

In these sentences, *a lot, leaves...to be desired, Fuji Sushi, came up, made...order, and carry out* are all **multiword expressions** (MWEs): their combined meanings can be thought of as “prepackaged” in a single lexical expression that happens to be written with spaces. MWEs such as these have attracted a great deal of attention within computational semantics; see Baldwin and Kim (2010) for a review. Schneider et al. (2014b) introduced an English corpus resource annotated for heterogenous MWEs, suitable for training and evaluating general-purpose MWE identification systems (Schneider et al., 2014a). Prior to that, most MWE evaluations were focused on particular constructions such as noun compounds (recently: Constant and Sigogne, 2011; Green et al., 2012; Ramisch et al., 2012; Vincze et al., 2013), though the corpus and identification system of Vincze et al. (2011) targets several kinds of MWEs.

Importantly, the MWEs in Schneider et al.’s (2014b) corpus are not required to be contiguous, but may contain **gaps** (viz.: *made...order*). The corpus also contains qualitative labels indicating the strength of MWEs, either **strong** (mostly non-compositional) or **weak** (compositional but idiomatic). For simplicity we only include strong MWEs in this task.

**Supersenses.** As noted above, relying on WordNet-like fine-grained, lexicalized **senses** creates problems for annotating at a large scale and covering new domains and languages. Named entity recognition (NER) does not suffer from these problems, as it uses a much smaller number of coarse-grained classes. However, these classes only apply to a subset of the nouns in a sentence and exclude verbs and adjectives. They therefore provide far from complete coverage in a corpus.

Noun and verb **supersenses** (Ciaramita and Altun, 2006) offer a middle ground in granularity: they generalize named entity classes to cover all nouns (with 26 classes), but also cover verbs (15 classes)—see table 1—and provide a human-interpretable high-level clustering. WordNet supersenses for adjectives and adverbs nominally exist, but are based on morphosyntactic rather than semantic properties. There is, however, recent work on developing supersense taxonomies for English adjectives and

| N:MOTIVE        | V:CHANGE     |                 |

**Table 1:** The 41 noun and verb supersenses in WordNet.

prepositions (Tsvetkov et al., 2014; Schneider et al., 2015).

The inventory for nouns and verbs originates from the top-level organization of WordNet, but can be applied directly to annotate new data—including out-of-vocabulary words in English or other languages (Schneider et al., 2012; Johannsen et al., 2014). Similar to NER, supersense tagging approaches have generally used statistical sequence models and have been evaluated in English, Italian, Chinese, Arabic, and Danish.<sup>3</sup>

Features based on supersenses have been exploited in downstream semantics tasks such as preposition sense disambiguation, noun compound interpretation, question generation, and metaphor detection (Ye and Baldwin, 2007; Hovy et al., 2010; Tratz and Hovy, 2010; Heilman, 2011; Hovy et al., 2013; Tsvetkov et al., 2013).

#### Relationship between MWEs and supersenses.

We believe that MWEs and supersenses should be tightly coupled: idiomatic combinations such as MWEs are best labeled holistically, since their joint supersense category will often differ from that of the individual words. For example, *spill the beans* in its literal interpretation would receive supersenses V:CONTACT and N:FOOD, whereas the idiomatic interpretation, ‘divulge a secret’, is represented as an MWE holistically tagged as V:COMMUNICATION. Schneider and Smith (2015) develop this idea at

<sup>3</sup>Evaluations used English SemCor (Ciaramita and Altun, 2006; Paaß and Reichartz, 2009), English-Italian MultiSemCor (Picca et al., 2008, 2009; Attardi et al., 2010), the Italian Syntactic-Semantic Treebank and Italian Wikipedia (Attardi et al., 2010; Rossi et al., 2013), Chinese Cilin (Qiu et al., 2011), Arabic Wikipedia (Schneider et al., 2013), and the Danish CLARIN Reference Corpus (Martínez Alonso et al., 2015).

**Figure 1:** Illustration of the target representation. MWE positional markers are shown above the sentence and noun and verb supersenses below the sentence. Links illustrate the behavior of the MWE tags. The supersense labeling must respect the MWEs; thus, *V.COGNITION* applies to a four-word unit—*to*, *be*, and *desired* must not receive separate supersenses from *leaves*.

length, and provide a web reviews data set with the integrated annotation. Here, we expand the paradigm to additional domains and compare the performance of several systems.

### 3 Representation

The analysis for each sentence is represented as a sequence of paired MWE and supersense tags. Figure 1 illustrates the MWE part above the sentence and the supersense part below the sentence.

The MWE portion is a BIO-style (Ramshaw and Marcus, 1995) positional marker. Of the schemes discussed by Schneider et al. (2014a), we adopt the 6-tag scheme, which uses case to allow gaps in an MWE (lowercase tag variants mark tokens within a gap). The positions are thus 0, o, B, b, I, i. Systems are expected to ensure that the full tag sequence for a sentence is valid: global validity can be enforced with first-order constraints to prohibit invalid bigrams such as 0 I and b I (see Schneider et al., 2014a for details).

Because strong MWEs receive a supersense as a unit (if at all), I and i are never accompanied by a supersense label. 0 or o indicates that the token is not part of any MWE, but many such tokens do bear a noun or verb supersense.

This task uses a CoNLL-style **main file format** consisting of one line per token, each line having 9 tab-delimited columns. Scripts to convert to and from the .sst format, which displays one sentence per line and contains annotations in a JSON data structure, are provided as well.

### 4 Data

The task built upon two existing data sets of social web text, which were harmonized to form the training data. Four new samples from three domains

were newly annotated to form the test set. The train and test sets are summarized in tables 2 and 3 and are publicly available on the web.<sup>4</sup>

The domains covered are **online customer reviews**, **tweets**, and **TED talks**. This section describes, for each domain, how its component data sets were sampled, preprocessed, and annotated.

#### 4.1 Annotation Process

We compiled data sets from various sources, with varying degrees of existing pre-annotation. Unless already provided, we added Universal POS tags as defined by the Universal Dependencies project (Nivre et al., 2015), and baseline supersenses (heuristically using the most frequent WordNet sense, and in some cases grouping sequences of proper nouns as MWEs). The pre-annotated supersenses were then manually corrected by a trained annotator, who simultaneously annotated the sentence for comprehensive MWEs.

The annotator (a linguist) was trained by the first author of this paper using Schneider and Smith’s (2015) web interface and annotation guidelines. Prior to starting on the data sets for this task, the annotator devoted approximately 8 hours to training practice on a separate data set which already had a gold standard. Periodic feedback was given on initial annotations as the annotator grew accustomed to the conventions. The annotator spent approximately 50 hours on DiMSUM data (not including the initial training phase), which amounts to roughly 90 seconds per sentence.

In order to estimate inter-annotator agreement (IAA), the first author independently annotated a sample of Ritter tweets (§4.3) in 6 groups of 11 sentences, spaced out across the main annotator’s annotation batches. IAA estimates for these sets ranged from 60% to 75%  $F_1$  for MWEs, and 67%–80% accuracy for supersenses (on tokens which had supersenses in both annotations). Resources did not allow for more systematic double annotation and IAA estimation throughout the data.

The test set newly annotated for this task comprises exactly 1,000 sentences and exactly 16,500 words. 3,120 word tokens (19%) differ from the pre-annotation with respect to gold MWE boundaries

**Table 2:** Source datasets and preprocessing to obtain 17-tag Universal POS tags (UPOS) version 1.2. Most sources already contained some form of POS tags, which we automatically converted to UPOS. We added missing necessary distinctions—e.g., UD-style UPOS distinguishes auxiliaries from main verbs, but Petrov-style (Petrov et al., 2011), PTB (Marcus et al., 1993), or TweetNLP (Owoputi et al., 2013) POS tagsets do not. Disambiguation was done manually or via a gold parse, where available. We also modified the tokenization of the Tweebank data, to be consistent with UPOS conventions for English (e.g., separating clitics).

Only some portions of the data group sentences into documents: N/A = not applicable; N.A. = not available.

**Table 3:** Annotated datasets: status of lexical semantic annotations (retained, revised, or newly annotated for this task) per subcorpus; word token and MWE instance counts; number and proportion (out of all MWEs) that are gappy; proportion of tokens that belong to an MWE; number of units labeled with a noun supersense, and proportion that are MWEs; likewise for verb supersenses.

Additional statistics relatively consistent across domains: MWEs per word: mean/median .055 (lowest: TED, .044; highest: STREUSLE, .090). Supersenses per word: mean/median 0.3. Just 8 MWEs contain more than one gap (all in STREUSLE or Ritter).

and/or supersenses.<sup>5</sup> In addition, portions of the training data were reannotated for improved quality and consistency with the STREUSLE annotations, as explained below.

## 4.2 REVIEWS

**Training.** The REVIEWS part of the training data consists of the STREUSLE corpus (Schneider et al., 2014b; Schneider and Smith, 2015),<sup>6</sup> comprising comprehensive multiword expression and supersense annotations on a 55,000-token portion of the English Web Treebank (EWTB; Bies et al., 2012) made up of 723 online user reviews for services (such as restaurants and beauticians).

STREUSLE annotation was done by linguists, who took pains to establish conventions and resolve disagreements. Each sentence was annotated independently by at least 2 annotators; disagreements were resolved by negotiation.

The task release is based on version 2.1 of STREUSLE, with weak MWEs removed and Penn Treebank-style POS tags replaced with Universal POS tags.<sup>7</sup>

**Test.** The test portion comprises 340 sentences (6,357 tokens) from the online review site Trustpilot, a subset of the data used in Hovy and Søgaard (2015) (the website as a general resource was described in Hovy et al. (2015)). The reviews were chosen to obtain a demographic balance (by age, gender, and location), and contained gold POS tags.

## 4.3 TWEETS

**Training.** Johannsen et al. (2014) recently annotated two samples of 987 Twitter messages (18,000 words) with supersenses: (a) the POS+NER-annotated data set of Ritter et al. (2011), and (b) Plank et al.’s (2014) sample of 200 tweets.<sup>8</sup> Annotators were shown pre-annotations from a heuristic supersense chunking/tagging system (based on

<sup>5</sup>On the surface, this might be taken to mean that the accuracy of the heuristic baseline used for pre-annotation is 81%. However, because the annotator saw the pre-annotation, we expect that this agreement rate is higher than if the gold standard had been produced from scratch.

<sup>6</sup><http://www.ark.cs.cmu.edu/LexSem/>

<sup>7</sup>The PTB-to-UPOS conversion script is available at: <http://tiny.cc/ptb2upos>

<sup>8</sup>The supersense-annotated tweets are available at <https://github.com/coastalcph/supersense-data-twitter>.

the most frequent sense of each word) and asked to correct the boundaries and supersense labels. Though there was no explicit MWE annotation phase, many of the multiword chunks tagged with a noun or verb supersense would be considered MWEs.

We fully reannotated both data sets to match the conventions of the REVIEWS data from the STREUSLE corpus. The annotator examined every sentence and corrected any MWE or supersense decisions deemed to be inconsistent with the guidelines.

**Test.** Our test set consists of 500 tweets (6,627 tokens) taken from the Tweebank corpus (Kong et al., 2014),<sup>9</sup> which already contained some gold-standard MWEs. We converted the POS tags from gold ARK TweetNLP POS + FUDG dependencies to UPOS and had an annotator supply supersenses.

## 4.4 TED TALKS

**Test.** To test the broad-coverage aspect of the submitted systems, the test set contained a “surprise” domain. We opted to sample transcribed sentences from TED talks. Because individual TED talks tend to heavily repeat vocabulary, we took the first 10 sentences from each of 16 documents in order to achieve a lexically diverse sample. Specifically, we chose (a) 100 sentences (2,187 tokens) from the 10 talks in the NAIST-NTT Ted Talk Treebank<sup>10</sup> (Neubig et al., 2014) (which in turn is a subset of the IWSLT training data); and (b) 60 sentences (1,329 tokens) from the IWSLT test data (Cettolo et al., 2012).<sup>11</sup> The latter 6 documents were chosen to maximize language pair diversity.<sup>12</sup>

We induced parts of speech by conversion from the gold PTB trees for the NAIST-NTT data, and

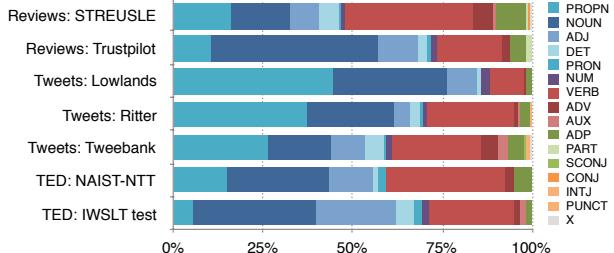

<sup>9</sup><http://www.cs.cmu.edu/~ark/TweetNLP/>

<sup>10</sup><http://ahclab.naist.jp/resource/tedtreebank/>

<sup>11</sup><https://wit3.fbk.eu/>

<sup>12</sup>These 6 talks are known to have been translated from English into (at least) the following languages: {ar, de, es, fa, he, hi, it, ko, nl, th, vi, zh}. Additionally, we note that 4 of the documents have Czech (cs) translations, while the other 2 have French (fr) translations.

Neubig et al. (2014) report that all the 10 documents in the NAIST-NTT Treebank have been translated from English into the following 18 languages: {ar, bg, de, el, es, fr, he, it, ja, ko, nl, pl, pt-BR, ro, ru, tr, zh-CN, zh-TW}. Many additional languages are represented for subsets of the documents.

**Figure 2:** Counts of MWE occurrences, grouped by the POS of the first word in the MWE. Blue bars represent POSEs that tend to start nominal MWEs; red bars roughly capture verbal MWEs.

for the remaining data, by automatic tagging with an averaged structured perceptron model (Rungsted<sup>13</sup>) trained on the English Universal Dependencies v1.2 treebank (Nivre et al., 2015).<sup>14</sup>

#### 4.5 Comparing Domains

A natural question to ask about lexical semantic annotations is whether we observe strong differences between domains. For example, which kinds of multiword expressions and which kinds of supersenses occur more often in some domains than in others? In this section, we report our observations but do not make any strong claims about their generality, for the following reasons: the samples are not necessarily representative of their domains overall, and, in fact, may have been sampled in a biased way (e.g., the Lowlands sample was limited to tweets containing a URL, and as a result, most of these tweets are headlines and advertisements). Furthermore, the annotation procedures differed by subcorpus, likely biasing the results.

**MWEs.** Figure 2 summarizes MWEs in the seven subcorpora with respect to syntactic status. Colors represent the POS tag of the first word in the MWE. Starting with proper nouns, the blue bars indicate POS tags that tend to begin nominal MWEs (noun, adjective, determiner, etc.). Red bar POS tags are characteristic of verbal MWEs. The remaining bars are prepositional (dark green) and other miscellaneous tags, which collectively comprise no more than 10% of the MWEs in each subcorpus.

It is worth noting that in this plot, subcorpora within the same domain are sometimes more diver-

gent than subcorpora in different domains. Lowlands stands out as having a large share of proper noun MWEs—presumably due to the headline-oriented nature of the sample. STREUSLE has the smallest proportion of nominal MWEs, perhaps owing to the way it was annotated: initial rounds of STREUSLE annotation targeted MWEs only, with noun and verb supersenses added only later; whereas in the other data sets, MWE and supersense annotation were performed jointly, so annotator attention may have been focused on nominal and verbal expressions rather than other MWEs.

**Supersenses.** In the spirit of Schneider et al. (2012), we performed an analysis to see which supersenses were more characteristic of some domains than others. Figure 3 plots the relative frequency (out of all supersense-labeled units) of each supersense in each of the three domains. We use the REVIEWS domain as base frequency: relative to that, the x-axis is the supersense’s occurrence rate in the TWEETS domain, and the y-axis represents the rate for the TED talks.

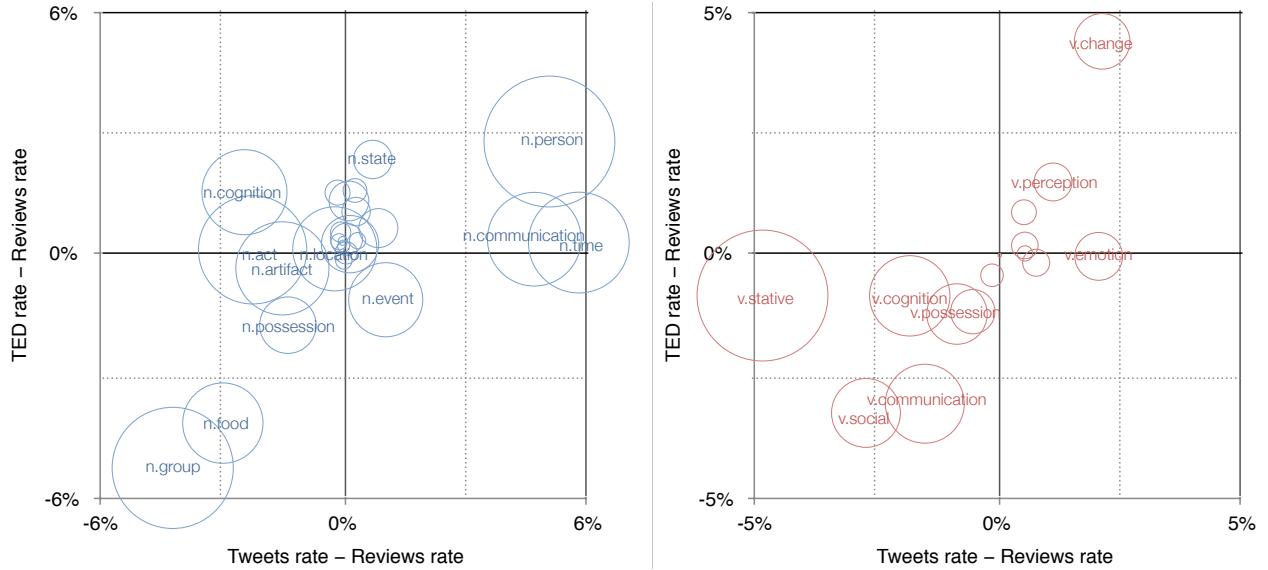

These plots show some clear outliers: among nouns (left plot), N.GROUP and N.FOOD are overrepresented in REVIEWS relative to the other domains—unsurprising because restaurants and other businesses are prominent in this subcorpus. On the other hand, N.PERSON is underrepresented in REVIEWS. N.TIME and N.COMMUNICATION are more popular in the TWEETS domain than the others. Among verbs (right plot), V.STATIVE is underrepresented, apparently due to the relative rarity of the copula (which often can be safely omitted in headlines and other telegraphic messages without obscuring the meaning).

## 5 Evaluation

**Submission conditions.** We invited submissions in multiple data conditions. The **open** condition encouraged participants to make wide use of any and all available resources, including for distant or direct supervision. A **closed** condition encouraged controlled comparisons of algorithms by limiting their training to specific resources distributed for the task. Lastly, we allowed for a **semi-supervised closed** condition, in which use of a specific large unla-

<sup>13</sup><https://github.com/coastalcph/rungsted>

<sup>14</sup><http://hdl.handle.net/11234/1-1548>

**Figure 3:** Supersense rate differences by domains, compared to reviews data set. Circle area proportional to the supersense’s *total* frequency across all domains. Noun supersenses on the left, verb supersenses on the right. Each domain’s rate is microaveraged across its subcorpora; thus, larger subcorpora weigh more heavily than smaller subcorpora in the same domain.

beled corpus—the Yelp Academic Dataset<sup>15</sup>—was permitted. Teams were permitted to submit no more than one run per condition. Only one team submitted a system in the semi-supervised closed condition.

All conditions had access to: 1) the annotated data we provided; 2) Brown clusterings (Brown et al., 1992) computed from large corpora of tweets and web reviews;<sup>16</sup> and 3) the English WordNet lexicon. The input at test time included POS tags.

No sentence-level metadata was provided in the input at test time: test set sentence IDs were obscured to hide the source domain, and the order of sentences was randomized to remove document structure. The training data, however, marked the domain from which the sentence was drawn (REVIEWS or TWEETS); systems were free to make use of this information, so long as it was not required as part of the input at test time.

**Scoring.** We provided an evaluation script to allow participants to check the format of system output and to compute all official scores.

The **MWE** measure looks at precision, recall, and  $F_1$  of the identified MWEs. Tokens not involved in a

predicted or gold MWE do not factor into this measure. To award partial credit for partial overlap between a predicted MWE and a gold MWE, these scores are computed based on *links* between consecutive tokens in an expression (Schneider et al., 2014a). The tokens must appear in order but do not need to be adjacent. The precision is the proportion of predicted links whose words both belong to the same expression in the gold standard. Recall is the same as precision, but swapping the predicted and gold annotations.<sup>17</sup> Figure 4 defines this measure in detail and illustrates the calculations for an example.

To isolate the **supersense** classification performance, we compute precision, recall, and  $F_1$  of the supersense-labeled word tokens. The numerator of both precision and recall is the number of tokens labeled with the correct supersense. (This interacts slightly with MWE identification, however, as supersenses are only marked on the first token of MWEs. We do not mark supersenses on all words of the MWE to avoid giving MWEs a disproportionate influence on the supersense score.)

Finally, **combined** precision, recall, and  $F_1$  aggregate the MWE and supersense subscores. The combined precision ratio is computed from the MWE

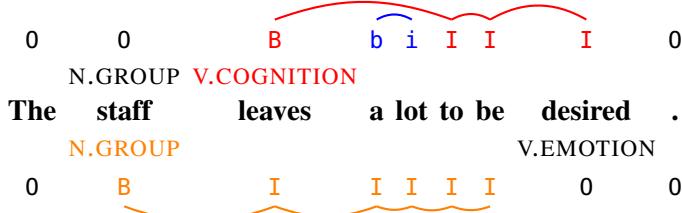

<sup>15</sup>[https://www.yelp.com/academic\\_dataset](https://www.yelp.com/academic_dataset)

<sup>16</sup>I.e., TweetNLP clusters (<http://www.cs.cmu.edu/~ark/TweetNLP/>) and the Yelp Academic Dataset clusters used in AMALGrAM (<http://www.cs.cmu.edu/~ark/LexSem/>).

<sup>17</sup>This computation on the basis of links is a slight simplification of the MUC coreference measure (Vilain et al., 1995).

*MWE Precision:* The proportion of predicted links whose words both belong to the same expression in the gold standard.

*MWE Recall:* Same as precision, but swapping the predicted and gold annotations.

**Figure 4:** A REVIEWS sentence with MWE and supersense analyses: gold above and hypothetical prediction below. MWE precision of the bottom annotation relative to the top one is  $2/5$ . (Note that a link between words  $w_1$  and  $w_2$  is “matched” if, in the other annotation, there is a path between  $w_1$  and  $w_2$ .) The MWE recall value is  $3/4$ . Supersense precision and recall are both  $1/2$ . Combined precision/recall scores add the respective subscores’ numerators and denominators: thus, combined precision is  $\frac{2+1}{5+2} = 3/7$ , and combined recall is  $\frac{3+1}{4+2} = 2/3$ . Combined  $F_1$  is their harmonic mean, i.e.  $12/23$ .

and supersense precision ratios by adding their numerators and denominators, and likewise for combined recall (see the example in figure 4).

Within each domain, scores are computed as microaverages. The official tri-domain scores reported here are domain macroaverages: per-domain measures are aggregated with the three domains weighted equally. The main score, tri-domain combined  $F_1$ , is the arithmetic mean of the three per-domain combined  $F_1$  scores. (Some system papers report domain microaverages, which give less influence to the TED domain because it is the smallest of the domains in the test set.)

## 6 Entries and Results

Six teams<sup>18</sup> participated in the task, submitting a total of nine unique system entries prior to the deadline. We give an overview of these systems and analyze their performance.

### 6.1 Synopsis of approaches

From the **UFRGS&LIF** team (Cordeiro et al., 2016), S106 detects MWEs by heuristic pattern-matching against sequences in the training data, and predicts the most frequent supersense observed for each type in the training data.

From the **UTU** team (Björne and Salakoski, 2016), S211, S254, and S255 match word sequences against a variety of resources and then choose a

supersense with an ensemble of classifiers. The method performs reasonably well for supersenses, but is weak at detecting MWEs.

The **UW-CSE** team (Hosseini et al., 2016) experimented with a sequence CRF as well as a double-chained CRF, with separate chains for MWE tags and supersenses, and some parameters shared between them. The closed-condition and open-condition feature sets were drawn from AMALGrAM (Schneider and Smith, 2015). Of the official submissions, S248 used a single-chain CRF and S249 a double-chained CRF. A full comparison demonstrates that the double-chained CRF performs best on the combined measure in both the closed and open conditions.

From the **ICL-HD** team (Kirilin et al., 2016), S214 uses the AMALGrAM sequence tagger (Schneider and Smith, 2015) with an augmented feature set that leverages word embeddings and a knowledge base. The word embedding features, the knowledge base-derived features, and their union all improve over the condition with no new features, with respect to both MWE performance and supersense performance. The best results for the combined measure are obtained with the word embedding features (but not the knowledge base features). The word embeddings are shown to be somewhat complementary to AMALGrAM’s Brown cluster features: ablating either reduces performance.

From the **WHUNlp** team (Tang et al., 2016), S108 uses a pipeline where a sequence CRF first identifies

<sup>18</sup>None of the teams included any DiMSUM organizers.

|   |        |               |       |           | S255 ++                      | 46.15        | 49.81        | 45.44        |

**Table 4:** Main results on the test set. Scores are tri-domain combined  $F_1$  percentages. Resource conditions are described in §6.2.

MWEs, and a maximum entropy classifier then predicts a supersense independently for each lexical expression. Each of these models has a small number of feature templates recording words and POS tags.

From the **VectorWeavers** team (Scherbakov et al., 2016), S227 relies on neural network classifiers to detect MWE boundaries and label supersenses, using features based on word embeddings and syntactic parses. Results show that syntax helps identify MWE boundaries accurately, and that simple incremental composition functions can help construct useful MWE representations.

## 6.2 Overall results

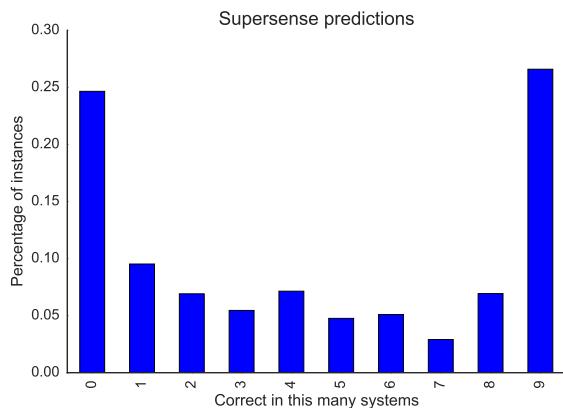

The main results appear in table 4. The first column of table 4 gives the ranking of the systems. Several systems may share a rank if they do not produce significantly different predictions, as detailed below. The score is the combined supersense and MWE measure, macroaveraged over the three test set domains as described above. The final column indicates the resource condition: systems entered in the open condition (all resources allowed) are designated “++”; “+” indicates the more restricted semi-supervised closed condition, while the remaining systems are in the closed condition (most restrictive). Details of the resource conditions and scoring appear in §5.

**Ranking and significance.** The overall best scoring system, with a combined measure of 57.77%, is S214. The competition, however, is close: S249 scored 57.71%, and S248 obtained a combined score of 57.10%. To check whether the predictions of the systems are significantly different from each other,

**Table 5:** Per-domain evaluation results. Figures are  $F_1$  percentages. The best value in each section and column is in bold. Refer to table 4 for the identities of the systems.

we ran McNemar’s test, a paired test that operates directly on the predicted system output. A consequence of this is that we do not directly test whether the computed *scores* are significantly different from each other, only whether the *predictions* are.

According to McNemar’s test, the predictions of the highest-ranking and the next-highest-ranking system are not significantly different at  $p < .05$ . The third highest ranking system performs significantly worse than the top system, but is *not* significantly different from the second-place system. We therefore decided to rank all three systems together. In general, adjacent entries in the sorted scoring table are ranked together if the difference between them is not statistically significant according to the test.

**Figure 5:** Number of systems predicting the correct supersense (for tokens where there is a gold supersense).

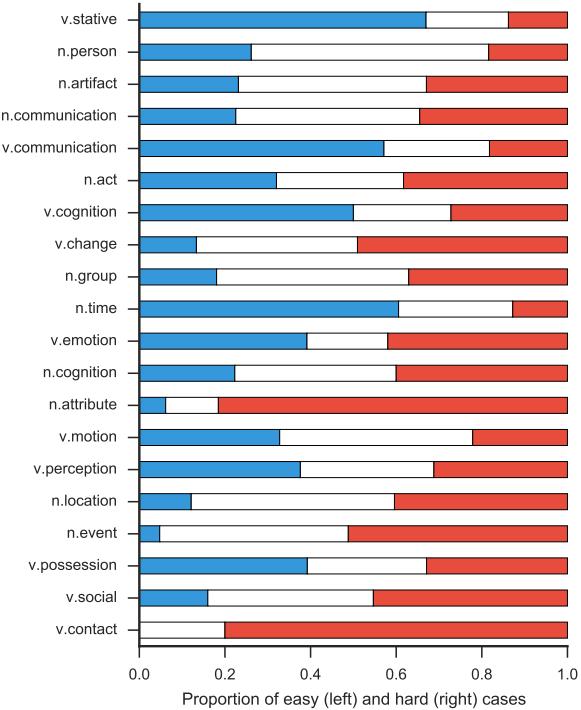

**Drilling down.** Table 5 offers a more detailed breakdown by domain and subscore (MWEs vs. supersenses vs. combined). The best scores are about 57% for both MWEs and supersenses. Systems S214 and S249 are the clear winners: the former is better in the surprise TED domain—particularly TED MWEs (by nearly 4 points). The latter is slightly better in TWEETS, and the systems are quite close in REVIEWS (the domain with the most training data).

S214 and S249 were in the open condition, taking advantage of additional resources. The best system in the closed condition is S248, which is very similar to S249—and recall that its predictions, overall, are not statistically worse. Table 5 reveals one striking difference, however: in MWE scores for TWEETS, S249 beats S248 by nearly 7 points.

When scores in the 3 domains are compared for each system, there is surprisingly little difference overall. We expected that the TED domain would be most difficult because it is not represented in the training data, but the scores in table 5 give no clear indication that this is the case. Perhaps systems escaped domain bias because the training data included two highly divergent genres; or perhaps other aspects of the data sets (e.g., topic) matter more for this task than differences in genre.

### 6.3 Easy and hard decisions

Overall, the results clearly show that the joint supersense and MWE tagging task is not yet resolved. Given the wide range of participating systems and previous work, it is reasonable to assume that the task itself is not easy. On the other hand, it is not

**Figure 6:** Easy and hard supersense decisions. Shown in blue in the left side of the plot is the proportion of instances of the given supersense type where at most one system gave the *wrong* answer. On the right side in red is the corresponding figure where at most one system gave the *right* answer. Supersenses are sorted by corpus frequency.

*uniformly* hard. In fact, some decisions are relatively easy, in the sense that most or all systems get them right; whereas others are hard, in that none or very few systems produce the correct answer. Figure 5 explores this for the supersense-tagging subtask. The tallest bars are near the left and right sides of the graph, representing the hard and easy instances, respectively. Hard instances account for about 25% of instances where the gold data has a supersense, which also puts an upper bound on any system combination. Even an oracle system allowed to choose the best prediction for each instance from among all the systems would still not push the accuracy above 75%.

The distribution of easy and hard instances varies a lot between labels, though. As shown for supersenses in figure 6, individual labels range from the fairly easy (e.g. V.STATIVE and V.COMMUNICATION) to the more difficult (e.g. N.ATTRIBUTE and V.CONTACT). The most common

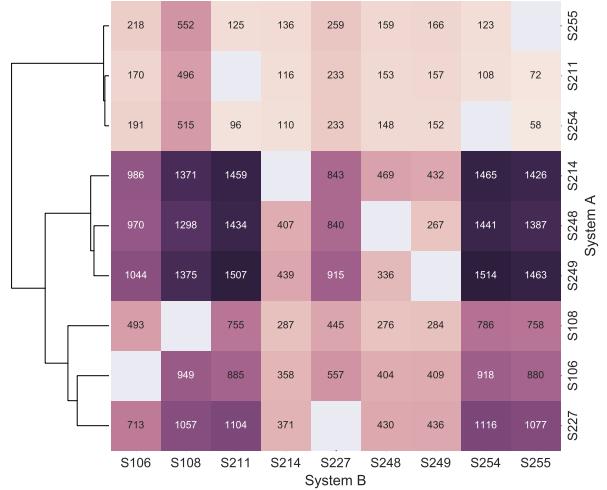

supersense, V.STATIVE, is easy because it has few distinct lexical forms (the ten most common lemmas make up more than 77% of the instances). Examples of V.STATIVE lemmas include *be*, *have*, *use*, and *get*.

Supersenses may be difficult for more than one reason. For instance, V.CONTACT—e.g. *deliver*, *receive*, and *take*—has more distinct forms than V.STATIVE and also a more complex mapping between lemmas and supersenses. In contrast, person names, job titles, etc. that should be tagged as N.PERSON are rarely ambiguous with respect to supersense. The main challenge in that case is that the category is open-ended and not in general evident from syntactic structure.

## 6.4 System correlation

Finally, we examine whether the submitted approaches capture different aspects of the task. I.e., could we produce a better system by combining the individual systems? We cannot estimate this from the results tables, since, combinatorially, there are many ways to obtain a given score. However, we can estimate it from the prediction overlap between systems. The  $N \times N$  labeled matrix in figure 7 shows how the  $N$  systems relate to each other. Each cell compares the predictions of two systems  $a$  and  $b$  in the joint supersense and MWE task. The value of a cell  $T_{a,b}$  is the number of correct predictions made by  $a$  that were not correctly predicted by  $b$ . This is an asymmetric measure of predictive similarity. A single low number indicates one out of two things: either the systems are similar, or  $a$  is better than  $b$ . When the sum  $T_{a,b} + T_{b,a}$  is small, the two systems make similar predictions.

Clustering the systems in figure 7 (shown on the left side of the plot) results in groups that correspond to the ranking in table 4. Inside the cluster of systems ranked at 1, the asymmetric predictive advantage ranges between 267 and 469. Lower-ranked systems all have a smaller predictive advantage with respect to the top-ranked systems. The best combination system would thus likely be between two of the rank-1 systems. However, the gains are small, and overall the systems seem to extract the same knowledge, or subsets of the same knowledge, out of the training data.

**Figure 7:** System clusters. Each cell compares the predictions of two systems  $i$  and  $j$  with respect to a gold standard. The value in the  $i,j$ -th cell is the number of predictions that  $i$  got right but  $j$  did not.

## 7 Conclusion

This task featured a broad-coverage lexical semantic analysis task that combines MWE identification and supersense tagging. The semantic tagset strikes a balance between the extremely difficult fine-grained distinctions in classical WSD, and the restrictiveness of the NER task. To guard against domain bias, we provided training data from two different genres, namely online reviews and tweets, as well as a test-only data set with TED talk transcripts. The training and test data sets are publicly available at <https://github.com/dimsum16/dimsum-data>.

The best scoring systems obtained 57.7%  $F_1$  on a composite measure over the two subtasks of MWE and supersense tagging, averaged over the three test domains. This level of performance suggests that the task is not yet resolved. Furthermore, our error analysis suggests that the submitted systems arrived at similar generalizations from the training data. Substantially improving performance would thus seem to require novel approaches.

## Acknowledgments

We are grateful to Sam Gibbon for the lexical semantic annotation, which was generously supported by Carlsberg infrastructure grant No. CF14-0694.

# SemEval 2016 Task 11: Complex Word Identification

Gustavo Henrique Paetzold and Lucia Specia

Department of Computer Science

University of Sheffield, UK

{ghpaetzold1,l.specia}@sheffield.ac.uk

## Abstract

We report the findings of the Complex Word Identification task of SemEval 2016. To create a dataset, we conduct a user study with 400 non-native English speakers, and find that complex words tend to be rarer, less ambiguous and shorter. A total of 42 systems were submitted from 21 distinct teams, and nine baselines were provided. The results highlight the effectiveness of Decision Trees and Ensemble methods for the task, but ultimately reveal that word frequencies remain the most reliable predictor of word complexity.

## 1 Introduction

Complex Word Identification (CWI) is the task of deciding which words should be simplified in a given text. It is commonly connected with the task of Lexical Simplification (LS), which has as goal to replace complex words and expressions with simpler alternatives. In the usual LS pipeline, which was first introduced by (Shardlow, 2014), CWI is the first step. An effective CWI strategy can prevent LS approaches from replacing simple words, and hence prevent them from making grammatical and/or semantic errors. Early LS approaches (Devlin and Tait, 1998; Carroll et al., 1999) do not include CWI. As shown in (Paetzold and Specia, 2013; Shardlow, 2014), ignoring this step can considerably decrease the quality of the output produced by a simplifier.

CWI has been gaining popularity in recent research. The LS approach in (Horn et al., 2014) employs an implicit CWI strategy in which a target

word is only deemed complex if the LS model can find a candidate substitution which is simpler. Their results, however, show that the approach is unable to find simplifications for one third of the complex words in the dataset. (Shardlow, 2013b) presents the CW corpus: the first dataset for CWI. Although a relevant contribution, this dataset contains only 731 instances extracted automatically from the Simple English Wikipedia edits, which raises concerns about its reliability and applicability.

The results obtained by Shardlow (2013a) highlight some of the issues of the dataset. They use the CW corpus to compare the performance of three solutions to CWI: a Threshold-Based approach, a Support Vector Machine (SVM), and a “Simplify Everything” approach. In their experiments, the “Simplify Everything” approach achieves higher Accuracy, Recall and F-scores than all other systems, suggesting that simplifying all words in a sentence is the most effective approach for CWI. These results are clearly counter intuitive and conflicting with the conclusions drawn in (Paetzold and Specia, 2013; Paetzold, 2013; Shardlow, 2014).

In this paper we describe the first edition of the Complex Word Identification task, organized at SemEval 2016. This is an initiative that aims to provide reliable resources and new insights for CWI, as well as to establish the state of the art performance in CWI for English texts, and bring more visibility to the area of Text Simplification.

## 2 Task Description

The Complex Word Identification task of SemEval 2016 invited participants to create systems that,

given a sentence and a target word within it, can predict whether or not a non-native English speaker would be able to understand the meaning of the target word. We chose non-native speakers as a target audience because, unlike second language learners and those with low literacy levels or conditions such as Aphasia and Dyslexia, non-native speakers of English have not yet been explicitly assessed with respect to their simplification needs. In addition, the broad availability of such an audience makes data collection more feasible.

We have established main goals for the task:

1. To learn which words challenge non-native English speakers and to understand what their traits are.
2. To investigate how well one's individual vocabulary limitations can be predicted from the overall vocabulary limitations of others in the same category.
3. To introduce a new corpus to be used in Text Simplification and other tasks related to Topic Modelling and Semantics.
4. To evaluate the reliability of various resources commonly used in the creation of Lexical Simplification approaches.
5. To establish the state of the art performance in CWI for English texts.
6. To investigate and establish evaluation metrics for the task of CWI.

In order to achieve these objectives for the shared task, we started by creating a manually annotated dataset through a user study.

### 3 User Study

In the study, volunteers were asked to judge whether or not they could understand the meaning of each word in a given sentence. In the following we provide more details on the sentences used and the annotation process.

#### 3.1 Data Sources

We selected 9,200 sentences to be annotated, after filtering out cases with spurious characters, HTML

or CSS markup, or outside the 20-40 word-length range. These sentences were taken from three sources:

**CW Corpus** (Shardlow, 2013b): composed of 731 sentences from the Simple English Wikipedia in which exactly one word had been simplified by Wikipedia editors from the standard English Wikipedia. Commonly used for the training and evaluation of Complex Word Identification systems. 231 sentences that conformed to our criteria were extracted.

**LexMTurk Corpus** (Horn et al., 2014): composed of 500 sentences from the Simple English Wikipedia containing one target word that had been simplified from the standard English Wikipedia. Commonly used for the training and evaluation of Lexical Simplification systems. 269 sentences that conformed to our criteria were extracted.

**Simple Wikipedia** (Kauchak, 2013): composed of 167,689 sentences from the Simple English Wikipedia, each aligned to an equivalent sentence in the standard English Wikipedia. We selected a set of 8,700 sentences from the Simple Wikipedia version that conformed to our criteria and were aligned to an identical sentence in Wikipedia. The goal was to evaluate the ability of the Wikipedia (human) editors in identifying complex words for readers of the Simple Wikipedia.

#### 3.2 Annotation Process

400 non-native speakers of English participated in the experiment, mostly university students or staff. Volunteers provided anonymous information about their native language, age, education level and English proficiency level according to CEFR (Common European Framework of Reference for Languages). They were asked to judge whether or not they could understand the meaning of each content word (nouns, verbs, adjectives and adverbs, as tagged by Freeling (Padr and Stanilovsky, 2012)) in a set of sentences, each of which was judged independently. Volunteers were instructed to annotate all words that they could not understand individually, even if they could comprehend the meaning of the sentence as a whole.

A subset of 200 sentences was split into 20 subsets of 10 sentences, and each subset was annotated by a total of 20 volunteers. The remaining 9,000 sentences were split into 300 subsets of 30 sentences, each of which was annotated by a single volunteer.

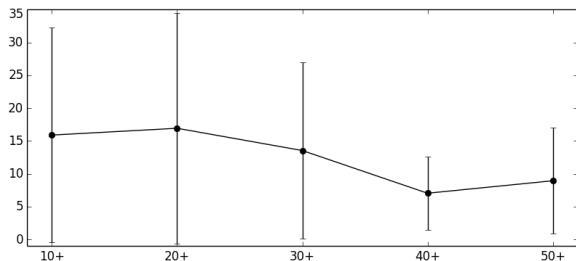

## 4 Analysis

A total of 35,958 distinct words were annotated (232,481 in total). Out of these, 3,854 distinct words (6,388 in total) were deemed as complex by at least one annotator. In the following sections, we discuss details of the data collected.

### 4.1 Profile of Annotators

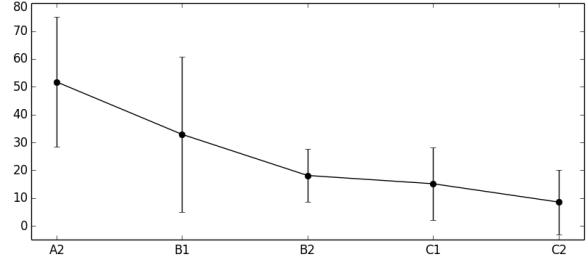

Annotators are speakers of 45 languages. The most predominant languages were Portuguese (15.3%), Chinese (13%) and Spanish (11.3%). Annotators are between 18 and 66 years old (average 28.2). 63.7% of the volunteers were Postgraduate students, 32.3% Undergraduate, and 4% were in High School. 36.8% claimed to have Advanced (C2) English proficiency skills, 37.7% Pre-Advanced (C1), 16.6% Upper-Intermediate (B2), 6.4% Intermediate (B1), 2% Pre-Intermediate (A2) and 0.5% Elementary (A1).

By inspecting the data, we found interesting correlations between the number of complex words annotated and volunteers' age or English proficiency level. Figures 1 and 2 illustrate average and standard deviation values using 10-year age bands and proficiency levels, respectively.

**Figure 1:** Age bands over number of complex words

Both graphs show that, although the average number of complex words drops as age and proficiency level increase, the variance within each group is very high, suggesting that such groups may not be significantly distinct from each other. By performing F-tests with  $p=0.05$ , we found a significant difference between the band of 40+ years of age and the bands

**Figure 2:** Proficiency levels over number of complex words

of 10+, 20+ and 30+ years of age, which suggests that one's English knowledge peaks at such age. We also found significant differences between almost all English proficiency levels above A2, except between B2 and C1. We did not find significant differences among education levels.

### 4.2 Analysis of Data Sources

Evaluating the data, we found that the words deemed complex by Wikipedia editors were marked as complex by our annotators in only 0.8% of the CW instances, and 19.7% of the LexMTurk instances. In contrast, 51.9% of the edited words in the CW corpus and 40.8% of those in the LexMTurk corpus were deemed complex by at least one of our annotators. As for the remaining Simple Wikipedia instances, we found that at least one word in 27.3% of the instances was deemed complex by an annotator, which shows that the simplified version of Wikipedia may still be challenging to non-native speakers.

We also inspected these and other datasets for the purposes of LS. In addition to the aforementioned CW and LeXMturk corpora, we took the dataset used in the English Lexical Simplification task of SemEval 2012, composed of 2,010 instances total, and LSeval, the LS evaluation dataset introduced by (De Belder and Moens, 2012), composed by 430 instances. Each instance in all these datasets contains a sentence and a target complex word. Table 1 shows the number of target words included in each dataset, how many of them appear in at least one of our 9,200 sentences, and the proportion of the latter that was deemed complex by at least one of our annotators.

The figures suggest that the aforementioned resources may not be ideal for the training or evaluation of CWI or LS approaches targeting non-native speakers, since they do not necessarily capture their

|          | Total | Appear in 9,200 | Complex |
|----------|-------|-----------------|---------|
| CW       | 272   | 260             | 34.6%   |
| LexMTurk | 454   | 420             | 33.3%   |
| SemEval  | 410   | 342             | 26.0%   |
| LSeval   | 80    | 59              | 20.3%   |

**Table 1:** Results of dataset analysis

needs with respect to simplification.

### 4.3 Features of Complex Words

We collected statistics that highlight the differences between simple words and those deemed complex by at least one annotator. We consider words’ log-probability in a trigram language model built from the Simple Wikipedia corpus (Kauchak, 2013), their length, number of syllables, and number of senses, synonyms, hypernyms and hyponyms registered in Wordnet (Fellbaum, 1998). Table 2 shows average values for these features. According to F-tests with  $p = 0.01$ , for all features considered, complex and simple words are significantly different. On average, complex words are less ambiguous, shorter, and occur less in Simple Wikipedia.

| Feature      | Complex             | Simple              |
|--------------|---------------------|---------------------|
| Length       | $7.490 \pm 2.683$   | $7.966 \pm 2.724$   |
| Syllables    | $2.313 \pm 1.101$   | $2.557 \pm 1.163$   |
| -Probability | $5.974 \pm 5.956$   | $5.599 \pm 3.784$   |
| Senses       | $4.169 \pm 5.945$   | $4.739 \pm 5.649$   |
| Synonyms     | $10.501 \pm 15.663$ | $11.893 \pm 14.889$ |
| Hypernyms    | $3.141 \pm 4.732$   | $3.586 \pm 4.612$   |
| Hyponyms     | $10.389 \pm 28.687$ | $12.253 \pm 30.989$ |

**Table 2:** Mean and standard deviation for word features

We also noticed that the words most frequently deemed complex by annotators were nouns of technical nature, such as “undercroft”, “malleus” and “chalybeatus”.

### 4.4 Agreement Analysis

We calculated the Krippendorff’s Alpha agreement coefficient (Hayes and Krippendorff, 2007) for each set of 10 sentences that were annotated by 20 volunteers. The Cohen’s Kappa coefficient (Cohen, 1968) was not used due to the large disparity between the number of complex and simple words, which causes the likelihood of annotators agreeing by chance to be higher than the relative observed agreement. The sets have an average agreement coefficient of 0.244, and a standard deviation of 0.1. The relatively low

agreement value highlights the expected heterogeneity among non-native speakers with different language backgrounds and proficiency levels.

## 5 Datasets

We have created two training datasets for the task: **joint** and **decomposed**. Both contain all instances which were annotated by 20 non-native speakers. The **joint** dataset contains a single label for each instance, which is 1 if at least one of the 20 annotators has deemed it complex, and 0 otherwise. Differently, the **decomposed** dataset contains one label for each of the 20 annotators, which is 1 if they have judged it to be complex, and 0 otherwise. Along with the labels, the dataset instances also include the sentence, target word and its position. Participants were allowed to use any additional external resources to build their models. A participant could, for an example, use other (not necessarily publicly available) datasets to complement the one provided.

The test set is composed by all the instances annotated by only one non-native speaker. While the training sets contain the data pertaining to the same 2,237 instances, the test set contains 88,221 instances. Using this setup, we are able to replicate a realistic scenario in Text Simplification, where the needs of many readers must be predicted based on the needs of a sample of the reader population.

Table 3 shows some examples of instances from our **joint** training set.

## 6 Systems

Each team was allowed to submit at most two systems. In total, 42 systems were submitted by 21 teams:

**AI-KU** Introduces two SVM classifiers trained with a Radial Basis Function over the joint dataset. While one of their systems use as features the word embeddings of the target word itself and its substrings (native), the other uses the embeddings of the surrounding words as well (native1).

**AKTSKI** Presents two SVM classifiers: one that weighs labels according to the annotators’ judgements (wsys), and another that does not (svmbasic). Their systems use various semantic and morphological features, and were trained over the joint dataset.

| Sentence  | Word   | Position | Label |
|---|--------|----------|-------|
| Leo, on December 23, took an oath of purgation concerning the charges brought against him, and his opponents were exiled. | took   | 6        | 0     |
| Leo, on December 23, took an oath of purgation concerning the charges brought against him, and his opponents were exiled. | oath   | 8        | 1     |
| It resembles five deep spoons with the handles linked, or, alternately, the hammocks resemble five fig halves.            | deep   | 3        | 0     |
| It resembles five deep spoons with the handles linked, or, alternately, the hammocks resemble five fig halves.            | halves | 19       | 1     |
| If the growth rate is known, the maximum lichen size will give a minimum age for when this rock was deposited.            | growth | 2        | 0     |
| If the growth rate is known, the maximum lichen size will give a minimum age for when this rock was deposited.            | lichen | 9        | 1     |

**Table 3:** Dataset instances

**Amrita-CEN** Introduces two SVM classifiers trained over the joint dataset. While one of them uses word embeddings as well as various semantic and morphological features (w2vecSim), the other also includes POS tag information (w2vecSimPos).

**BHASA** Presents two systems: an SVM (SVM) classifier and a Decision Tree (DECISIONTREE) classifier. The instances in the dataset are first pre-processed, then classified according to various lexical and morphological features. Finally, the results are post-processed with hand-crafted rules. Both systems are trained over the joint dataset.

**ClacEDLK** Uses Random Forests to train two classifiers over the joint dataset with semantic, morphological, lexical and psycholinguistic features. While one classifier uses a class-assignment threshold of 0.5 (RandomForest-0.5), the other uses a threshold of 0.6 (RandomForest-0.6).

**CoastalCPH** Introduces a Neural Networks and a Logistic Regression solution. Their Neural Networks system (NeuralNet) is trained over the joint dataset, and uses two hidden layers leading to a single activation node. Their Logistic Regression system (Concatenation) is trained over the decomposed dataset. Both systems use the same set of features, which include word frequency measures and word embedding values.

**GARUDA** Presents two solutions: a hybrid model (HSVM&DT) and an SVM classifier ensemble (SVMPP). HSVM&DT obtains predictions from various SVM models, which are then validated by Decision Tree classifiers trained specifically to judge

whether the predictions are correct. The validated predictions are then combined into a final label. SVMPP trains a single SVM classifier for each of the 20 annotators of the decomposed dataset, then uses a weighted average to combine their predictions.

**HMC** Performs CWI through a Decision and a Regression Tree, both with a maximum depth of four. During training, their systems deem complex those words which were judged so by at least 25% (DecisionTree25) and 5% (RegressionTree05) of the first 19 annotators in the decomposed dataset. Their systems are then tuned based on the judgment of the 20th annotator.

**IIT** Resorts to Nearest Centroid Classification to perform CWI. While one of their classifiers uses the Manhattan distance during training (NCC), the other uses the Euclidean distance (NCC2). As features, they use semantic and morphological features. Their systems are trained over the joint dataset.

**JUNLP** Presents a Random Forest (RandomForest) and a Naive Bayes (NaiveBayes) classifier trained over the joint dataset. Among the semantic, Lexicon-Based and morphological features used are the words' POS tag and Named Entity information.

**LTG** Uses a very simple setup of Decision Trees trained over the decomposed dataset. Both of their systems learn a Threshold Based on the number of complex judgments in the decomposed dataset. While one of them learns only one threshold (System1), the other combines various (System2).

**MACSAAR** Introduces a Random Forest (RFC) and an SVM (NNC) classifier. They use Zipfian features, such as the percentile ranking of the target word, and character n-gram features, such as the probability sum of all character n-grams in the sentence. For training, they use the joint dataset.

**MAZA** Employs ensemble methods over the joint dataset. They train a context-independent system (A) that uses various word frequency features, and a context-aware system (B) that also includes frequency of the previous and following words.

**Melbourne** Uses weighted Random Forest classifiers along with various lexical and semantic features. While one of their systems attributes weight 1.5 to the complex class (runw15), the other attributes weight 3 (runw3).

**PLUJAGH** Presents two Threshold-Based solutions to CWI. Their first system (SEWDF) judges a word to be complex if its frequency in Simple Wikipedia is lower than 147. Their other system learns the frequency threshold from the joint dataset that maximises the F-Score (SEWDFF).

**Pomona** Uses Threshold-Based bagged classifiers with bootstrap re-sampling. The thresholds of their classifiers are determined through brute-force over the target words' frequencies in a given corpus. They use bag sizes of 10 re-samplings selected through 10-fold cross validation, repeated 20 times. The corpora used are Wikipedia (NormalBag) and the Google Web Corpus (GoogleBag). Their systems are trained over the joint dataset.

**Sensible** Provides a solution that combines Recurrent Neural Networks and Ensemble Methods. Their Neural Networks are composed of Long Short-Term Memory layers leading to a single activation node. They predict that a word is only complex if the activation node outputs a value equal or bigger than 0.5. The architecture of their networks is determined through cross-validation over the joint dataset. While one of their systems consist of the best performing Neural Network architecture found (Baseline), the other combines the five best architectures using an eXtreme gradient boosted ensemble (Combined).

**SV000gg** Employs two System Voting techniques that combine various Lexicon-Based, Threshold-Based and Machine Learning voter sub-systems into one. Their first system (Hard) uses Hard Voting: it increases the prediction likelihood of a label by one for each voter that has predicted it for a given instance. Their second system (Soft) uses Performance-Oriented Soft Voting: instead of increasing it by one, they increase it by the systems' G-Score over a held-out portion of the joint dataset. Their voters use a total of 69 morphological, lexical, collocational and semantic features.

**TALN** Uses Random Forests to perform CWI. While one of their systems is trained over the joint dataset (RandomForest\_SIM), the other is trained over the decomposed dataset (RandomForest\_WEI), and includes the number of annotators that deemed the word to be complex as a feature. Both systems also include various lexical, morphological, semantic and syntactic features.

**USAAR** Presents two Bayesian Ridge classifiers. Their first system (Entropy) is trained based solely on a hand-crafted Word Sense Entropy metric, which is calculated for each target word in the joint dataset. Their other system (Entropolarity) combines Word Sense Entropy with perplexity measures calculated with a language model.

**UWB** Performs CWI with the help of Maximum Entropy classifiers. Both classifiers use only one feature: document frequencies of words in Wikipedia. While one of them is trained over the joint dataset (All), the other is trained over the decomposed dataset (Agg).

## 7 Baselines

Along with the submitted systems, we include eleven baselines:

- All Complex: Predicts that all words are complex.
- All Simple: Predicts that all words are simple.
- (TB) Simple Wiki: Threshold-Based approach that exploits the word's language model probabilities from the Simple Wikipedia.

- (TB) Wikipedia: Threshold-Based approach that exploits the word’s language model probabilities from Wikipedia.
- (TB) Length: Threshold-Based approach that exploits the word’s length.
- (TB) Senses: Threshold-Based approach that exploits the word’s number of senses.
- (LB) Ogden: Lexicon-Based approach that classifies as simple words which are in the Ogden’s vocabulary<sup>1</sup>.
- (LB) Simple Wiki: Lexicon-Based approach that classifies as simple words which are in the Simple Wikipedia.
- (LB) Wikipedia: Lexicon-Based approach that classifies as simple words which are in Wikipedia.

We train 3-gram language models with SRILM (Stolcke, 2002). The Wikipedia and Simple Wikipedia corpora are the ones made available by (Kauchak, 2013). Sense counts were extracted from WordNet (Fellbaum, 1998).

For completion, we also assess the performance of two ensemble methods:

- (HV) All Systems: Ensemble approach that combines all systems submitted, including the aforementioned baselines, through Hard Voting, in which the final label of each instance is the one that was most frequently predicted by the systems.
- (HV) No Baselines: Identical to the previous baseline, except it does not include our baselines.

## 8 Evaluation

To assess the systems’ performance, we choose to complement the typical F-score, which is the harmonic mean between Precision and Recall. Even though F-score is arguably the most frequently used evaluation metric to compare the performance of classifiers, we feel that, as far as the relationship between Complex Word Identification and Lexical

Simplification are concerned, it does not accurately capture the effectiveness of a solution for the task.

To motivate our decision, we must first outline the characteristics of a great lexical simplifier. In order to be both effective and reliable, it must accomplish two things simultaneously:

1. Not to make any replacements that compromise the sentences’ grammaticality and/or meaning.
2. To make a text as simple as possible.

In order to help a simplifier achieve these goals, a complex word identifier must consequently:

1. Avoid labeling complex words as simple, and hence impede them from being simplified.
2. Avoid labeling simple words as complex, and hence allow for unnecessary, possibly erroneous simplifications.
3. To capture as many complex words as possible, and hence maximise the simplicity of a sentence.

Now that we have outlined what the ideal identifier must do, we can translate these objectives into typical evaluation expressions used in the context of classification problems. In this context, “positive” and “negative” decisions refer to labeling words as complex and simple, respectively.

While objectives number one and two state that the identifier must minimise the number of false negatives and false positives, item three states that it must maximise the number of true positives. One way to measure the proficiency of a classifier in achieving these goals is through **Accuracy** and **Recall**, respectively. In order to balance these two metrics, we have conceived the **G-score**, which measures the harmonic mean between Accuracy and Recall. For completion, we also report the systems’ ranking according to **F-score**.

## 9 Results

The official G and F-score ranks obtained by each system are reported in the first two columns of Table 4 (G and F). The systems that have achieved the highest G-scores are the ones submitted by the

**Table 4:** Final system ranks and scores. Baselines are in boldface.

SV000gg team, which combine various Threshold-Based, Lexicon-Based and Machine Learning approaches with minimalistic voting techniques. Similarly, the system from the TALN team, which has the third highest G-score, uses an ensemble method that combines various Decision Tree classifiers. Interestingly, the (HV) All Systems and (HV) No Baselines systems, which combine the submitted systems using the same Hard Voting strategy employed by the runner up SV000gg-Hard, did not manage to outperform it.

One of the most clearly highlighted phenomena in our results is the recurring effectiveness of Decision Trees and Random Forests in CWI: out of the systems with the 10 best G-scores, only three do not employ them. Their reliability is also highlighted by the variety of distinct feature sets used to train them, which range from morphological to syntactic. In contrast, the scores obtained by the BHASHA-DECISIONTREE and GARUDA-HSVM&DT systems reveal that these techniques can be much less effective when incorporated in more elaborate setups.

When it comes to F-score, Decision Trees and Random Forests remain dominant among the top 10 systems, but ultimately lose to a much more minimalistic Threshold-Based strategy. The PLUJAGH-SEWDFF system, which obtained the highest F-score, simply learns the threshold of word frequencies in Wikipedia that maximises the F-score over the joint dataset. Similarly, the LTG systems, which achieved the second and third highest F-scores, use Decision Trees to learn a threshold over the number of annotators that judged a word to be complex.

Another interesting finding refers to the difference between raw word frequencies and single-word language model probabilities. The systems submitted by the PLUJAGH team, which learn thresholds over raw word frequencies from Simple Wikipedia, have consistently outperformed the “(TB) Simple Wiki” baseline, which uses language model probabilities, in both G and F-scores.

Perhaps the biggest surprise from our results comes from the overall performance of systems which employ Neural Networks and/or word embedding models: systems that do so – the ones submitted by AI-KU, AmritaCEN, CoastalCPH and Sensible – ranked no better than 20th in G-score and

31th in F-score. This comes as a surprise, given that these techniques have been employed in state of the art solutions to a range of tasks in recent years. We hypothesize that the small amount of training data available is the main cause for their unsatisfactory performance.

## 10 Conclusions

In this paper we have described the findings of the Complex Word Identification task of SemEval 2016. The task was framed as a simple, accessible and yet interesting challenge, such that researchers with any background can participate. It attracted a very large number of participants, particularly given that this was its first edition.

To create the task’s dataset, we conducted a user study with 400 non-native English speakers, which resulted in a total of 158,624 individual annotations. By analyzing the data obtained we were able to confirm that, according to non-native speakers of English, there is a statistically significant difference between complex and simple words. We have also found a noticeable correlation between the number of complex words annotated and English proficiency level, which is positive evidence that our CWI datasets do, at least to some extent, capture the CWI needs of non-natives. In contrast, we have found that other available resources, such as the CW, LexMTurk and LSeval datasets, may not necessarily do so.

A total of 42 systems were submitted to the task. They reach upwards of impressive 77% in G-score, suggesting that predicting one’s individual simplification needs based on the profile of a more diverse audience is feasible. The strategies used range from very simple Threshold-Based approaches to elaborate Ensemble methods that combine various Deep Recurrent Neural Networks and word embeddings. We have ranked systems according to two metrics: F-score and G-score. We found that, likely due to the nature of the task and the reduced number of training instances available, Decision Trees and Ensemble methods perform better than Neural Networks and word embedding models. Additionally, it remains very clear that the most effective way to determine a word’s complexity is by searching for its frequency in corpora. The quality of the corpora plays an im-

portant role.

In the future, we plan to propose more SemEval tasks in the Text Simplification domain, so that we can continue to learn about word complexity, and hopefully further increase this topic’s reach and popularity.

## Abstract

This paper describes the system by FBK HLT-MT for cross-lingual semantic textual similarity measurement. Our approach is based on supervised regression with an ensemble decision tree. In order to assign a semantic similarity score to an input sentence pair, the model combines features collected by state-of-the-art methods in machine translation quality estimation and distance metrics between cross-lingual embeddings of the two sentences. In our analysis, we compare different techniques for composing sentence vectors, several distance features and ways to produce training data. The proposed system achieves a mean Pearson’s correlation of 0.39533, ranking 7<sup>th</sup> among all participants in the cross-lingual STS task organized within the SemEval 2016 evaluation campaign.

## 1 Introduction

Semantic textual similarity (STS) measures the degree of equivalence between the meanings of two text sequences (Agirre et al., 2015). The similarity of the text pair can be represented as a continuous or discrete-time value ranging from irrelevance to exact semantic equivalence (Agirre et al., 2015).

STS has been one of the official shared tasks in SemEval since 2013 and has attracted the participation of many researchers from the scientific community; enabling the evaluation of several different approaches in natural language processing with a common benchmark and the production of novel annotated data sets that can be used in future

research. State-of-the-art monolingual STS methods make use of several approaches including word alignments and distributional semantics, which are typically employed in a machine learning scenario (Sultan et al., 2015; Häning et al., 2015).

This is the first year in which SemEval has organized a cross-lingual STS (CL-STS) sub-task, for which a baseline system applicable to the problem has not been defined yet. Similar to the monolingual STS task, the cross-lingual task requires the interpretation of the semantic similarity of two cross-lingual sentences, one in English and another one in Spanish, with a score ranging from 0 to 5. CL-STS measurement could be extremely useful for achieving textual entailment, paraphrase identification, word-sense disambiguation or sentiment analysis at the cross-lingual level as well as providing new means for an adequacy-oriented evaluation of machine translation outputs.

A related task in natural language processing is quality estimation. Quality estimation (QE) is used for automatically predicting the quality of machine translation outputs with respect to the source sentences in the original language (Mehdad et al., 2012; Turchi et al., 2014; C. de Souza et al., 2014a; C. de Souza et al., 2014b; C. de Souza et al., 2015). One shortcoming of QE approaches is that the QE system may not capture all aspects of the semantic representations of sentences. For instance, from a QE perspective, under which the number of edit operations required to fix a translation is used as a proxy of quality, a fluent translation containing an unnecessary negation would likely be labelled as a “good” translation. Therefore, a better solution would be

geared to also capture the adequacy aspects of cross-lingual comparison of the sentences. In order to improve the quality of the comparison, the features used in a QE system can be improved using distributional semantics. Neural language models, such as CBOW or Skipgram (Mikolov et al., 2013a) have proved to be useful in the monolingual STS task before (Agirre et al., 2015). Recent studies have extended these models to create bilingual word embeddings such that the embeddings are mapped to a common cross-lingual vector space by using a parallel training corpus or a dictionary (Klementiev et al., 2012; Mikolov et al., 2013b; Luong et al., 2015).

In light of these considerations, our submission to the first SemEval CL-STS task combines features derived from QE with distance features obtained by applying cross-lingual word embeddings. These features are used to feed an Extremely Randomized Trees (ET) regressor (Geurts et al., 2006) trained to predict the similarity score of the two sentences.

The rest of this paper is organized as follows. Section 2 describes the components of our CL-STS system. The details of the experimental analysis carried out on different composition approaches, the characteristics of the system under the influence of each vector space feature and varying data distributions are presented in Section 3. The final ranking of our system can be found in Section 4 along with the conclusions of our study in Section 5.

## 2 System Description

This section describes the proposed CL-STS system. The data to be semantically compared is first pre-processed as described in Section 2.1. The embedding corresponding to each word is retrieved and composed to form a sentence embedding using one of the methods described in Section 2.2. The features to be used in the regression are extracted from the sentence embeddings using 8 different distance measures listed in Section 2.2. These features are combined with 79 more features obtained by QE (Section 2.3) to produce a final set of 87 features, which is used to predict the similarity score of the two sentences. The overall system is illustrated in Figure 1.

### 2.1 Pre-processing

The data used in training and testing the system are processed before feature extraction in the following way. First of all, a language identification package developed by Lui et al. (2012) is used to detect the order of English and Spanish sentences in each line of the data set. This step is meant as a first sanity check since some of the next processing steps are language-dependent and hence sensitive to the order in which the two sentences are presented. The data is then tokenized and lowercased before the extraction of features using the text processing system of Moses (Koehn et al., 2007).

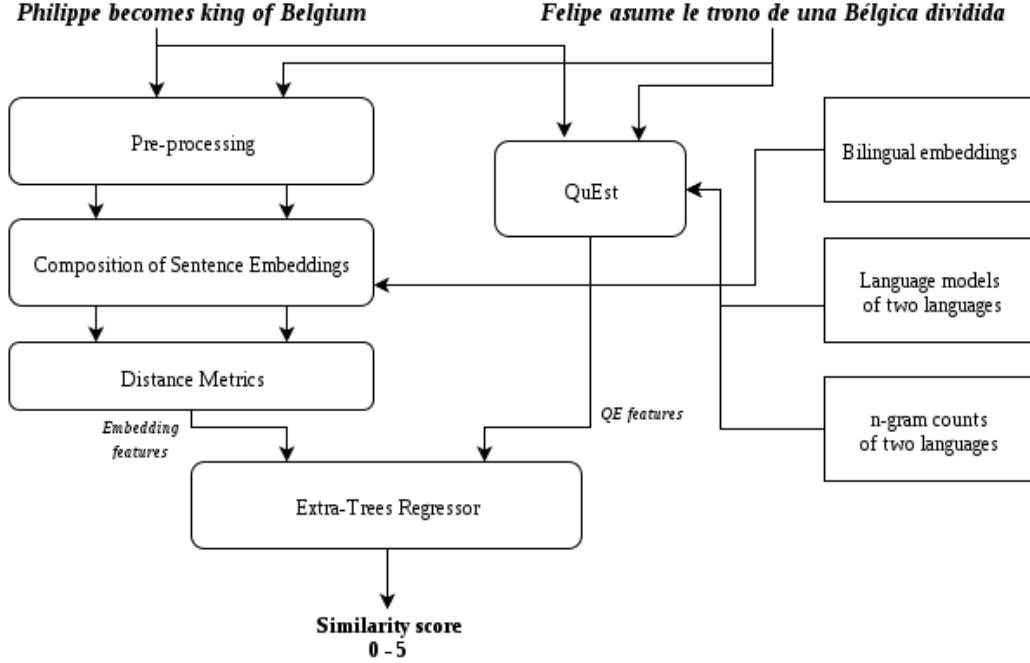

### 2.2 Bilingual Embedding Features

To obtain word embeddings, we use the bilingual Skipgram model by Luong et al. (2015). The embeddings are trained using the default parameters described by the authors and with a dimension of 200. We constructed an English-Spanish parallel corpus from Europarl (Koehn, 2005), UN (Rafalovitch et al., 2009), data sets of the quality estimation shared task in WMT 2012 (Callison-Burch et al., 2012), as well as the training data of the monolingual STS task from previous years (See Subsection 3.1) and used this data to train our bilingual embeddings.

Sentence embeddings are then generated by averaging the word embeddings in each sentence. Averaging is a simple and powerful composition method for monolingual word embeddings which has not been outperformed yet by much more sophisticated schemes, such as the recurrent neural networks and long short-term memories (Blacoe and Lapata, 2012; Wieting et al., 2015). Moreover, the latter often requires language-specific syntactic parsers which are not available in all languages, thus are not generally suitable for cross-lingual applications.

In our system, we implement three different averaging strategies to see the influence of stop words or term frequencies in the final sentence embedding. Our approaches consist of:

1. Averaging with all the tokens in the sentence including punctuation;
2. Averaging after removing stop words and punctuation in the sentence;

**Figure 1:** The schematic of the overall system for CL-STS

3. Averaging by weighting each word in the sentence by their inverse term frequencies.

During processing of the two sentences in English and Spanish, the words and punctuation in each corresponding sentence are averaged according to one of the methods above to generate one final embedding representing each sentence in the two languages.

In order to apply semantic comparison between the sentence embeddings, we select 8 distance measures that are defined in vector space. Given the two sentence vectors, the selected distance metrics include:

1. Cosine distance
2. Euclidean distance
3. Manhattan distance
4. Chebyshev distance
5. Canberra distance
6. Pearson's correlation
7. Ratio of number of words
8. Ratio of means

We further analyze the usefulness of these features through a set of experiments before using in the CL-STS task (Section 3).

### 2.3 Quality Estimation Features

The QE features used in our system are obtained by QuEst tool (Specia et al., 2013). The QuEst tool uses language models, POS-taggers or word aligners to extract many features that can represent complexity (e.g. language model probabilities or n-gram counts in the source segment) fluency (e.g. language model probabilities or number of tokens in the target segment), adequacy (e.g. word alignment features such as ratio of nouns/verbs/etc. in each sentence) or confidence (e.g. global scores or n-best lists) of a translation pair. For a more detailed description of each feature, we refer the reader to Specia et al. (2013). The language models used to extract the features are trained with the NY Times portion of English Gigaword (v.5) (Parker et al., 2011) and Spanish Gigaword (v.2) (Mendonca et al., 2009) and the same parallel data as described in the training of bilingual word embeddings (See Section 2.2)

| Features                                | # Features | Pearson's correlation |                              |                      |  |  |  |
|---|------------|-----------------------|------------------------------|----------------------|--|--|--|
| QE                                      | 79         | 0.5899                |                              |                      |  |  |  |
| Embeddings                              | 8          | 0.4690                |                              |                      |  |  |  |
| <b>QE + sentence embedding features</b> |            |                       |                              |                      |  |  |  |
| <b>Composition method</b>               |            |                       |                              |                      |  |  |  |
|   |            | Average               | Average w/o stop words       | ITF-weighted Average |  |  |  |
| + Cosine                                | 80         | 0.6106                | 0.6399                       | 0.6017               |  |  |  |
| + Manhattan                             | 81         | 0.6127                | 0.6429                       | 0.5897               |  |  |  |
| + Euclidean                             | 82         | 0.6152                | <b>0.6445<sup>run1</sup></b> | 0.5906               |  |  |  |
| + Canberra                              | 83         | 0.6149                | 0.6435                       | 0.5962               |  |  |  |
| + Pearson's correlation                 | 84         | 0.6145                | 0.6361                       | 0.6039               |  |  |  |
| + Chebyshev                             | 85         | 0.6136                | 0.6364                       | 0.5907               |  |  |  |
| + Ratio of NumWords                     | 86         | 0.6138                | 0.6366                       | 0.5915               |  |  |  |
| + Ratio of Means                        | 87         | 0.6154                | <b>0.6375<sup>run2</sup></b> | 0.5996               |  |  |  |

**Table 1:** Pearson's correlation of system predictions using cross-validation. The first and second entries in the table indicate performance of the system using the two approaches separately. The second part indicates the system performance when the two approaches are combined, revealing the effect of each distance-based feature on the performance. Each column represents a different sentence composition method; including averaging, averaging after removing stop words and weighted averaging. Numbers in bold are the two runs, [run1] wth 82 and [run2] wth 87 features respectively, submitted to the SemEval 2016 - CL-STS shared task.

## 2.4 Ensemble Regression

An ET regressor is used as the learning method in the system. The ET regressor applies bagging to generate a number of random subsets of the training data and fits individual decision trees using different subsets of features and hyper parameters. The final prediction is produced by an ensemble average over all of the decision trees.

## 3 Experiments

### 3.1 Corpus

For this first round of the CL-STS task, training data was not released by the organizers. Therefore, the data for training the regressor was generated using those from the monolingual STS tasks organized in 2012, 2013, 2014 and 2015 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). The data was translated to Spanish using the MateCat tool (Federico et al., 2014) to create a cross-lingual data set where one of the sentences is in English and the other is in Spanish. In order to compensate for the different characteristics of data which occur after translation, we generate three different sets as follows:

1. The first sentence in the data set is selected as the English sentence, the second sentence

is translated to Spanish, denoted as:  $s_1(en)$  -  $\overline{s}_2(es)$ .

2. The second sentence in the data set is selected as the English sentence, the first sentence is translated to Spanish, denoted as:  $s_2(en)$  -  $\overline{s}_1(es)$ .
3. The first two data sets are concatenated, denoted as the *merged* set.

The size of each set is given in Table 2. The three data sets are evaluated during our experiments in terms of the capability to represent the true data distribution and used in the test phase with the selected settings (Section 3.3).

| Data set  | # sent | # src   | # tgt   |
|---|--------|---------|---------|
| <b><math>s_1(en)</math> - <math>\overline{s}_2(es)</math></b> | 18,105 | 233,141 | 250,359 |
| <b><math>s_2(en)</math> - <math>\overline{s}_1(es)</math></b> | 18,091 | 230,300 | 253,115 |
| <b>merged</b>   | 36196  | 463441  | 503474  |

**Table 2:** Sizes of the training sets: number of sentence pairs and number of words in source and target languages

### 3.2 Cross-validation on the merged set

The performance of our ET regressor is evaluated using 10-fold cross-validation on the merged set. The results are presented in Table 1.

We run a detailed analysis to evaluate each individual distance metric according to their effect on the performance. For evaluating the performance of the system we use Pearson’s correlation. The experiments show that QE features and embedding features perform poorly when used as two different groups, but the performance can be improved when they are integrated together. The best correlation is achieved when cosine, manhattan and euclidean distances are combined with the QE features. All distance metrics show a consistent improvement over the system trained only on QE features, except for the Pearson’s correlation (Table 1).

The experiments also reveal that averaging after removing the stop words and punctuation is the best sentence composition method among the three averaging strategies. Compared to this method, inverse term-frequency weighted averaging aims to decrease the effect of stop words in a less greedy way. However, we see that this approach results in even poorer performance than straightforward averaging; suggesting that we may lose important information from word semantics necessary in composing the sentence meaning when we weight each word with their inverse term frequencies. Thus, we select averaging without stop words as the composition method to use in our system to participate in the SemEval 2016 CL-STS shared task.

### 3.3 Performance of different training data sets on the evaluation data

In the second phase, we compare the performance of our ET regressor in terms of three different training sets, as explained in Section 3.1. 30% of the training set is used for validation and the remaining 70% is used for training purposes. The regressor then performs predictions for the same validation set using the different sets. Finally, we implement an ensemble model which is an average of the predictions of the three subsystems. The results of these experiments can be seen in Table 3.

In light of these experiments, we choose the feature sets composing of 82 and 87 features and the merged set for training purposes (See Table 1). These two systems are submitted as our **[run1]** and **[run2]** to the CL-STS shared task. We contribute with the ensemble average system as shown in Ta-

| Data set        | Pearson’s correlation        |
|-----------------|------------------------------|
| s1(en) - s2(es) | 0.5499                       |
| s2(en) - s1(es) | 0.5815                       |
| merged          | 0.6227                       |
| Average         | <b>0.6131<sup>run3</sup></b> |

**Table 3:** Pearson’s correlation of system (run2) predictions using 30-70 split in the (merged) data set. Performance is shown according to three different training data distributions. Average indicates the performance of ensemble of the three approaches, and is the system chosen to be submitted as **[run3]** to the SemEval 2016 - CL-STS shared task.

ble 3 for **[run3]**.

| System      | News    | Multi-source | Mean    |
|-------------|---------|--------------|---------|
| <b>run3</b> | 0.25507 | 0.53892      | 0.39533 |
| <b>run1</b> | 0.24318 | 0.53465      | 0.3872  |
| <b>run2</b> | 0.24372 | 0.5142       | 0.37737 |

**Table 4:** Official results of SemEval 2016 - CL-STS shared task

## 4 Results

The performance of our system in the SemEval 2016 - CL-STS task is given in Table 4. The test set of the CL-STS task contains two parts with different characteristics. The first set contains 301 sentence pairs in the news domain and the second set consists of 2973 sentence pairs drawn from different domains. By using these data sets to test our system, we achieve a Pearson’s correlation of 0.539 on the multi-source test set and 0.255 on the news set between our predictions and the true labels (Table 4).

We observe that using **[run3]**, which combines the three systems trained on three data sets with different distributions, is the most successful approach. The decreased values of Pearson’s correlation are consistent with the fact that test data of the task and our training set are sampled from different distributions. Moreover, our system performs better in the general domain and worse in the specific domain of news. However, this performance can be improved by extending the training corpus to a similar content with the test corpus. Other aspects to improve are the quality of bilingual word embeddings, which should also be trained with more data and parameters that are more suitable for the specific task, and addition of feature selection quality to the system.

The results also show that performance of the system using only QE features and the three distance metrics consisting of cosine, manhattan and euclidean distances provide better results than the system using all features. Therefore, one can see that these three features can provide significant information when comparing two sentence embeddings and could be reliably used in future applications.

## 5 Conclusion

We have presented the CL-STS measurement system with which we participated in the SemEval 2016 CL-STS shared task. Our system used QE and distance features based on bilingual word embeddings to train an ET regressor that predicts the cross-lingual semantic similarity between a pair of sentences. We used an ensemble method to generate and use training data for the task and saw that this approach improved the performance of our system. Our best performance achieves a Pearson’s correlation of 0.53892 while placing FBK HLT-MT as the 7<sup>th</sup> out of 10 teams in the task.

## Abstract

VRep is a system designed for SemEval 2016 Task 1 - Semantic Textual Similarity (STS) and Task 2 - Interpretable Semantic Textual Similarity (iSTS). STS quantifies the semantic equivalence between two snippets of text, and iSTS provides a reason why those snippets of text are similar. VRep makes extensive use of WordNet for both STS, where the Vector relatedness measure is used, and for iSTS, where features are extracted to create a learned rule-based classifier. This paper outlines the VRep algorithm, provides results from the 2016 SemEval competition, and analyzes the performance contributions of the system components.

## 1 Introduction

VRep competed in SemEval 2016 Task 1 - Semantic Textual Similarity (STS) and Task 2 - Semantic Interpretable Textual Similarity (iSTS). Both of these tasks compute STS between two fragments of text. Task 2 expands upon Task 1 by requiring a reason for their similarity. VRep uses an STS measure based on the Vector relatedness measure (Pedersen et al., 2004), and a reasoning system based on JRIP (Cohen, 1995), an implementation of the iREP algorithm.

For Task 1, we are provided with paired sentences, and for each pair of sentences VRep assigns a number indicating their STS. The number ranges from 0 to 5, 0 indicating no similarity and 5 indicating equivalence.

For Task 2, we are provided with paired sentences and align the chunks of one sentence to the most

similar chunks in the other sentence. Next, a reason and score are computed for that alignment. A chunk is a fragment of text that conveys a single meaning such as in the following example for which chunks are bracketed.

[ Black Cow ] [ walking ] [ in a pasture ]  
[ Black and white Cow ] [ sitting ] [ in the grass ]

Alignment reasons are selected from a small list of possible labels created by the event organizers (Agirre et al., 2015):

1. Equivalent (EQUI) - the two chunks convey an equivalent meaning (“hot water”, “scalding water”)
2. Opposite (OPPO) - the two chunks convey an opposite meaning (“hot water”, “cold water”)
3. More General (SPE1) - this chunk conveys a more general meaning than the other chunk (“hot water”, “water”)
4. More Specific (SPE2) - this chunk conveys a more specific meaning than the other chunk (“water”, “hot water”)
5. Similar (SIMI) - the two chunks convey a similar meaning (“sip water”, “gulp water”)
6. Related (REL) - the two chunks are somehow related (“boil water”, “ocean water”)
7. No Alignment (NOALI) - there are no chunks in the other sentence that are semantically similar to this chunk

As in Task 1 the scores range from 0 to 5, 0 indicating no similarity and 5 indicating equivalence. VRep makes extensive use of WordNet (Fellbaum, 2005) to compute STS and assign a label in iSTS. Vrep is written in Perl and is freely available for download<sup>1</sup>.

## 2 Algorithm Description

The same measure of STS is used for both Task 1 and Task 2; however, the algorithm for Task 1 is simpler and consists of only the first two steps: Preprocessing and Semantic Textual Similarity. The steps are outlined below and are expanded on in subsequent subsections.

1. Preprocessing - text is standardized
2. Semantic Textual Similarity - the STS between two chunks or two sentences is computed. This is the final step for Task 1.
3. Chunk Alignment - align each chunk of one sentence to a chunk in another sentence. If no chunks are similar then no alignment (NOALI) is assigned.
4. Alignment Reasoning - assign a label to each aligned chunk pair
5. Alignment Scoring - assign an alignment score on a 0-5 scale

### 2.1 Preprocessing

In the first step, data is prepared for processing as outlined below:

1. Tokenization - spaces are used as a delimiter
2. Lowercase All Characters - standardizes string equivalence testing and prevents incorrect part of speech (POS) tagging. The POS tagger tends to tag most words that have a capital letter as a proper noun which is often incorrect. This is particularly problematic with the headlines data set.
3. Punctuation Removal - standardizes string equivalence testing

---

<sup>1</sup><http://www.people.vcu.edu/~henryst/>

4. POS tagging - Lingua::EN::Tagger<sup>2</sup> is used. POS tags are used for stop word removal and for alignment reasoning.
5. Stop Word Removal - remove any words that are not tagged as a noun, verb, adjective, or adverb. This reduces chunks and sentences to content words.

### 2.2 Semantic Textual Similarity (STS)

STS is computed in the same way for both tasks; however it is computed between two sentences for Task 1 and between two chunks for Task 2. While describing the computation of STS we refer to chunks; for Task 1 a sentence can be conceptualized as a chunk. VRep's STS computation is shown in Equation (1) and is similar to the method described by NeRoSim (Banjade et al., 2015) and Stefanescu (Ştefanescu et al., 2014). *chunkSim* takes two chunks ( $c_1, c_2$ ) as input and computes the weighted sum of maximum word to word similarities,  $sim(w_i, w_j)$ . To do this, the  $sim(w_i, w_j)$  is found for each word in  $c_2$  against  $c_1$ , and the maximum is added to a running sum.

$$chunkSim(c_1, c_2) = \frac{\sum_{i=1}^n \max_{j=1}^m sim(w_i, w_j)}{\min(n, m)} \quad (1)$$

where  $c_1$  and  $c_2$  are two chunks,  $n$  and  $m$  are the number of words in  $c_1$  and  $c_2$ ,  $w_i$  is word  $i$  of  $c_1$ ,  $w_j$  is word  $j$  of  $c_2$

$sim(w_i, w_j)$  is defined differently for words in WordNet and words not in WordNet. For words in WordNet,  $sim(w_i, w_j)$  is the Vector relatedness measure<sup>3</sup> (Pedersen et al., 2004) with a threshold applied. The Vector measure was chosen for several reasons. Firstly it returns values scaled between 0 and 1 which is beneficial for applying thresholds in both chunk alignment and alignment reasoning. A known scale also allows for a direct mapping from the weighted sum to the answer space of Task 1 (scaled 0-5). Secondly the Vector measure works well when  $w_i$  and  $w_j$  are different parts of speech because it does not rely on WordNet hierarchies. When calculating  $sim(w_i, w_j)$  all possible senses of both  $w_i$  and  $w_j$  are used, and  $sim(w_i, w_j)$  is chosen as

---

<sup>2</sup><http://search.cpan.org/~acoburn/Lingua-EN-Tagger/>

<sup>3</sup>WordNet::Similarity::Vector

the maximum value. This eliminates the need for word sense disambiguation (WSD). After computing the measure, a threshold is applied that reduces any value less than 0.9 to 0.0. This value was tuned separately using the training data for both tasks via a grid search and 0.9 was found to be optimum for both. The threshold prevents dissimilar terms from impacting the STS which improves the accuracy and prevents noisy chunk alignments.

For words not in WordNet,  $chunkSim(w_i, w_j)$  is a binary value: 1 if all the characters in both words match, 0 otherwise. Words not in WordNet tend to be proper nouns, abbreviations, or short words such as “he” or “she”, “is” or “in”, all of which are generally spelled identically making this a suitable measure.

$chunkSim$  is defined as the sum of maximum word to word similarities normalized by the number of words in the shorter of the chunk pair. Normalization prevents similarity scores from increasing as chunk length increases. It also scales  $chunkSim$  within a predictable range of about 0.0 – 1.0.

$chunkSim$  is used directly in Task 1 where it is linearly scaled by 5 to produce final output. We experimented with multiple regression fits (linear, exponential, logarithmic, power, and polynomial) between our  $chunkSim$  output and the provided gold standard values with little to no improvement, so the linear scaling of 5 was chosen for simplicity.

### 2.3 Chunk Alignment

$chunkSim$  is computed between each chunk of two aligned sentences and the chunk with the highest  $chunkSim$  is selected for alignment. Multiple alignments are allowed for a single chunk. If all chunks have a similarity of 0, no alignment (NOALI) is assigned. Due to the high  $sim(w_i, w_j)$  threshold, no threshold is required for  $chunkSim$  as with NeRoSim(Banjade et al., 2015).

### 2.4 Alignment Reasoning

Alignment Reasoning takes as input a chunk pair and provides a reason why that chunk pair is aligned. VRep’s alignment reasoning is inspired by NeRoSim (Banjade et al., 2015), and SVCTSTS (Karumuri et al., 2015). Both these systems classify a chunk pair using features extracted from the chunk pair itself. NeRoSim’s features tend to focus

more on the semantic relationship between chunk pairs, such as whether or not the two chunks contain antonyms, synonyms, etc. The features of SVCSTS focus more on the syntactic form of the chunks, such as the number of words or counts of parts of speech in a chunk pair. VRep combines the two approaches and extracts a total of 72 syntactic and semantic features for each chunk pair.

Gold Standard chunk pairs of the SemEval 2015 Task 2 Test Data<sup>4</sup> were used to train our classifier, WEKA’s (Hall et al., 2009) JRIP algorithm (Cohen, 1995) which creates a decision list for classification. The classifier uses only 24 of original 72 features and a series of 10 rules.

JRIP was chosen as a classifier due to its performance (see Table 5), and its concision. The rules generated are human readable which provides insight into how the classification occurs and the types of features that are discriminative. Classifiers were trained with chunk pairs from every data set (student answers, headlines, and images), both individually and combined. The best performing classifier for each topic was generated from the combined data. The set of features used and classification rules are shown below.  $\alpha$  and  $\beta$  designate the individual chunks in the chunk pair being classified, and  $\vec{x}_i$  indicates a feature vector created from a chunk pair.  $i$  indicates the feature number in the feature list below.

#### Features used in Classification:

- 1 - unmatched content word percentage of  $\alpha$
- 2 - unmatched content word percentage of  $\beta$
- 3 - 1 if  $\alpha$  contains a location
- 4 - 1 if  $\beta$  contains a location
- 5 - 1 if  $\alpha$  has a verb
- 6 - 1 if  $\alpha$  has an adjective
- 7 - 1 if  $\alpha$  has an adverb
- 8 - 1 if  $\alpha$  and  $\beta$  contain antonyms
- 9 - 1 if  $\alpha$  and  $\beta$  have a equivalent nouns
- 10 - 1 if  $\alpha$  and  $\beta$  contain numeric quantities
- 11 - number of words in  $\alpha$  (before stop word removal)
- 12 - number of words in  $\beta$  (before stop word removal)
- 13 - ratio of the number content words to all words in  $\alpha$  (before stop word removal)

---

<sup>4</sup>[http://alt.qcri.org/semeval2016/task2/data/uploads/train\\_2015\\_10\\_22.utf-8.tar.gz](http://alt.qcri.org/semeval2016/task2/data/uploads/train_2015_10_22.utf-8.tar.gz)

- 14 - difference in number of content words in  $\alpha$  and  $\beta$   
 15 - difference in number of words in  $\alpha$  and  $\beta$  (before stop word removal)  
 16 - absolute value of the difference in number of content words in  $\alpha$  and  $\beta$   
 17 - absolute value of the difference in number of words in  $\alpha$  and  $\beta$  (before stop word removal)  
 18 - ratio of the number of content words in  $\alpha$  to all words in  $\alpha$  (before stop word removal) over the ratio of the number of content words in  $\beta$  to all words in  $\beta$  (before stop word removal)  
 19 - number of nouns in  $\beta$   
 20 - ratio of the number of nouns in  $\alpha$  to the number of content words in  $\alpha$   
 21 - ratio of the number of verbs in  $\alpha$  to the number of content words in  $\alpha$   
 22 - ratio of the number of adjectives in  $\alpha$  to the number of content words in  $\alpha$   
 23 - ratio of the number of conjunctions in  $\alpha$  to the number of content words in  $\alpha$   
 24 - difference in the number of verbs in  $\alpha$  and  $\beta$

---

#### Algorithm 1 Alignment Reasoning Rules

---

```

1: if  $x_8 \geq 1$  &  $x_{22} \geq 1$ 
2: or  $x_8 \geq 1$  &  $x_4 \geq 1$  &  $x_5 \geq 1$  &  $x_{16} \geq 1$ 
3: or  $x_8 \geq 1$  &  $x_{23} \geq \frac{1}{2}$  &  $x_1 \geq \frac{1}{2}$ 
4: or  $x_{21} \geq \frac{1}{2}$  &  $x_7 \geq 1$  &  $x_{12} \leq 1$ 
    return OPPO
5: if  $x_2 \geq \frac{1}{3}$  &  $x_{14} \leq -1$  &  $x_9 \geq 1$  &  $x_{19} \leq 0$ 
    &  $x_{13} \geq \frac{4}{7}$ 
    return SPE2
6: if  $x_{14} \geq 1$  &  $x_9 \geq 1$  &  $x_2 \leq 0$  &  $x_6 \geq 1$ 
    &  $x_{11} \leq 4$  &  $x_{24} \leq 0$ 
7: or  $x_{14} \geq 1$  &  $x_{17} \geq 2$  &  $x_{13} \geq \frac{5}{7}$ 
8: or  $x_{15} \geq 1$  &  $x_{18} \geq \frac{8}{9}$  &  $x_2 \leq 0$  &  $x_3 \geq 1$ 
9: or  $\frac{1}{4} \leq x_1 \leq \frac{2}{3}$  &  $x_{14} \geq 1$  &  $x_5 \leq 0$ 
    &  $x_{20} \leq \frac{1}{5}$  &  $x_{18} \leq 1$  &  $x_{13} \geq \frac{2}{3}$ 
    return SPE1
10: if  $x_2 \geq \frac{1}{2}$  &  $x_1 \geq \frac{1}{3}$  &  $x_{10} \geq 1$ 
    return SIMI
11: return EQUI

```

---

It is interesting to note that there is no classifier for the REL class. The data set was heavily skewed towards the EQUI class which consisted of 60% of the total data, leaving a small percentage to be divided among the remaining 5 classes, with just around 5% being REL. With a larger training set we would ex-

pect a classifier for REL to be generated.

## 2.5 Alignment Scoring

Alignment scores are assigned as either the required scores, 0 for NOALI and 5 or EQUI, or the average alignment score for each class as in (Karumuri et al., 2015). The average alignment score for classes were computed both for each topic alone and for all topics combined. The best performing set of scores came for all topics, came from the images data set alone. Scores used for each class are as follows: EQUI = 5.00, OPPO = 4.00, SPE1 = 3.24, SPE2 = 3.69, SIMI = 2.975, REL = 3.00, NOALI = 0.00.

## 3 Results

The performance of VRep is shown below for SemEval 2016 Task 1 and Task 2 test data sets. The baseline described by the task organizers (Agirre et al., 2015) is shown for comparison for Task 2. Baseline results were not made available for Task 1.

### 3.1 Task 1 - Semantic Similarity

For Task 1 the Pearson Correlation Coefficient between VRep's results and Gold Standard results are reported for the 2016 Task 1 Test Data<sup>5</sup>. A value of 1.0 indicates perfect correlation, 0.0 indicates no correlation. We ran VRep on five data sets with the results of each data set shown in Table 1. More details on the data sets and evaluation metrics are described in the competition summary<sup>6</sup>.

| Data set          | VRep            |
|-------------------|-----------------|
| answers-answers   | 0.29487         |
| headlines         | 0.68185         |
| plagiarism        | 0.69730         |
| post editing      | 0.72966         |
| question-question | 0.49029         |
| <b>Mean</b>       | <b>0.578794</b> |

Table 1: Results of VRep on SemEval 2016 Task 1 Test Data

### 3.2 Task 2 - Interpretable Semantic Similarity

For Task 2, we report results for the Gold Chunks scenario (data is pre-chunked). Each data set is evaluated using the F1 score in four categories:

<sup>5</sup><http://alt.qcri.org/semeval2016/task1/data/uploads/sts2016-english-with-gs-v1.0.zip>

<sup>6</sup><http://alt.qcri.org/semeval2016/task1/>

- (Ali)** - Alignment - F1 score of the chunk alignment
- (Type)** - Alignment Type - F1 score of the alignment reasoning
- (Score)** - Alignment Scoring - F1 score of alignment scoring
- (Typ+Scor)** - Alignment Type and Score - a combined F1 score of alignment reasoning and scoring

F1 scores range from 0.0 to 1.0 with 1.0 being the best score. Data sets are available online<sup>7</sup> and evaluation metrics are described in more detail in the competition summary (Agirre et al., 2015).

| Data set                | Baseline | VRep   |
|-------------------------|----------|--------|
| <b>Answers-Students</b> |          |        |
| F1 Ali                  | 0.8203   | 0.7723 |
| F1 Type                 | 0.5566   | 0.5249 |
| F1 Score                | 0.7464   | 0.7014 |
| F1 Typ+Scor             | 0.5566   | 0.5226 |
| <b>Headlines</b>        |          |        |
| F1 Ali                  | 0.8462   | 0.8908 |
| F1 Type                 | 0.5462   | 0.6015 |
| F1 Score                | 0.7610   | 0.8027 |
| F1 Typ+Scor             | 0.5461   | 0.5964 |
| <b>Images</b>           |          |        |
| F1 Ali                  | 0.8556   | 0.8539 |
| F1 Type                 | 0.4799   | 0.5516 |
| F1 Score                | 0.7456   | 0.7651 |
| F1 Typ+Scor             | 0.4799   | 0.5478 |

**Table 2:** Results of VRep on SemEval 2016 Task 2 Test Data

## 4 Component Analysis

In this section the contributions of system components and possible additions are evaluated. VRep can be split into two major components, STS and Alignment Reasoning, both of which have different evaluation criteria. Data used for this section comes from the SemEval 2015 Task 1<sup>8</sup> training data and SemEval 2016 Task 2<sup>9</sup> training data. Two-Tailed p-values are shown in the Tables 3 and 4.

<sup>7</sup>[http://alt.qcri.org/semeval2016/task2/data/uploads/test\\_goldsstandard.tar.gz](http://alt.qcri.org/semeval2016/task2/data/uploads/test_goldsstandard.tar.gz)

<sup>8</sup><http://ixa2.si.ehu.es/stswiki/images/2/21/STS2015-en-rawdata-scripts.zip>

<sup>9</sup>[http://alt.qcri.org/semeval2016/task2/data/uploads/train\\_2015\\_10\\_22.utf-8.tar.gz](http://alt.qcri.org/semeval2016/task2/data/uploads/train_2015_10_22.utf-8.tar.gz)

$$\text{LevenshteinMeasure} = \begin{cases} \frac{\beta-\delta}{\beta} & \delta < \beta \\ 0 & \delta \geq \beta \end{cases} \quad (2)$$

where  $\delta$  is the Levenshtein distance between the two words, and  $\beta$  is the threshold used

### 4.1 STS Component Analysis

Pearson Correlation Coefficients of STS scores of Task 1 and the F1 Ali Task 2 are used as evaluation metrics for the STS portion of VRep. Tables 3 and 4 show the effects of adding a component to the *Basic* system. Each component and the *Basic* system are described below:

1. As a baseline a *Basic* system which only applies Equation (1) is used. For Task 1 the result is scaled by 5. For Task 2 each chunk is aligned with the chunk with the highest *chunkSim*. No thresholding, or preprocessing is performed.
2. *Threshold* adds a threshold to  $\text{sim}(w_i, w_j)$  in Equation (1). A modest threshold of 0.4 was used. The optimum threshold of 0.9 used in the final system was found with the system as a whole. We did not perform a grid search to optimize the threshold for all component tests.
3. *Stop Removal* adds stop word removal as described in subsection 2.1.
4. *Levenshtein* modifies  $\text{sim}(w_i, w_j)$  for words not in WordNet. Rather than using a binary value for exact string matching the Levenshtein measure shown in Equation (2) is used. This allows for slight differences in spelling, plurality, tenses, etc. The measure requires a threshold parameter,  $\beta$  which limits the maximum Levenshtein distance ( $\delta$ ) and scales the Levenshtein Measure between 0.0 and 1.0.  $\beta = 2.0$  was found via a grid search to perform best. The Levenshtein Measure is unnecessary for these tasks most likely because, as stated in section 1, words not in WordNet tend to be proper nouns or abbreviations for which the spelling is the same, and for short words such as “he” or “she”, “is” or “in”, even small edit distances can transform the word into a completely unrelated word.

|                     | <b>F1 Ali</b> | <b>p-value</b> | <b>significant</b> |
|---------------------|---------------|----------------|--------------------|
| <b>Basic</b>        | 65.40         | -              | -                  |
| <b>Threshold</b>    | 0.7263        | <0.0001        | yes                |
| <b>Stop Removal</b> | 0.7349        | <0.0001        | yes                |
| <b>Levenshtein</b>  | 0.6586        | 0.1445         | no                 |

**Table 3:** The effects of additional components to the core VRep system on Task 1

|                        | <b>F1 Ali</b> | <b>p-value</b> | <b>significant</b> |
|------------------------|---------------|----------------|--------------------|
| <b>Basic</b>           | 0.7508        | -              | -                  |
| <b>Threshold</b>       | 0.8812        | <0.0001        | yes                |
| <b>Stop Removal</b>    | 0.7511        | 0.9920         | no                 |
| <b>Levenshtein</b>     | 0.7524        | 0.7795         | no                 |
| <b>WSD</b>             | 0.7799        | <0.0001        | yes                |
| <b>Threshold + WSD</b> | 0.8216        | <0.0001        | yes                |

**Table 4:** The effects of components to the core VRep system on Task 2

5. Word Sense Disambiguation (*WSD*) should help to reduce noisy alignments by using the correct synset when computing the Vector relatedness measure. We used the entire sentence (all chunks) as input to SenseRelate::AllWords (Patwardhan et al., 2003). *WSD* improves results when used as a single component, but when used in combination with a threshold (*Threshold + WSD*) results are worse than a threshold alone. This is likely due to the fact that both *WSD* and thresholding aim to reduce noisy STS and chunk alignments. When used singularly they both achieve this task, but in combination *WSD* errors reduce performance.

Analysis of the test data indicated that the addition of these extra components was unnecessary, however to further analyze their contributions three runs were submitted for the both tasks 1 and 2. Run 1 used the *basic* system, run 2 eliminated the stop removal preprocessing step, and run 3 used the *basic* system with the *Levenshtein* measure described above. Test results were mixed and data set dependant, see the respective competition summaries (Agirre et al., 2016) for complete results.

#### 4.2 Alignment Reasoning Component Analysis

For alignment reasoning, only the assignment of a label (Type) to a chunk pair is evaluated. We used the gold standard alignments provided for each data set, converted each gold standard chunk pair to the

|                       | <b>Answers</b> | <b>Headlines</b> | <b>Images</b> |
|-----------------------|----------------|------------------|---------------|
| <b>Baseline</b>       | 67.9           | 61.4             | 54.2          |

**Table 5:** The performance of different classifiers on alignment reasoning

entire set of 72 features and tested multiple classification algorithms. All classifiers are WEKA (Hall et al., 2009) implementations; results are shown in Table 5. The baseline score is calculated as simply assigning the most common class, EQUI.

## 5 Conclusions and Future Work

In future iterations, more analysis should be done to refine the features used in classification. Using JRIP and other analysis criteria we can see why certain features are discriminative, and develop more informative features.

Rather than relying solely on the *Levenshtein* measure for words outside of WordNet, additional metrics, such as word2vec (Mikolov et al., 2013) could be incorporated.

Additional data should be added for training classifiers. The top performing classifier was generated from all data combined indicating that additional samples are necessary. It is likely that given more data, topic specific classifiers will outperform the general classifier we evaluated. Additional data will also help to reduce the class imbalance and will likely result in a set of rules for the REL class.

Since VRep already makes use of WordNet, it could be easily expanded to compete in the polarity subtask by implementing a polarity classifier using SentiWordNet (Baccianella et al., 2010).

## 6 Acknowledgments

We would like to thank Dr. Bridget McInnes for her advice during the development of VRep, and Uzair Abbasi for his contributions to the initial development of the system.

## Abstract

In this paper, we propose a deep neural network based natural language processing system for semantic textual similarity prediction. We leverage multi-layer bidirectional LSTM to learn sentence representation. After that, we construct matching features followed by Highway Multilayer Perceptron to make predictions. Experimental results demonstrate that this approach can't get better results on standard evaluation datasets.

## 1 Introduction

Traditional approaches (Lai and Hockenmaier, 2014; Zhao et al., 2014; Jimenez et al., 2014) for semantic textual similarity prediction usually build the supervised model using a variety of hand crafted features. Hundreds of features generated at different linguistic levels are exploited to boost classification. With the success of deep learning in many machine learning related applications, there has been much interest in applying deep neural network based techniques to further improve the prediction tasks in natural language processing (NLP) (Socher et al., 2011b; Iyyer et al., 2014; Tai et al., 2015).

A key component of deep neural network is word embeddings which serves as a lookup table to get word representations. From low-level NLP tasks such as language modeling, POS tagging, name entity recognition, and semantic role labeling, to high-

To whom all correspondence should be addressed. This work was partially supported by NSF-IIS 1117965, NSF-IIS 1302675, NSF-IIS 1344152, NSF-DBI 1356628, NIH R01 AG049371.

level tasks such as machine translation, information retrieval and semantic analysis (Kalchbrenner and Blunsom, 2013; Socher et al., 2011a; Tai et al., 2015). Deep word representation learning has demonstrated its importance for these tasks. All the tasks get performance improvement via further learning either word level representations or sentence level representations.

In this work, we focus on deep neural network based semantic textual similarity prediction. We use multi-layer bidirectional LSTM (Long Short Term Memory) (Graves et al., 2013) to learn sentence representations. After that, we construct matching features followed by Highway Multilayer Perceptron to learn high-level hidden matching feature representations. Below, we will briefly introduce Multi-Layer Bidirectional LSTM.

## 2 Multi-Layer Bidirectional LSTM

### 2.1 RNN vs LSTM

Recurrent neural networks (RNNs) are capable of modeling sequences of varying lengths via the recursive application of a transition function on a hidden state. For example, at each time step  $t$ , an RNN takes the input vector  $\mathbf{x}_t \in \mathbb{R}^n$  and the hidden state vector  $\mathbf{h}_{t-1} \in \mathbb{R}^m$ , then applies affine transformation followed by an element-wise nonlinearity such as hyperbolic tangent function to produce the next hidden state vector  $\mathbf{h}_t$ :

$$\mathbf{h}_t = \tanh(\mathbf{W}\mathbf{x}_t + \mathbf{U}\mathbf{h}_{t-1} + \mathbf{b}). \quad (1)$$

A major issue of RNNs using these transition functions is that it is difficult to learn long-range de-

pendencies during training step because the components of the gradient vector can grow or decay exponentially (Bengio et al., 1994).

The LSTM architecture (Hochreiter and Schmidhuber, 1998) addresses the problem of learning long range dependencies by introducing a memory cell that is able to preserve state over long periods of time. Concretely, at each time step  $t$ , the LSTM *unit* can be defined as a collection of vectors in  $\mathbb{R}^d$ : an *input gate*  $\mathbf{i}_t$ , a *forget gate*  $\mathbf{f}_t$ , an *output gate*  $\mathbf{o}_t$ , a *memory cell*  $\mathbf{c}_t$  and a hidden state  $\mathbf{h}_t$ . We refer to  $d$  as the *memory dimensionality* of the LSTM. One step of an LSTM takes as input  $\mathbf{x}_t$ ,  $\mathbf{h}_{t-1}$ ,  $\mathbf{c}_{t-1}$  and produces  $\mathbf{h}_t$ ,  $\mathbf{c}_t$  via the following transition equations:

$$\begin{aligned}\mathbf{i}_t &= \sigma(\mathbf{W}^{(i)}\mathbf{x}_t + \mathbf{U}^{(i)}\mathbf{h}_{t-1} + \mathbf{b}^{(i)}), \\ \mathbf{f}_t &= \sigma(\mathbf{W}^{(f)}\mathbf{x}_t + \mathbf{U}^{(f)}\mathbf{h}_{t-1} + \mathbf{b}^{(f)}), \\ \mathbf{o}_t &= \sigma(\mathbf{W}^{(o)}\mathbf{x}_t + \mathbf{U}^{(o)}\mathbf{h}_{t-1} + \mathbf{b}^{(o)}), \\ \mathbf{u}_t &= \tanh(\mathbf{W}^{(u)}\mathbf{x}_t + \mathbf{U}^{(u)}\mathbf{h}_{t-1} + \mathbf{b}^{(u)}), \\ \mathbf{c}_t &= \mathbf{i}_t \odot \mathbf{u}_t + \mathbf{f}_t \odot \mathbf{c}_{t-1}, \\ \mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t),\end{aligned}\quad (2)$$

where  $\sigma(\cdot)$  and  $\tanh(\cdot)$  are the element-wise sigmoid and hyperbolic tangent functions,  $\odot$  is the element-wise multiplication operator.

## 2.2 Model Description

One shortcoming of conventional RNNs is that they are only able to make use of previous context. In semantic text similarity prediction task, the decision is made after the whole sentence pair is digested. Therefore, exploring future context would be better for sequence meaning representation. Bidirectional RNNs architecture (Graves et al., 2013) proposed a solution of making prediction based on future words. At each time step  $t$ , the model maintains two hidden states, one for the left-to-right propagation  $\overrightarrow{\mathbf{h}}_t$  and the other for the right-to-left propagation  $\overleftarrow{\mathbf{h}}_t$ . The hidden state of the Bidirectional LSTM is the concatenation of the forward and backward hidden states. The following equations illustrate the main ideas:

$$\begin{aligned}\overrightarrow{\mathbf{h}}_t &= \tanh(\overrightarrow{\mathbf{W}}\mathbf{x}_t + \overrightarrow{\mathbf{U}}\overrightarrow{\mathbf{h}}_{t-1} + \overrightarrow{\mathbf{b}}) \\ \overleftarrow{\mathbf{h}}_t &= \tanh(\overleftarrow{\mathbf{W}}\mathbf{x}_t + \overleftarrow{\mathbf{U}}\overleftarrow{\mathbf{h}}_{t+1} + \overleftarrow{\mathbf{b}}),\end{aligned}\quad (3)$$

Deep RNNs can be created by stacking multiple RNN hidden layer on top of each other, with the

output sequence of one layer forming the input sequence for the next. Assuming the same hidden layer function is used for all  $N$  layers in the stack, the hidden vectors  $\mathbf{h}^n$  are iteratively computed from  $n = 1$  to  $N$  and  $t = 1$  to  $T$ :

$$\mathbf{h}_t^n = \tanh(\mathbf{W}\mathbf{h}_{t-1}^{n-1} + \mathbf{U}\mathbf{h}_{t-1}^n + \mathbf{b}). \quad (4)$$

Multilayer bidirectional RNNs can be implemented by replacing each hidden vector  $\mathbf{h}^n$  with the forward and backward vectors  $\overrightarrow{\mathbf{h}}^n$  and  $\overleftarrow{\mathbf{h}}^n$ , and ensuring that every hidden layer receives input from both the forward and backward layers at the level below. Furthermore, we can apply LSTM memory cell to hidden layers to construct multilayer bidirectional LSTM.

Finally, we can concatenate sequence hidden matrix  $\overrightarrow{\mathbf{M}} \in \mathbb{R}^{n \times d}$  and reversed sequence hidden matrix  $\overleftarrow{\mathbf{M}} \in \mathbb{R}^{n \times d}$  to form the sentence representation. Here  $n$  is the number of layers,  $d$  is the *memory dimensionality* of the LSTM. In the next section, we will use the two matrices to generate matching feature planes via linear algebra operations.

## 3 Learning from Matching Features

Inspired by (Tai et al., 2015), we apply element-wise merge to first sentence matrix  $M_1 \in \mathbb{R}^{n \times 2d}$  and second sentence matrix  $M_2 \in \mathbb{R}^{n \times 2d}$ . Similar to previous method, we can define two simple matching feature planes (*FPs*) with below equations:

$$\begin{aligned}FP_1 &= M_1 \odot M_2, \\ FP_2 &= |M_1 - M_2|,\end{aligned}\quad (5)$$

where  $\odot$  is the element-wise multiplication. The  $FP_1$  measure can be interpreted as an element-wise comparison of the signs of the input representations. The  $FP_2$  measure can be interpreted as the distance between the input representations.

### 3.1 Highway MLP

Inspired by (Kim et al., 2016), we build Highway Multilayer Perceptron (HMLP) layer to further enhance representation learning. Conventional MLP applies an affine transformation followed by a non-linearity to obtain a new set of features:

$$\mathbf{z} = g(\mathbf{W}\mathbf{y} + \mathbf{b}). \quad (6)$$

One layer of a highway network does the following:

$$\mathbf{z} = \mathbf{t} \odot g(\mathbf{W}_H \mathbf{y} + \mathbf{b}_H) + (1 - \mathbf{t}) \odot \mathbf{y}, \quad (7)$$

where  $g$  is a nonlinearity,  $\mathbf{t} = \sigma(\mathbf{W}_T \mathbf{y} + \mathbf{b}_T)$  is called as the transform gate, and  $(1 - \mathbf{t})$  is called as the carry gate. Similar to the memory cells in LSTM networks, highway layers allow adaptively carrying some dimensions of the input directly to the input for training deep networks.

## 4 Experiments

We use all previous dataset to train our LSTM classifier. The total number of training examples is 12912, and the number of dev examples is 680. Note that we didn't use cross validation to find the best model. Table 1 shows the Pearson correlation results of STS task.

### 4.1 Hyperparameters and Training Details

We first initialize our word representations using publicly available 300-dimensional Glove word vectors<sup>1</sup>. LSTM memory dimension is 100, the number of layers is 2. Training is done through stochastic gradient descent over shuffled mini-batches with the AdaGrad update rule (Duchi et al., 2011). The learning rate is set to 0.05. The mini-batch size is 25. The model parameters were regularized with a per-minibatch L2 regularization strength of  $10^{-4}$ . Note that word embeddings were fixed during training.

### 4.2 Objective Functions

The task of semantic similarity prediction tries to measure the degree of semantic similarity of a sentence pair by assigning a similarity score ranging from 1 (completely unrelated) to 5 (semantically equivalent). Inspired by (Tai et al., 2015), given a sentence pair, we wish to predict a real-valued similarity score in a range of  $[1, K]$ , where  $K > 1$  is an integer. The sequence  $1, 2, \dots, K$  is the ordinal scale of similarity, where higher scores indicate greater degrees of similarity. We can predict the similarity score  $\hat{y}$  by predicting the probability that the learned hidden representation  $x_h$  belongs to the ordinal scale. This is done by projecting an input representation onto a set of hyperplanes, each of which corresponds to a class. The distance from the input

to a hyperplane reflects the probability that the input will located in corresponding scale.

Mathematically, the similarity score  $\hat{y}$  can be written as:

$$\begin{aligned} \hat{y} &= r^T \cdot \hat{p}_\theta(y|x_h) \\ &= r^T \cdot \text{softmax}(W \cdot x_h + b) \\ &= r^T \cdot \frac{e^{W_i x_h + b_i}}{\sum_j e^{W_j x_h + b_j}} \end{aligned} \quad (8)$$

where  $r^T = [1 \ 2 \ \dots \ K]$  and the weight matrix  $W$  and  $b$  are parameters.

In order to introduce the task objective function, we define a sparse target distribution  $p$  that satisfies  $y = r^T p$ :

$$p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & i = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

where  $1 \leq i \leq K$ . The objective function then can be defined as the regularized KL-divergence between  $p$  and  $p_\theta$ :

$$J(\theta) = -\frac{1}{m} \sum_{k=1}^m \text{KL}(p^{(k)} || p_\theta^k) + \frac{\lambda}{2} \|\theta\|_2^2, \quad (10)$$

where  $m$  is the number of training pairs and the superscript  $k$  indicates the  $k$ -th sentence pair (Tai et al., 2015).

## 5 Conclusions and Discussions

In this paper, we propose a deep neural network architecture that leverages pre-trained word embeddings to learn sentence meanings. Our approach first generates word sequence representations as inputs into a multilayer bidirectional LSTM to learn sentence representations. After that, we construct matching features followed by highway MLP to learn high-level hidden matching feature representations. Experimental results on benchmark datasets demonstrate that our model didn't achieve the state-of-the-art performance compared with other approaches. Our approach is above the median scores only on question-question domain. We suspect our model have worse capability of domain adaption. Also the Highway MLP may increase the model complexity and lead to worse performance.

## **Abstract**

We present our UWB system for Semantic Textual Similarity (STS) task at SemEval 2016. Given two sentences, the system estimates the degree of their semantic similarity.

We use state-of-the-art algorithms for the meaning representation and combine them with the best performing approaches to STS from previous years. These methods benefit from various sources of information, such as lexical, syntactic, and semantic.

In the monolingual task, our system achieves mean Pearson correlation 75.7% compared with human annotators. In the cross-lingual task, our system has correlation 86.3% and is ranked first among 26 systems.

## **1 Introduction**

Semantic Textual Similarity (STS) is one of the core disciplines in Natural Language Processing (NLP). Assume we have two textual fragments (word phrases, sentences, paragraphs, or full documents), the goal is to estimate the degree of their semantic similarity.

STS systems are usually compared with the manually annotated data. In the case of SemEval the data consist of pairs of sentences with a score between 0 and 5 (higher number means higher semantic similarity). For example, English pair

Two dogs play in the grass.  
Two dogs playing in the snow.

has a score 2.8, i.e. the sentences are not equivalent, but share some information.

This year, SemEval's STS is extended with the Spanish-English cross-lingual subtask, where e.g. the pair

Tuve el mismo problema que tú.  
I had the same problem.

has a score 4.8, which means nearly equivalent.

Each year STS belongs to one of the most popular tasks at SemEval competition. The best STS system at SemEval 2012 (Bär et al., 2012) used lexical similarity and Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007). In SemEval 2013, the best model (Han et al., 2013) used semantic models such as Latent Semantic Analysis (LSA) (Deerwester et al., 1990), external information sources (WordNet) and n-gram matching techniques. For SemEval 2014 and 2015 the best system comes from (Sultan et al., 2014a; Sultan et al., 2014b; Sultan et al., 2015). They introduced new algorithm, which align the words between two sentences. They showed that this approach can be efficiently used also for STS. Overview of systems participating in previous SemEval competitions can be found in (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015).

The best performing systems from previous years are based on various architectures benefiting from lexical, syntactic, and semantic information. In this work we try to use the best techniques presented during last years, enhance them, and combine into a single model.

## **2 Semantic Textual Similarity**

This section describes various techniques for estimating the text similarity.

## 2.1 Lexical and Syntactic Similarity

This section presents the techniques exploiting lexical and syntactic information in the text. Some of them have been successfully used by (Bär et al., 2012). Many of the following techniques benefit from the weighing of words in a sentence using *Term Frequency - Inverse Document Frequency* (TF-IDF) (Manning and Schütze, 1999).

- **Lemma n-gram overlaps:** We compare word  $n$ -grams in both sentences using *Jaccard Similarity Coefficient* (JSC) (Manning and Schütze, 1999). We do it separately for different orders  $n \in \{1, 2, 3, 4\}$ . *Containment Coefficient* (Broder, 1997) is used for orders  $n \in \{1, 2\}$ . We extend original metrics by weighing of  $n$ -grams. We define this weight as a sum of *IDF* values of words in  $n$ -gram.  $N$ -gram match is not counted as 1 but as the weight of this  $n$ -gram. According to our experiments, this weighing significantly improves performance.

We also use information about the length of *Longest Common Subsequence* compared to the length of the sentences.

- **POS n-gram overlaps:** In similar way as for lemmas, we calculate *Jaccard Similarity Coefficient* and *Containment Coefficient* for  $n$ -grams of part-of-speech (POS) tags. Again, we use  $n$ -gram weighing and  $n \in \{1, 2, 3, 4\}$ . These features exploit syntactic similarity of the sentences.

- **Character n-gram overlaps:** Similarly to lemma or POS  $n$ -grams, we use *Jaccard Similarity Coefficient* and *Containment Coefficient* for comparing common substrings in both sentences. Here the *IDF* weights are computed on character  $n$ -gram level. We use  $n$ -gram weighing and  $n \in \{2, 3, 4, 5\}$ .

We enrich these features also by *Greedy String Tiling*(Wise, 1996) allowing to deal with reordered text parts and by *Longest Common Substring* (LCS) measuring the ration between LCS and length of the sentences.

- **TF-IDF:** For each word in a sentence we calculate *TF-IDF*. Given the word vocabulary  $V$ , the

sentence is represented as a vector of dimension  $|V|$  with *TF-IDF* values of words present in the sentence. The similarity between two sentences is expressed as cosine similarity between corresponding *TF-IDF* vectors.

## 2.2 Semantic Similarity

In this section we describe in detail the techniques that are more semantically oriented and are based on *Distributional Hypothesis*. This principle states that we can induce (to some degree) the meaning of words from their distribution in the text. This claim has multiple theoretical roots in psychology, structural linguistics, or lexicography (Firth, 1957; Rubenstein and Goodenough, 1965; Miller and Charles, 1991).

- **Semantic composition:** This approach is based on *Frege’s principle of compositionality*, which states that the meaning of a complex expression is determined as a composition of its parts, i.e. words. To represent the meaning of a sentence we use simple linear combination of word vectors, where weights are represented by the *TF-IDF* values of appropriate words. We use state-of-the-art word embedding methods, namely Continuous Bag of Words (CBOW) (Mikolov et al., 2013) and Global Vectors (GloVe) (Pennington et al., 2014). We use cosine similarity to compare vectors.
- **Paragraph2Vec:** Paragraph vectors were proposed in (Le and Mikolov, 2014) as an unsupervised method of learning text representation. Resulting feature vector has fixed dimension while the input text can be of any length. The paragraph vectors and word vectors are concatenated to predict the next word in a context. The paragraph token acts as a memory that remembers what information is missing from the current context. We use cosine similarity for comparing two paragraph vectors.
- **Tree LSTM:** Long Short-Term Memory (LSTM) is a type of Recurrent Neural Network (RNN) with a complex computational unit. We use tree-structured representation of LSTM presented in (Tai et al., 2015). Tree model

represents the sentence structure. RNN processes input sentences of variable length via recursive application of a transition function on a hidden state vector  $h_t$ . For each sentence pair it creates sentence representations  $h_L$  and  $h_R$  using Tree-LSTM model. Given these representations, model predicts the similarity score using a neural network considering distance and angle between vectors.

- **Word alignment:** Method presented in (Sultan et al., 2014a; Sultan et al., 2014b; Sultan et al., 2015) has been very successful in last years. Given two sentence we want to compare, this method finds and aligns the words that have similar meaning and similar role in these sentences.

Unlike the original method, we assume that not all word alignments have the same importance for the meaning of the sentences. The weight of a set of words  $A$  is a sum of word's *IDF* values  $\omega(A) = \sum_{w \in A} \text{IDF}(w)$ , where  $w$  is a word.

Then the sentence similarity is given by

$$\text{sim}(\mathbf{S}_1, \mathbf{S}_2) = \frac{\omega(\mathbf{A}_1) + \omega(\mathbf{A}_2)}{\omega(\mathbf{S}_1) + \omega(\mathbf{S}_2)}, \quad (1)$$

where  $\mathbf{S}_1$  and  $\mathbf{S}_2$  are input sentences (represented as sets of words).  $\mathbf{A}_1$  and  $\mathbf{A}_2$  denote the sets of aligned words for  $\mathbf{S}_1$  and  $\mathbf{S}_2$ , respectively. The weighing of alignments improves our results significantly.

### 2.3 Similarity Combination

The combination of STS techniques is in fact a regression problem where the goal is to find the mapping from input space  $\mathbf{x}_i \in \mathbb{R}^d$  of  $d$ -dimensional real-valued vectors (each value  $x_{i,a}$ , where  $1 \leq a \leq d$  represents the single STS technique) to an output space  $y_i \in \mathbb{R}$  of real-valued targets (desired semantic similarity). These mapping are learned from the training data  $\{\mathbf{x}_i, y_i\}_{i=1}^N$  of size  $N$ . There exist a lot of regression methods. We experiment with several of them:

- **Linear Regression:** Linear Regression (LR) is probably the simplest regression method. It is defined as  $y_i = \lambda \mathbf{x}_i$ , where  $\lambda$  is a vector of

weights that can be estimated for example by the *least squares method*.

- **Gaussian processes regression:** Gaussian process regression (GPR) is nonparametric kernel-based probabilistic model for non-linear regression (Rasmussen and Williams, 2005).
- **SVM Regression:** We use Support Vector Machines (SVM) for regression with the radial basis functions (RBF) as a kernel. We use improved Sequential Minimal Optimization (SMO) algorithm for parameter estimation introduce in (Shevade et al., 2000).
- **Decision Trees Regression:** The output of the Decision Trees Regression (DTR) (Breiman et al., 1984) is predicted by the sequence of decisions organized in a tree.
- **Perceptron Regression:** Multilayer Perceptron (MLP) is feed-forward artificial neural network that uses back-propagation to classify instances.

## 3 System Description

This section describes the settings of our final STS system. For monolingual STS task we submitted two runs. First is based on supervised learning and the second is unsupervised system:

- **UWB sup:** Supervised system based on SVM regression with RBF kernel. We use all techniques described in 2 as features for regression. During the regression we also use the simple trick. We create another features represented as a product of each pair of features  $x_{i,a} \times x_{i,b}$  for  $a \neq b$ . We do so to better model the dependencies between single features. Together, we have 301 STS features. The system is trained on all SemEval datasets from prior years (see Table 1).
- **UWB unsup:** Unsupervised system based only on weighted word alignment (Section 2.2).

We handled with the cross-lingual STS task with Spanish-English bilingual sentence pairs in two steps. Firstly, we translated Spanish sentences to English via *Google translator*. The English sentences

| <b>Corpora</b>     | <b>Pairs</b> |
|--------------------|--------------|
| SemEval 2012 Train | 2,234        |
| SemEval 2012 Test  | 3,108        |
| SemEval 2013 Test  | 1,500        |
| SemEval 2014 Test  | 3,750        |
| SemEval 2015 Test  | 3,000        |

Table 1: STS gold data from prior years.

|           | <b>News</b>   | <b>Multi-Source</b> | <b>Mean</b>   | <b>RR</b> | <b>TR</b> |
|-----------|---------------|---------------------|---------------|-----------|-----------|
| UWB sup   | 0.9062        | <b>0.8190</b>       | <b>0.8631</b> | 1         | 1         |
| UWB unsup | <b>0.9124</b> | 0.8082              | 0.8609        | 2         | 1         |

Table 4: Pearson correlations on cross-lingual STS task of SemEval 2016. *RR* denote the run (system) ranking and *TR* denote our team ranking.

were left untouched. Secondly, we used the same STS systems as for monolingual task.

For preprocessing pipeline we used Standford CoreNLP library (Manning et al., 2014), i.e. for tokenization, lemmatization and POS tagging. Most of our STS techniques (apart from word alignment and POS *n*-gram overlaps) work with lemmas instead of word forms (this leads to slightly better performance). Some of our STS techniques are based on unsupervised learning and thus they need large unannotated corpora to train. We trained Paragraph2Vec, GloVe and CBOW models on *One billion word benchmark* presented in (Chelba et al., 2014). Dimension of vectors for all these models was set to 300. TF-IDF values were also estimated on this corpus.

All regression methods mentioned in Section 2.3 are implemented in WEKA (Hall et al., 2009).

## 4 Results and Discussion

This section presents the results of our systems for both English monolingual and Spanish-English cross-lingual STS task of SemEval 2016. In addition we present detailed results on the test data from SemEval 2015. As an evaluation measure we use *Pearson correlation* between system output and human annotations.

In the tables we present the correlation for each individual test set. Column *Mean* represents the weighted sum of all correlations, where the weight

are given by the ratio of data set length compared to the full length of all datasets together. The mean value of Pearson correlations is also used as the main evaluation measure for ranking the system submissions.

In the Table 2 we show the results for the test data from 2015. We trained our systems on SemEval STS data from years 2012–2014. We provide comparison of individual STS techniques as well as of different types of regressions. Clearly, the SVM regression and Gaussian processes regression perform best and with our feature set it is 1% better than the winning system of SemEval 2015. The best performing single technique is indisputably the weighed word alignment correlated by 79.6% with gold data. Note that without weighing, we achieved only 74.2% on this data. The original result from authors of this approach was, however, 79.2%. This is probably caused by some inaccuracies in our implementation. Anyway, the weighing improves the correlation even if we compare it to the original results. Note that for estimating regression parameters we use the data from all years apart from 2015 (see Table 1).

The results for monolingual STS task of SemEval 2016 are shown in Table 3. In the time of writing this paper the ranks of submitted systems were not known. Thus we present only our correlations. We can see that our supervised system (SVM regression) performs approximately 3% better than the unsupervised one (weighed word alignment). On the data from SemEval 2015 this difference was not so significant (approximately 1.5%).

Finally, the results for cross-lingual STS task of SemEval 2016 are shown in Table 4. We achieved very high correlations. To be honest we must say that we expected much lower correlation through the fact that we use the machine translation via Google translator causing certainly some inaccuracies (at least in the syntax of the sentence). On the other hand, it proves that our model efficiently generalizes the learned patterns. Here, there is almost no difference in performance between supervised and unsupervised version of submitted systems. Our submitted runs finished first and second among 26 competing systems.

## 5 Conclusion

In this paper we described our UWB system participating in SemEval 2016 competition in the task of Semantic Textual Similarity. We participated on both monolingual and cross-lingual parts of competition.

Our best results have been achieved by SVM regression of various STS techniques based on lexical, syntactic, and semantic information. This approach has been shown to work well for both subtasks.

## Abstract

This paper describes our participation in the SemEval-2016 Task 1: *Semantic Textual Similarity* (STS). We developed three methods for the English subtask (STS Core). The first method is unsupervised and uses WordNet and word2vec to measure a token-based overlap. In our second approach, we train a neural network on two features. The third method uses word2vec and LDA with regression splines.

## 1 Introduction

Measuring semantic textual similarity (STS) is the task of determining the similarity between two different text passages. The task is important for various natural language processing tasks like topic detection or automated text summarization because languages are versatile and authors can express similar content or even the same content with different words. Predicting semantic textual similarity has been a recurring task in SemEval challenges (Agirre et al., 2015; Agirre et al., 2014; Agirre et al., 2013; Agirre et al., 2012). As in previous years, the purpose of the STS task is the development of systems that automatically predict the semantic similarity of two sentences in the continuous interval [0, 5] where 0 represents a complete dissimilarity and 5 denotes a complete semantic equivalence between the sentences (Agirre et al., 2015).

The organizers provide sentence pairs whose semantic similarities have to be predicted by the contestants. The quality of a system is determined by calculating the Pearson correlation between the predicted values and a human gold standard that has

been created by crowdsourcing. The data from previous STS tasks can be used for training supervised methods.

The test data consists of text content from different sources. In this year’s shared task, the systems are tested on five different categories with different topics and varying textual characteristics like text length or spelling errors: *answer-answer*, *plagiarism*, *postediting*, *headlines*, and *question-question*.

The remainder of the paper is structured as follows: Section 2 discusses related approaches to automatically determining semantic textual similarity. Section 3 describes our three methods in detail. We discuss their results in section 4. Finally, we conclude in chapter 5 and outline future work.

## 2 Related Work

In the last shared tasks, most of the teams used natural languages processing techniques like tokenization, part-of-speech tagging, lemmatization, named entity recognition and word embeddings. External resources like WordNet (Miller, 1995) and word2vec (Mikolov et al., 2013) are commonly used. In (Agirre et al., 2012) and (Agirre et al., 2013), the organizers provide a list and a comparison of the tools and resources used by the participants in the first two years, respectively.

In each year, the organizers provide a baseline value by calculating the cosine similarity of the binary bag-of-words vectors from both sentences in each sample. Since 2013, TakeLab (Šarić et al., 2012), the best ranked system in 2012, has also been used as another baseline value.

Most of the teams used machine learning in 2015

(Agirre et al., 2015). In 2014, the best two submitted runs were from unsupervised systems.

The work most closely related to our Overlap method is (Han et al., 2015), which uses a two-phased approach called *Align-and-Differentiate*. In the first phase, they compute an alignment score. Afterwards, they modify the alignment score in a differentiate phase by subtracting a penalty score for terms that can not be aligned. The idea behind the computation of our alignment scores is the same: For each sample, we average over the crosswise similarities between the sentences by aligning them, accumulating similarities between tokens and dividing by sentence lengths. The results of the alignment score in our Overlap method differ because (i) our alignment is different, (ii) we use another similarity function for tokens, and (iii) our preprocessing is different.

In (Vu et al., 2015), the similarity between LDA vectors calculated from documents is used together with syntactic and lexical similarity measures to compute the similarity between text fragments. This idea is also incorporated in our Deep LDA method. Moreover, both approaches use different flavors of regression analysis for the final model prediction. Regression analysis was also used in (Sultan et al., 2015), where the authors combine an unsupervised method with ridge regression analysis. Our approach differs in the sense that it introduces  $k$ -nearest neighbors as a lazy training layer before the regression analysis phase to decrease the effect of noisy data points.

### 3 Methods

In this section, we describe our three system runs. The ideas behind our methods are independent of the word order in a sentence. Our first method is unsupervised, whereas the other two methods are supervised. The first and second method share the same preprocessing.

#### 3.1 Run 1: Overlap Method

Our first method is unsupervised. It measures the overlap between the tokens in sentence  $s_1$  and the tokens in sentence  $s_2$ .

##### 3.1.1 Preprocessing

For preprocessing the input text, we first process each sentence with Stanford CoreNLP (Manning et al., 2014). Afterwards, we use Hunspell<sup>1</sup> with the latest OpenOffice English dictionaries to suggest spelling corrections for tokens with at least two characters in length. For each token, we calculate the Levenshtein distance for all suggestions. If suggestions have the same lowest distance, we choose the longest word and replace the former misspelt word. Abbreviations are also replaced by their full forms. Afterwards, we process the corrected sentence with Stanford CoreNLP again. We use the WordnetStemmer from the *Java Wordnet Interface* (Finlayson, 2014) to look up lemmas with the help of WordNet (Miller, 1995). If the WordnetStemmer can not provide a lemma for a token, we use the predicted lemma from the Stanford CoreNLP.

Instead of accessing all tokens in a sentence, we start from the root token and recursively follow outgoing dependency edges and add all visited tokens to a list. This approach improves our results slightly because some tokens will be ignored. Furthermore, the tokens are filtered for stopwords<sup>2</sup>.

##### 3.1.2 Method

The Overlap method measures the token-based overlap between two sentences. Therefore, we need to define a similarity function for tokens: We first try to identify a textual similarity of 1 by comparing the lower case lemmas of both tokens or by checking if their most common WordNet synsets are the same. We assess their similarity as 0.5 if they share any synset. If this is not the case, we use word2vec (Mikolov et al., 2013) with the 300-dimensional *GoogleNews-vectors-negative300* model. We look up both words (or their lemmas if the words are not present in the model) and calculate the cosine similarity of their word embeddings. Otherwise, we return a default value.

This yields the following similarity function for two tokens:

---

<sup>1</sup><http://hunspell.github.io/>

<sup>2</sup><http://xpo6.com/list-of-english-stopwords/>

$$\text{sim}(t_1, t_2) := \begin{cases} 1 & \text{if } t_1.\text{lemma} == t_2.\text{lemma} \\ 1 & \text{if } t_1 \text{ and } t_2 \text{ have the same} \\ & \text{most common synset} \\ 0.5 & \text{if } t_1 \text{ and } t_2 \text{ share any} \\ & \text{synset} \\ d(t_1, t_2) & \text{if } t_1 \text{ and } t_2 \text{ have word} \\ & \text{embeddings} \\ \text{default} & \text{otherwise} \end{cases}$$

where  $d(t_1, t_2)$  denotes the cosine similarity between the two word embeddings of the tokens.

Given a token  $t$  from one sentence, we calculate its similarity to another sentence  $S$  by taking the maximum similarity between  $t$  and all tokens of  $S$ :

$$\text{msim}(t, S) := \max_{t_2 \in S} \text{sim}(t, t_2)$$

We define the similarity score between two sentences in  $[0, 1]$  as follows:

$$\text{ssim}(s_1, s_2) := \frac{\sum_{t \in s_1} \text{msim}(t, s_2)}{2 \cdot |s_1|} + \frac{\sum_{t \in s_2} \text{msim}(t, s_1)}{2 \cdot |s_2|}$$

To predict the semantic similarity score in  $[0, 5]$ , we multiply ssim by 5, however, this does not change our evaluation results because the Pearson correlation is scale invariant:

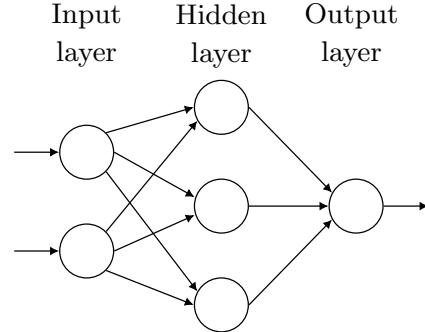

$$\text{STS}(s_1, s_2) := 5 \cdot \text{ssim}(s_1, s_2)$$

We observed that some samples in the STS 2016 test data consist almost entirely of stopwords. For example, the STS 2016 evaluation data contained a sample with the sentences “*I think you should do both.*” and “*You should do both.*” before the final filtering. After filtering stop words, the first sentence would only contain the word “*think*” and the second sentence would be empty, which would result in a predicted score of zero. To avoid these extreme cases, we do not filter stop words if this would result in a sentence length of less than two tokens in both sentences.

### 3.2 Run 2: Same Word Neural Network Method

We train a neural network with 3 layers and a sigmoid activation function in Accord.NET (de Souza,

2014). Our network consists of 2 neurons in the input layer, 3 neurons in the hidden layer and 1 neuron in the output layer, as illustrated in Figure 1. The layer weights are initialized by the Nguyen-Widrow function (Nguyen and Widrow, 1990). We use the Levenberg-Marquardt algorithm (Levenberg, 1944; Marquardt, 1963) to train our network on the STS Core test data from 2015 and 2014.

**Figure 1:** Architecture of our neural network

All samples are preprocessed as described in section 3.1.1. For each sample  $(s_1, s_2, gs)$  in the training set, we create a vocabulary list of the lowercase lemmas from both sentences. Lemmas that share a most common synset in WordNet are grouped together. Let  $n$  be the size of the vocabulary. We create two bag-of-words vectors  $\text{bow}_{s_1}$  and  $\text{bow}_{s_2}$ . For each lemma  $l$ , we calculate the minimum number of times  $l$  occurs in each sentence and the delta between the minimum and the maximum:

$$\min_i := \min(\text{bow}_{s_1}[i], \text{bow}_{s_2}[i])$$

$$|\Delta_i| := |\text{bow}_{s_1}[i] - \text{bow}_{s_2}[i]|$$

As input vectors for the neural net, we build two sums per sample and use them as the two dimensional feature vector (sameWords, notSameWords) for the expected output  $gs$ :

$$\text{sameWords} := \sum_{i=1}^n \min_i$$

$$\text{notSameWords} := \sum_{i=1}^n |\Delta_i|$$

Table 1 shows an example of the same word neural network method for the two input sentences “*Tim plays the guitar*” and “*Tim likes guitar songs*”, which have the input vector  $(2, 3)$ .

| $i$      | Lemma  | $\text{bow}_{s_1}$ | $\text{bow}_{s_2}$ | $\min_i$ | $ \Delta_i $ |
|----------|--------|--------------------|--------------------|----------|--------------|
| 1        | tim    | 1                  | 1                  | 1        | 0            |
| 2        | play   | 1                  | 0                  | 0        | 1            |
| 3        | guitar | 1                  | 1                  | 1        | 0            |
| 4        | like   | 0                  | 1                  | 0        | 1            |
| 5        | song   | 0                  | 1                  | 0        | 1            |
| $\Sigma$ |        |                    |                    | 2        | 3            |

**Table 1:** An example for creating the two-dimensional feature vector for the *Same Word Neural Network* method

We trained the neural net until the error rate between two iterations did not change more than  $\varepsilon = 10^{-5}$ .

### 3.3 Run 3: Deep LDA Method

We represent the semantic similarity between two documents  $s_1$  and  $s_2$  by means of a vector  $F = [f_1, f_2, f_3, f_4] \in \mathbb{R}^4$ , where each component of  $F$  is responsible for modelling a different aspect of the semantic similarity, namely the *surface-level similarity*, *context similarity*, and the *topical similarity*.

#### Surface-level Similarity

The surface-level similarity can to some extent (although not entirely) capture the semantic similarity between documents. Let  $s_1$  and  $s_2$  be the reference and the candidate documents respectively. We compute the components  $f_1, f_2 \in \mathbb{R}$  as follows:

$$f_1(s_1, s_2, N) = \frac{m_N}{l_N^{s_1}}$$

$$f_2(s_1, s_2, N) = \left( \prod_{n=1}^N \frac{m_N}{l_n^{s_2}} \right)^{\frac{1}{N}}$$

where  $m_N$  is the number of matched  $N$ -grams between  $s_1$  and  $s_2$ ,  $l_N^{s_1}$  denotes the total number of  $N$ -grams in  $s_1$  and  $l_n^{s_2}$  is the total number of  $n$ -grams in  $s_2$ .  $f_1$  is the common ROUGE (Lin, 2004) metric used in automatic text summarization and  $f_2$  is a modified version of the BLEU (Papineni et al., 2002) metric (standard machine translation metric) where the brevity penalty is eliminated. Note that  $f_1$  can be interpreted as the recall-oriented surface similarity and  $f_2$  as the precision-oriented one.

#### Context Similarity

In order to model the context similarity between documents, we use word embeddings that learn semantically meaningful representations for words from local co-occurrences in sentences. More specifically we use *word2vec* (Mikolov et al., 2013) which seems to be a reasonable choice to model context similarity as the word vectors are trained to maximize the log probability of context words. We denote the context similarity of two documents  $s_1$  and  $s_2$  by  $f_3 \in \mathbb{R}$  and compute it as follows:

$$f_3(s_1, s_2) = \cos(\tilde{v}_{s_1}, \tilde{v}_{s_2})$$

$$= \cos\left(\frac{\sum_{v \in s_1} v}{|s_1|}, \frac{\sum_{v' \in s_2} v'}{|s_2|}\right)$$

where  $v$  is the dense vector representation of a token and  $\tilde{v}$  represents the centroid of the word vectors in a document.

#### Topical Similarity

To model the topical similarity between two documents, we use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to train models on the English Wikipedia. For both documents  $s_1$  and  $s_2$ , we compute the topic distributions  $\theta_1$  and  $\theta_2$  and use the Hellinger distance to measure the similarity between the documents. This can be formally written as

$$f_4(s_1, s_2) = 1 - \frac{1}{\sqrt{2}} \sqrt{\sum_{i=1}^k (\sqrt{\theta_{1i}} - \sqrt{\theta_{2i}})^2}$$

where  $k$  represents the number of learned LDA topics.

#### Similarity Prediction

In order to predict the semantic similarity between two documents, we use a combination of  $k$ -NN and Multivariate Adaptive Regression Splines (MARS) (Friedman, 1991).

Let  $T = \{(s_1, s'_1, gs_1), \dots, (s_m, s'_m, gs_m)\}$  be the training set consisting of  $m$  document pairs together with their corresponding gold standard semantic similarity and  $(s_i, s'_i) \notin T$  be a document pair for which the semantic similarity has to be computed. We construct a set  $\mathcal{F} = \{(F_1, gs_1), \dots, (F_m, gs_m)\}$  where each  $F_j$  is the four-dimensional vector representation of the semantic similarity between  $s_j$  and  $s'_j$ . Moreover, we

| Sentence 1  | Sentence 2  | gs | STS     |

| Unfortunately the answer to your question is we simply do not know. | Sorry, I don't know the answer to your question.      | 4  | 4.05800 |
| You should do it.   | You can do it, too.                                   | 1  | 4.39817 |
| Unfortunately the answer to your question is we simply do not know. | My answer to your question is "Probably Not".         | 1  | 3.70982 |
| $P(A B)$ is the conditional probability of A, given B.              | $P(B A)$ is the conditional probability of B given A. | 3  | 4.32017 |

**Table 2:** Examples for the results of the Overlap method with the corresponding gold standards

compute the vector  $F_i$ . Next, we construct a set  $\mathcal{F}_k$  containing the  $k$ -nearest neighbors to the vector  $F_i$ . In order to calculate the distances between the vectors, we use the Euclidean distance. Finally, we construct a vector  $gs_k$  containing the gold standard similarity values of the  $k$ -nearest neighbors and feed it into a MARS model to predict the semantic similarity of the pair  $(s_i, s'_i)$ . The choice of MARS is due to its capability to automatically model non-linearities between variables.

## 4 Results

We report the results of our three approaches for the STS Core test from 2016 and 2015.

### 4.1 STS 2016 Results

In this years shared task, 117 runs were submitted. We achieved weighted mean Pearson correlations of 0.71134, 0.67502 and 0.62078. In this year's run, our best result was the Overlap method, followed by the Same Word Neural Network method and the Deep LDA approach. Table 2 shows examples of good and bad results of our Overlap method on the 2016 data. Detailed results of our runs are given in Table 3 per test set. Our three approaches achieved different results.

From a semantic point of view, the most obvious value for the default value in our Overlap method is 0. However, we have discovered that a default value 0.15 returned better results on the STS Core test data from 2015 and also chose this default value for our submission.

In the Deep LDA approach, we set the parameter  $N = 2$ , although the use of unigrams did not show any significant statistical difference in the results. We choose the number of topics in the LDA model to be 300. In the prediction phase of the al-

**Table 4:** Pearson correlation of the 2015 test data

gorithm, we select  $k = 100$  nearest neighbors from the data sets provided from 2012 to 2015.

### 4.2 STS 2015 Results

We list the results of our methods for the 2015 test data in Table 3 to discuss the effect of different evaluation sets. It is interesting to see that the Deep LDA method performed best out of our three systems on 2015. Its results on 2016 were surprisingly lower. We attribute this difference to the lack of domain specific training data for 2016. As an unsupervised approach, the Overlap method has fewer problems with the domain change.

It should be noted that the gold standard of the 2015 test data was available during the development of our methods. For the training phase, the Same Word Neural Network method used the STS Core test from 2014. The Deep LDA method was trained

on the data from 2012 to 2014.

## 5 Conclusion and Future Work

We have presented three approaches to measure textual semantic similarity. This year, our unsupervised method achieved the best result. By comparing our result for 2016 and 2015, we showed that the approaches yielded different results in a different order.

In our future work, we will try to modify the Overlap method, by also using a penalty score and by applying certain similarity score shifters, for instance modifying the score by applying a date extraction with a specific distance function for dates. We tried to group words into phrases by using a sliding window approach with a shrinking window size and matching phrases in word2vec. In our initial attempt, this worsened the results for the Overlap method. We will adjust the similarity function to increase the weight of phrases in comparison to unigrams.

We aim to adapt the techniques for German and Spanish.

## Abstract

This paper describes our proposed solutions designed for a STS core track within the SemEval 2016 English Semantic Textual Similarity (STS) task. Our method of similarity detection combines recursive autoencoders with a WordNet award-penalty system that accounts for semantic relatedness, and an SVM classifier, which produces the final score from similarity matrices. This solution is further supported by an ensemble classifier, combining an aligner with a bi-directional Gated Recurrent Neural Network and additional features, which then performs Linear Support Vector Regression to determine another set of scores.

## 1 Introduction

The tasks from the Semantic Textual Similarity (STS) contest have always attracted vivid interest from the NLP community. The goal is to measure the semantic similarity between two given sentences on a scale from 0 to 5, trying to emulate the idea of similarity degrees, thus replicating human language understanding.

After processing two pieces of text, semantic textual similarity software captures degrees of semantic equivalence. One of the goals of the STS task is to create a unified framework for extracting and measuring semantic similarity. Improvements achieved in the course of this task can be useful in many research areas, such as question answering (Marsi and Krahmer, 2005), machine translation (Callison-Burch, 2008), and plagiarism detection (Clough et al., 2002).

We present a solution designed to detect both the similarity between single words and longer, multi-word phrases. It employs two important components: the unfolding recursive autoencoder (RAE) (Socher et al., 2011) and the penalty-award weight system based on WordNet (Miller et al., 2002). First, RAE is used to perform unsupervised learning on parse trees, then the WordNet module adjusts the distances of RAE vectors using awards and penalties based on semantic similarities of words. The complete pipeline includes a deep net (RAE) module, a WordNet module, a normalization module and a sentence similarity matrices computing module.

Another solution that ran in parallel to the RAE pipeline, was the monolingual word aligner (in some cases we used its corrected version with additional features, including a bag-of-words). Finally an ensemble classifier was used to perform Linear Support Vector Regression (Drucker et al., 1996) over the results from all the other classifiers. This included: the base word aligner (Sultan et al., 2015), bi-directional Gated Recurrent Neural Network (Cho et al., 2014; Chung et al., 2014), the RAE with WordNet features and the corrected aligner.

## 2 System Overview

This section describes the modules that constitute our three runs. Detailed information about the configuration of these runs can be found in Section 3.

### 2.1 RAE with WordNet Features

RAE with the WordNet module is composed of two major parts: a recursive autoencoder (RAE) for unsupervised training of sentence representations and

additional WordNet-based submodule for enhancing the performance of the RAE.

The RAE takes unlabeled parse trees and word vectors as input and learns phrase features for each node in the tree. The learned features can be used to recursively reconstruct the vectors at each node in the tree. The encoding part follows the Semantic Dependency Tree Recursive Neural Network (SDT-RNN) structure described in (Socher et al., 2014). In the decoding part, the tree structure used to encode the sentence is mirrored. The reconstruction error (the total error of the network) is counted for all subtrees as the summed Euclidean distance between a subtree’s decoded terminal nodes and the original word vectors. The network learns to encode representations of meaningful phrases in tree nodes. We use the word representation vectors published by (Pennington et al., 2014).

The RAE is first trained in an unsupervised way on the Corpus of Contemporary American English (Davies, 2008) combined with SemEval STS training sets released before 2015 (only sentences without labels), then a sentence similarity matrices computing module (Section 2.1.2) is used to generate similarity scores for two candidate sentences. Our first experiment involved a procedure described in (Socher et al., 2011) with unmodified word representation vectors, using Euclidean distance as a measure of word-to-word similarity.

However, we noticed that some pairs of vectors representing related concepts (e.g., ‘lady’ and ‘woman’) were located surprisingly far from each other in the Euclidean space, while others were too close. As shown in (Cho et al., 2014), words and phrases which merely belong to the same class of concepts without being exact synonyms have a low distance in Euclidean space (e.g., phrases ‘a few seconds’ and ‘two years’ are grouped together). The representation vectors returned by the RAE do not amend this problem. For this reason, we created an additional module which uses WordNet (Miller, 1995) to enhance our word similarity measures in RAE trees. In Table 1 we show the influence of individual modules.

### 2.1.1 WordNet awards and penalties

The WordNet module adjusts the Euclidean distance between RAE vectors with awards and penal-

ties based on the semantic similarity of pairs of words. We combined the following ideas:

- awarding pairs of words with positive semantic similarity;
- penalizing out-of-context words and disjoint similar concepts;
- propagating scores to higher nodes of the dependency trees.

The concept of semantic similarity reflects the work of (Han et al., 2013), while out-of-context words and disjoint similar concepts reflect the ideas presented in (Han et al., 2015), but there are differences in both implementation and usage.

**Awards.** WordNet is used to extract semantic relations between pairs of nouns, verbs, adjectives and adverbs. Semantic distance  $D$  is measured using the following conditions for two words:

- being equal or first-sense synonyms ( $D(x, y) = 0$ ), e.g. *car auto*;
- sharing common sense with WordNet frequency of at least 5 ( $D(x, y) = 1$ ) e.g. *track chase*;
- being hypernyms or two-link hypernyms (applicable for nouns and verbs) ( $D(x, y) = 2$ ), e.g. *orange citrus*;
- being similar due to satellite synsets (applicable for adjectives and adverbs) ( $D(x, y) = 3$ ), e.g. *soggy waterlogged*;
- sharing any common sense ( $D(x, y) = 3$ ), e.g. *grind mash*;
- being derivationally related ( $D(x, y) = 4$ ), e.g. *rocket missile*;
- being enclosed in the glosses of the other word’s meanings ( $D(x, y) = 5$ ), e.g. *Florida Fla*.

If none of the conditions are met, the semantic distance  $D$  is set to a negative value, which facilitates the counting of an award  $A$  described below. Thus, effectively, the value of  $D$  is an integer such that  $D(x, y) \in \{-1, 0, 1, 2, 3, 4, 5\}$ .

The semantic distance  $D(x, y)$  is transformed to an award  $A$  using the formula  $e^{-\alpha D(x, y)}$  introduced by (Li et al., 2003), where  $\alpha$  is set to 0.25, as this value seemed to yield the best results:

$$A(x, y) = \begin{cases} \beta e^{-\alpha D(x, y)}, & \text{if } D(x, y) \geq 0 \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where  $\beta$  is a positive number (5 by default) used to control the level of adjustment made by the WordNet-related score. If  $\beta = 5$  the maximum score for  $A(x, y)$  is 5. The Euclidean distances of RAE vectors are usually in the range of [0, 10], thus the parameter ensures that the WordNet-related similarity is sufficiently important.

**Penalties.** The out-of-context penalty for word  $x$ ,  $OOC(x)$ , is defined as a penalty for a word not paired in the second input sentence  $SS$  (Han et al., 2015). The word is not paired if its semantic similarity (or award)  $A = 0$  with all the words (referenced below by the index  $i$ ) in the second sentence:

$$OOC(x) = \begin{cases} -1, & \text{if } \sum_i A(x, SS(i)) = 0 \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

We allow three strategies for out-of-context penalization: penalize all recognizable parts of speech (nouns, verbs, adjectives and adverbs), penalize only nouns, penalize only physical objects (i.e. words which have *physical\_object* in their WordNet's hypernyms path). The third option is used by default, since both the original research of (Han et al., 2015) and ours suggest that it usually is the best option (although, in a minority of tests, the penalization of all out-of-context nouns yields better results).

We also penalize disjoint similar concepts. Disjoint similar concepts  $DSC(x, y)$  are defined as 'special care antonyms' or words of disjoint meaning (i.e. *Monday Tuesday*). In our solution they are found using WordNet's hypernyms hierarchy. If two words have a common direct hypernym, they are disjoint similar concepts (e.g. both *Monday* and *Tuesday* have *weekday* as a common hypernym in the WordNet hierarchy). By default, the  $DSC(x, y)$  function returns a penalty of  $-2$  when two words are found to be antonyms or disjoint similar concepts, and 0 otherwise. Thus, the penalty  $P$  for two words  $x$  and  $y$  is:

$$P(x, y) = OOC(x) + OOC(y) + DSC(x, y) \quad (3)$$

A complete framework of WordNet-related awards and penalties is defined by:

$$sim_{WN} = \begin{cases} A(x, y), & \text{if } D(x, y) \geq 0 \\ P(x, y), & \text{if } P(x, y) < 0 \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

**Propagation.** In the Sentence similarity matrices computing module 2.1.2, scores are calculated for all sentence subtrees, while WordNet's awards and penalties are calculated for words. Thus, to use WordNet's scores on all subtrees, the awards and penalties have to be propagated up, until they affect all nodes. To propagate WordNet's scores on a tree containing more than one word, we define a function:

$$sim_{WN}(\text{subtree}) = \sum_{i=1}^n \frac{sim_{WN}(i)}{depth(i)} \quad (5)$$

where  $i$  is an index for a single leaf in the subtree, and  $n$  is the total number of leaves in the subtree.  $sim_{WN}(i)$  is a similarity score for a leaf  $i$ . The scores for particular leaves are divided by their depth  $depth(i)$  relative to the root of the subtree to account for their importance in the more complex trees, and then the scores are summed up at the root. For example, if we have a leaf with a score of 0.75, then this score is added up at the root level with its full weight only if the leaf is a direct child of the root. If it is located deeper in the subtree, the score is divided by this leaf's depth relative to the root of the subtree. The same procedure applies to all the leaves in the current subtree. In Table 1 we compare the efficiency of the WordNet module with and without propagation.

An alternative strategy for incorporating the WordNet scores is to refine the vectors associated with particular leaves and then use these refined vectors to recompute complex tree nodes using RAE. For example, given the WordNet similarity  $\epsilon$  for words 'woman' and 'lady', and the vectors  $A$  for 'woman' and  $B$  for 'lady', the vector  $A$  is refined using the following formula:

$$A_{refined} = \epsilon A + (1 - \epsilon)B. \quad (6)$$

The vector  $B$  stays the same. The tests have proven that the former strategy offers better results, so we decided to stick with it.

**Table 1:** The synergy of all parts of the solution (weighted mean presented).

### 2.1.2 Sentence Similarity Matrices Computing

As a first step in our full algorithm, the RAE computes vectors for every node in the dependency parse tree. Then the subtrees of these trees are used to create the distance matrix. The matrix is created in a number of steps: the trees are traversed in level order, the subtrees are then sorted by depth and the leaves representing stop words are removed<sup>1</sup>. The remaining subtrees are used to construct the distance matrix, which is then filled with Euclidean distance measures  $d$  between each pair of subtrees  $x$  and  $y$ .

$$D_{RAE} = d(x, y) - sim_{WN} \quad (7)$$

The above score is further transformed in two ways: it is made certain that the score value falls within the range 0-5, and that the distance is set to 0 if the WordNet similarity  $sim_{WN}$  has a maximum value:

$$D'_{RAE} = \begin{cases} 0, & \text{if } sim_{WN} = max \\ 0, & \text{if } D_{RAE} < 0 \\ 5, & \text{if } D_{RAE} > 5 \\ D_{RAE}, & \text{otherwise} \end{cases} \quad (8)$$

The original score  $D_{RAE}$  is replaced with the adjusted score  $D'_{RAE}$  in the distance matrix. Finally, we use dynamic pooling module as described in (Socher et al., 2011). The pooling module accounts for the varying lengths of the two trees.

<sup>1</sup>Stop words list contains about 60 most common words in training data set and all punctuation characters.

### 2.1.3 Final RAE-based solution

The final score was produced by Linear Support Vector Regression over cells from the distance matrices after pooling as well as 12 additional features:

- adjustment of roots (the Euclidean distance between WordNet-adjusted tree roots);
- cosine distance between vectors representing tree roots of sentences;
- information about the negation status of the two sentences (if both sentences contain/do not contain negation = true, otherwise = false);
- mean out of context penalty over full tree;
- mean disjoint penalty over full tree;
- mean WordNet similarity score over full tree;
- score from aligner (Section 2.2);
- if both sentences agree on the numbers (true for no numbers or the same numbers; false otherwise);
- if both sentences have the same numbers (binary);
- the absolute difference in tokens between two sentences;
- if the numbers in one sentence contain the numbers from the second sentence (binary);
- the percentage of tokens similarity between two sentences.

A new SVM classifier was created for every test set, since for every test set a different subset of training sets was used<sup>2</sup>. Distance matrices for all classifiers were created and normalized independently.

$$norm_c = 0.4 \left( \frac{\max(\min(\frac{c}{\mu}, 3\sigma), -3\sigma)}{3\sigma} + 1 \right) + 0.1 \quad (9)$$

First the normalization process was used to calculate mean  $\mu$  and standard deviation  $\sigma$  for the matrix, next we performed calculations according to Equation 9 for every cell  $c$  of the matrix. The equation comes from (Socher et al., 2013) and normalizes the values to range [0.1, 0.9].

<sup>2</sup>The training data contains all previous SemEval datasets from 2012 to 2015.

## 2.2 Aligner

As a monolingual word aligner we use two algorithms: a basic aligner and a corrected aligner. Both are based on the aligner described in (Sultan et al., 2014). The basic algorithm performs the following steps for the two sentences: align identical word sequences, align named entities, align content words using dependencies and align content words using surrounding words. Scoring is calculated according to (Sultan et al., 2015):

$$score(S^1, S^2) = \frac{n^a(S^1) + n^a(S^2)}{n(S^1) + n(S^2)},$$

where  $n(S^i)$  and  $n^a(S^i)$  are the number of content words and aligned content words in a sentence  $S^i$ , respectively.

An aligner using only the basic algorithm could not handle negations and antonyms well, so we modified it by adding two modules. The negation module checks whether there is a negation component present in only one sentence, and if so, the module reduces the score to 0. The antonym module verifies whether the two sentences contain at least one pair of antonyms from a list based on the WordNet, and if so, also reduces score to 0.

The corrected aligner is a Linear Support Vector Regression (Drucker et al., 1996) using the following features: the modified basic aligner feature, Bag of Words features inspired by (Han et al., 2015) (element-wise absolute value difference between vectors for words and bigrams, sentences' length

difference, percentage of exact lemma to lemma matches) and additional features used in (Hänig et al., 2015):

- length of the longest common subsequence of characters (some characters may be skipped),
- length of the longest common sequence of characters,
- cosine similarity between vectors of words,
- edit distance between sentences,
- WordNet word overlap (Šarić et al., 2012).

## 2.3 Ensemble

The ensemble classifier was actually a Linear Support Vector Regression over results from the other classifiers used for semantic similarity measurement. Each one of them returned score from 0 up to 5. The following classifiers were chosen for the ensemble approach:

- modified basic aligner, presented in Section 2.2;
- Bi-directional Gated Recurrent Neural Network (Cho et al., 2014; Chung et al., 2014) with the output neural network described in (Tai et al., 2015);
- RAE with WordNet Features, described in Section 2.1;
- corrected aligner, described in Section 2.2

The training data set was split into 75% vs 25%. All classifiers except the aligner (which does not need to be trained) were trained on the 75%. The ensemble classifier was trained on a subset of the remaining data set.

Scores returned by the above classifiers were used as features in the Linear Support Vector Regression. The final result was rescaled to get score from the  $[0, 5]$  range.

## 3 Evaluation

In order to separately train models for each evaluation set, we created reference test sets that are similar to the evaluation sets, e.g. for headlines we used

**Table 3:** The results obtained over three runs in the evaluation period of SemEval 2016.

|                | Answer-answer | Headlines | Plagiarism | Postediting | Question-question | Weighted mean |
|----------------|---------------|-----------|------------|-------------|-------------------|---------------|
| RAE (AE)       | 0.6577        | 0.8180    | 0.8129     | 0.7885      | 0.5867            | 0.7357        |
| Ensemble (EN1) | 0.6924        | 0.8275    | 0.8414     | 0.8352      | 0.6870            | 0.7781        |
| Merged (EN2)   | 0.6924        | 0.8275    | 0.8129     | 0.8352      | 0.5867            | 0.7547        |

**Table 4:** Comparison of our solutions with the 2015 winning system on SemEval 2015 evaluation datasets.

| Run                              | Answers forums | Answers students | Belief | Headlines | Images | Weighted mean |
|----------------------------------|----------------|------------------|--------|-----------|--------|---------------|
| RAE (AE)                         | 0.6836         | 0.7747           | 0.7517 | 0.8363    | 0.8625 | 0.7949        |
| Aligner (with our modifications) | 0.6725         | 0.7715           | 0.7282 | 0.8223    | 0.8478 | 0.7854        |
| BiGRU                            | 0.5424         | 0.5925           | 0.5917 | 0.7947    | 0.8588 | 0.7032        |
| Ensemble (EN1)                   | 0.6489         | 0.7664           | 0.7549 | 0.854     | 0.8884 | 0.8027        |
| Merged (EN2)                     | 0.6836         | 0.7747           | 0.7549 | 0.8540    | 0.8884 | <b>0.8091</b> |
| DLS@CU                           | 0.7390         | 0.7725           | 0.7491 | 0.8250    | 0.8644 | 0.8015        |

30% of headlines 2015; for answer-answer we used 30% of answers-students 2015; for plagiarism 30% of MSRpar 2012 test set; for postediting 30% deft-news 2014 and for question-question 30% of deft-forum 2014. These randomly selected samples that constituted the test sets were removed from the training sets. We used these reference test sets to find the best parameters of our models and chose the best model for run EN2. The final model uses all samples from sets assigned to each evaluation set in Table 2. Our final results are presented in Table 3.

For the AE run, we used RAE with WordNet Features, as described in Section 2.1. For each test, a separate classifier was created with its own training set, as presented in Table 2. The mapping was based on the average number of words per sentence in the set.

For the EN1, run we used the ensemble model described in Section 2.3. In the EN2 model we chose either RAE or ensemble based on the results for test sets matched with evaluation sets.

As shown in Table 3, the ensemble model (EN1) yields better results than RAE (AE) for all sets. Thus, the merged model (EN2) falls between the two.

We also present the results (Table 4) of our solution for SemEval 2015 sets. Comparing them with the best run from SemEval 2015 competition (weighted mean), we concluded that bi-GRU yields

the worst results. Second and third worst results came from the modified aligner and RAE respectively. The ensemble and merged model yield the best results that surpass the performance of the 2015 winning solution.

## 4 Conclusions and Future Work

Our solution combines a vector similarity feature derived from word embeddings without losing the information contained in lexical similarity relations. As it turned out, one of the primary limitations of our paraphrase detection system is its heavy reliance on word order, which makes the solution less universal in its application. The other drawback of converting words to word vectors is being unable to account for situations where the same information is formatted differently (for instance, units of measurement, time expressions, etc.) Thus, our future works include improving our preprocessing module, so that it would produce a unified input, e.g., all numbers written in words will be converted into numerals and all dates will be unified into one format. We will also use specifically designed training modes to prevent overfitting and create a new curriculum learning dataset to make RAE training easier.

## Abstract

In this paper we describe our participation in the STS Core subtask which is the determination of the monolingual semantic similarity between pair of sentences. In our participation we adapted state-of-the-art approaches from related work applied on previous STS Core subtasks and run them on the 2016 data. We investigated the performance of single methods but also the combination of them. Our results show that Convolutional Neural Networks (CNN) are superior to both the Monolingual Word Alignment and the Word2Vec approaches. The combination of all the three methods performs slightly better than using CNN only. Our results also show that the performance of our systems varies between the datasets.

## 1 Introduction

Semantic Textual Similarity (STS) is a metric which aims to determine the likeness between two short textual entities. Therefore, STS is widely used in many research areas such as Natural Language Processing, for a large amount of tasks like Information Retrieval (IR), Natural Language Understanding (NLU) or even Machine Translation (MT) evaluation, for which

STS allows capturing more information than traditional metrics based on  $n$ -grams match like BLEU (Papineni et al., 2002).

Part of the SemEval campaign, STS competition benefits from a growing interest over the year (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirrea et al., 2015). In 2016, participants had the possibility to compete in two tasks: (i) STS split into 'STS Core' and 'Cross-lingual STS' which are respectively an English monolingual and English/Spanish bilingual subtasks; (ii) iSTS which focuses on the interpretable aspect of STS assessment. Introduced for the first time in 2015, iSTS became a standalone task this year.

This paper describes our participation in the STS Core subtask and is organised as follows: we first describe in Section 2 methods we have adapted to tackle the task. Next, we present and discuss our results (Section 3). Finally, Section 4 will conclude this system description paper with some remarks.

## 2 System description

For addressing monolingual semantic similarity between two sentences different methods have been proposed in related work. In our monolingual STS participation we have focused on some methods that were reported as state-of-

the-art systems. Given that those methods have been reported separately a natural question that arises from this is what the performance is when those methods are combined. This is exactly what we did and what we propose in this paper. We adapted methods from related work that have been applied on the monolingual STS task and used their combined version on the new 2016 monolingual task. Methods adapted and the strategy we used to combine them are described in the following sections.

## 2.1 Monolingual Alignment

We use an alignment-based approach, which was among the top-perfoming submissions in the past year’s task (Sultan et al., 2015). Sentence similarity score is computed in two separate steps. First, an alignment between related words in the input sentences is established using Monolingual Word Aligner (MWA) (Sultan et al., 2014). Next, sentence similarity is calculated based on the proportion of aligned content words:

$$sim(S^1, S^2) = \frac{n_c^a(S^1) + n_c^a(S^2)}{n_c(S^1) + n_c(S^2)} \quad (1)$$

where  $n_c(S^i)$  and  $n_c^a(S^i)$  are the number of content words and the number of aligned content words in sentence  $i$ , respectively. MWA makes alignment decisions based on lexical similarity and contextual evidence. Lexical similarity component identifies word pairs that are possible candidates for alignment. Context words are considered as evidence for alignment if they are lexically similar and have the same or equivalent syntactic relations with the words to be aligned. Word pairs are aligned in decreasing order of a weighted sum of their lexical and contextual similarity.

## 2.2 Convolutional Neural Network Score

Another method adapted in our system is a Convolutional Neural Network (CNN), which generates a similarity score for each pair of sen-

tences. More specifically, we replicated the system presented in (He et al., 2015), using previous SemEval data for training the network and generating similarity values between 0 and 5, for each of the test sentences given by the organizers. In the following subsections, we briefly summarize the CNN system, although specific details can be found in the cited paper.

## Word Representation

Words in the sentences to be compared are first transformed into vectors using the GloVe word embeddings (Pennington et al., 2014). These embeddings are trained on 840 billion tokens, and the resulting vectors are 300-dimensional. Hence, each sentence  $sent$  with  $n$  words will be transformed into a matrix  $M_{sent} \in \mathbb{R}^{n \times 300}$ . Hence,  $sent_{i:j}$  denotes the word embeddings of words  $i$  to  $j$  inside the sentence,  $sent_i^{[k]}$  denotes the  $k$ -th dimension of word embedding  $i$  and  $sent_{i:j}^{[k]}$  the  $k$ -th dimension of words  $i$  to  $j$  inside the sentence.

## Sentence modelling

The technique makes use of two different types of filters for extracting features from the sentences: holistic and per-dimension. Holistic filters generate a vector representing a "temporal" convolution, this is, complete regions of the word sequence. On the other hand, per-dimension filters perform spatial convolutions, limited to a predefined dimension  $k$ . After the application of those filters, the last step of the convolutional layer is to perform pooling operations over the vectors generated by the filters, in order to convert those vectors into scalar values. The system defines three types of pooling: *max*, *min* and *mean*. Finally, the system also defines a *group* as a specific convolution layer (with either holistic or per-dimension filters) with width  $ws$  and a specific type of pooling, which operates over a sentence. A set of groups composed by convolution layers with the same width which explore different pooling functions is called a *block*.

## Similarity Measurement Layer

Once that the sentence representation is done through the use of filters and pooling functions, a way to compare two sentences has to be defined. The comparison of two different sentences is made over local regions of the sentence representation. For this purpose, the system consider the output of the convolutional layers in order to perform both “horizontal” and “vertical” comparisons. Given two vectors, each of them representing the same region of an input sentence, a new output vector is created by measuring cosine distance,  $L_2$  Euclidean distance and element-wise absolute difference. This output vector is added to an accumulated vector which stores the outputs of all the compared regions of the input sentences. The final output of the system generates an output similarity score through a final log-softmax layer, which receives the accumulated vector. System parameters (window size, number of filters, learning rate, regularization parameter, hidden units) are maintained with respect to the original work in which the system is presented.

### 2.3 Word2Vec

Word embeddings using Word2vec (Mikolov et al., 2013) have been extensively used to measure the semantic similarity between words. Our word embeddings comprise the vectors published by Baroni et al. (2014). To measure the similarity between a pair of sentences we first remove from each sentence stop-words as well as punctuations, query for each word its vector representation and create a averaged sum of the word vectors. The number of remaining words in each sentence is used to average that sentence. Finally, we use the resulting averaged sum vectors and determine their similarity using cosine.

### 2.4 Model Combination

In this section, we present the experiments to combine all methods described in previous sections. We formulated the problem as a regres-

sion task where we are given multiple features capturing different attributes of inputs along with gold labels and we predict the output for unseen examples. Support Vector Regression (SVR) (Chang and Lin, 2001) is the most commonly used algorithm for such tasks. We used the 3 features described in previous sections and trained SVR models to estimate a continuous score within [0,5]. We evaluated different settings of these models including various available kernels. Based on optimum performance, we used a radial basis function (RBF) kernel, which has been shown to perform very well in quality estimation tasks (Callison-Burch et al., 2012). Kernel parameters are optimised using grid search with 5-fold cross-validation. The correlation scores using SVR as learning algorithm are reported in Table 3. It can be seen that adding all features together improves the results in as compared to the individual scores for each of the methods.

### Application on SemEval Data

The described system has been trained with data from previous Semantic Textual Similarity tasks of SemEval, more specifically data from 2012, 2013, 2014 and 2015. The final training dataset is composed by 13,560 sentence pairs.

## 3 Results

In SemEval STS Core Task the performance of each method (or system) is evaluated using Pearson Correlation that measures the linear correlation between the system’s outputs and gold-standard data. A score of 1 indicates 100% correlation and 0 no correlation at all. Table 3 shows the individual results for methods adapted in this work as well as the result when all methods are combined together as a single system.

We can first observe that the best single performing method is CNN, with an overall achievement of 0.727 correlation score (see last column). The other two approaches achieve

| Method      | answer-answer | headlines | plagiarism   | postediting | question-question | OverALL |
|-------------|---------------|-----------|--------------|-------------|-------------------|---------|
| CNN         | 0.510         | 0.818     | <b>0.834</b> | 0.792       | 0.685             | 0.727   |
| MWA         | 0.436         | 0.704     | <b>0.749</b> | 0.587       | 0.579             | 0.611   |
| Word2vec    | <u>0.276</u>  | 0.642     | <b>0.787</b> | 0.750       | 0.688             | 0.622   |
| Combination | 0.508         | 0.820     | <b>0.838</b> | 0.794       | 0.689             | 0.728   |

**Table 1:** Pearson correlation between the prediction and gold standard data.

substantially lower correlation figures with a drop of about 0.10. Monolingual Word Alignment is the less performing method achieving 0.611, just behind Word2Vec with 0.622. From our results we can also remark that the combined version of all the three methods lead to 0.728 which is similar to the CNN method only.

Secondly, if we look at the results for each dataset individually, we can also remark that the performance of our system drastically change from one to another. While all approaches perform poorly on the answer-answer data, they achieve high correlation scores on the headlines, post-editing and plagiarism data sets. The latter being the data on which our approaches are the most efficient with a minimum of 0.749 correlation.

## 4 Conclusions and further studies

In this paper we described our participation to the STS Core Task for SemEval 2016. We adapted state-of-the-art methods from previous studies applied on the monolingual semantic similarity task and run them on the 2016 data. We investigated the performance of single methods individually but also combined altogether.

Overall, our results show that the CNN-based approach was the most effective compared to the others individual approaches. The combination of those methods achieves slightly better results than CNN only. We can also observe that results vary between the different dataset: they are highly satisfactory on both the headlines and plagiarism dataset, but perform poorly on the answer-answer data, especially Word2Vec with

only 0.276 Pearson Correllation compared to gold-standard.

For the future work we aim to conduct a deeper analysis about the performance of our different systems. This will also include the understanding concerning their effectiveness over on diverse datasets. Finally, we would like to investigate the QuEst framework (Specia et al., 2013) as additional method to describe the semantic similarity between sentences:

### QuEst framework

For our future work we aim to use the QuEst framework (Specia et al., 2013) and extract features to capture the semantic similarity between monolingual sentences. These features are used and have shown to perform well in the WMT shared tasks on QE. They include simple counts, e.g. number of tokens in the segments, language model probabilities and perplexities, number of punctuation marks in source and target segments, among other features reflecting the complexity and fluency of the given segments. Though these features are originally designed to estimate the quality of machine translation, we aim to adapt and explore their potential in addition to the methods discussed in previous sections.

## Abstract

We present a description of the system submitted to the Semantic Textual Similarity (STS) shared task at SemEval 2016. The task is to assess the degree to which two sentences carry the same meaning. We have designed two different methods to automatically compute a similarity score between sentences. The first method combines a variety of semantic similarity measures as features in a machine learning model. In our second approach, we employ training data from the Interpretable Similarity subtask to create a combined word-similarity measure and assess the importance of both aligned and unaligned words. Finally, we combine the two methods into a single hybrid model. Our best-performing run attains a score of 0.7732 on the 2015 STS evaluation data and 0.7488 on the 2016 STS evaluation data.

## 1 Introduction

If you ask a computer if two sentences are identical, it will return an accurate decision in a split-second. Ask it to do the same for a million sentence pairs and it will take a few seconds — far quicker than any human. But similarity has many dimensions. Ask a computer if two sentences mean the same and it will stall, yet the human can answer instantly. Now we have the edge. But what metrics do we use in our personal cognitive similarity-scoring systems? The answer is at the heart of the semantic similarity task. In our solution, we have incorporated several categories of features from a variety of sources. Our approach covers both low-level visual features such

as length and edit-distance as well as high-level semantic features such as topic-models and alignment quality measures.

Throughout our approach, we have found it easier to consider similarity at the lexical level. This is unsurprising, as each lexeme may be seen as a semantic unit with the sentence’s meaning built directly from a specific combination of lexemes. We have explored several methods for abstracting our lexical-level features to the sentence level as explained in Section 4. Our methods are built from both intuitive features as well as the results of error-analyses on our trial runs. We have combined multiple feature sources to build a powerful semantic-similarity classifier, discarding non-performing features as necessary.

## 2 Related Work

The presented system has been submitted to the Semantic Textual Similarity (STS) shared task at SemEval 2016, which has been organised since 2012 (Agirre et al., 2016). Existing approaches to the problem adopt a plethora of similarity measures including string-based, content-based and knowledge-based methods. String-based methods (Bär et al., 2012; Malakasiotis and Androutsopoulos, 2007; Jimenez et al., 2012) exploit surface features (e.g., character n-grams, lemmas) to compute a semantic similarity score between two sentences. Bär et al. (2012) showed that string-based features improve performance when using machine learning. Knowledge-based features (Mihalcea et al., 2006; Gabrilovich and Markovitch, 2007) estimate the semantic similarity of textual units using external

knowledge resources (e.g., WordNet). As an example, Liu et al. (2015) used the shortest path that links two words in the WordNet taxonomy as a similarity measure between words. To calculate a similarity score between sentences, the authors used the sum of the similarity scores of the constituent words. Content-based features are based upon the distributional similarity of words and sentences. Distributional semantics methods (Mikolov et al., 2013; Baroni et al., 2014) encode the lexical context of words into a vector representation. A vector representation of a sentence may be estimated as a function of the vectors of the constituent words (Mitchell and Lapata, 2010). The semantic relatedness between sentences is measured using the cosine of the angle of the composed sentence vectors.

### 3 Feature Sources

We have collected a variety of resources to help us create semantic similarity features. Some of these (Subsections 3.2 and 3.4) give features at the level of the sentence itself. Other resources (Subsections 3.1, 3.3, 3.5, 3.6 and 3.7) give features at the level of the individual words. We explain how we adapt these features to sentence-level metrics in Section 4.

#### 3.1 Distributional semantics

We use a count-based distributional semantics model (Turney and Pantel, 2010) and the Continuous Bag-Of-Words (CBOW) model (Mikolov et al., 2013) to learn word vectors. The training corpus that we used is a combination of all monolingual texts provided by the organiser of the 2014 Machine Translation Shared Task<sup>1</sup>, whose size is about 20 GB. Before training, we tokenised and transferred the corpus into lowercase text. The size of the context window is 5 for both of the models. The numbers of dimensions in the resulting vectors are 150,000 and 300 for the count-based and the CBOW models respectively.

#### 3.2 Machine translation

A pair of input sentences can be considered as the input and output of a machine translation system. Therefore, we can apply machine translation (MT)

metrics to estimate the semantic relatedness of the input pair. Specifically, we used three popular MT metrics: BLEU (Papineni et al., 2002), Translation Edit Rate (TER) (Snover et al., 2006), and METEOR (Denkowski and Lavie, 2014).

#### 3.3 Lexical paraphrase scores

Another promising resource for similarity estimation is the lexical paraphrase database (PPDB) by Ganitkevitch et al. (2013). Each of the word pairs in the PPDB has a set of 31 different features (Ganitkevitch and Callison-Burch, 2014). In this work, we calculate the similarity of a word pair by using the formula that Ganitkevitch and Callison-Burch (2014) recommended to measure paraphrases' quality. However, for word pairs that have been seen very rarely, i.e., their rarity penalty score in PPDB is higher than 0.1, we simply set the similarity score at 0 instead of applying the formula.

#### 3.4 Topic modelling

We induce a topic-based vector representation of sentences by applying the Latent Dirichlet Allocation (LDA) method (Blei et al., 2003). We hypothesise that a varying granularity of vector-representations provide complementary information to the machine learning system. Based upon this, we extract 26 different topic-based vector representations by varying the number of topics; starting from a small number of 5 topics which resulted in a coarse-grained topic-based representation to a larger number of 800 topics which produced a more fine-grained representation. In our experiments, we used the freely available MALLET toolkit (McCallum, 2002). Additionally, we performed hyper-parameter optimisation for every 10 Gibbs sampling iterations and set the total number of iterations to 2,000.

#### 3.5 WordNet

For WordNet-based similarity between a pair of words we have chosen Jiang-Conrath (Jiang and Conrath, 1997) similarity based on an evaluation by Budanitsky and Hirst (2006). To compute the score, we lemmatise the words using Stanford CoreNLP (Manning et al., 2014), find corresponding synsets in Princeton WordNet (Fellbaum, 1998) and obtain the Jiang-Conrath value using the WS4J library<sup>2</sup>.

---

<sup>1</sup><http://www.statmt.org/wmt14/translation-task.html#download>

---

<sup>2</sup><https://code.google.com/archive/p/ws4j/>

### 3.6 Character string

Sometimes semantically related words are very similar as sequences of characters, e.g. *cooperate* and *co-operate* or *recover* and *recovery*. To handle such cases we compute Levenshtein distance (Levenshtein, 1966) between words. To keep the similarity score  $x_l$  in the  $[0, 1]$  range, we adjust the obtained distance  $d$  by computing  $x_l = (l - d)/l$ , where  $l$  denotes the length of the longer word.

### 3.7 Word importance measures

We calculated the combined probability of each word occurring in a given context. We used smoothed unigram and bigram probabilities taken from the Google Web1T data (Brants and Franz, 2006). We multiplied the smoothed unigram probability of a word together with the smoothed bigram probability of both the word itself and the word immediately before it to give the 2-word contextual probability of a word’s appearance. Whilst this model could theoretically be extended to longer sequences, we found that memory resources limited our capacity to a sequence of 2 words.

$$p(w_i|w_{i-1}, w_i) = p(w_{i-1}, w_i) \times p(w_i)$$

We also investigated psycholinguistic properties as measures of word importance. We used the MRC Psycholinguistic norms (Wilson, 1988) to attain values for the ‘familiarity’, ‘imagery’ and ‘concreteness’ of each word. These metrics can be defined as follows:

**Familiarity:** This indicates how likely a word is to be recognised by a user. Words which occur very often such as *cat* are likely to be more familiar than less common words such as *feline*.

**Concreteness:** This indicates whether a reader perceives a word as referring to a physical entity. A conceptual phrase such as *truth* will have a lower value for concreteness than an object which is more easily relatable such as *house* or *man*.

**Imagery:** This metric indicates how easy it is to call-up images associated with a word. This is related to concreteness, but may differ in some

cases. For example, some actions (*jumping*, *flying*) or common emotions (*joy*, *sadness*, *fear*) may have high imagery, but low concreteness.

## 4 Feature Generation

We found that the greatest challenge of the task was to combine different existing word-level relatedness cues into a sentence-level similarity measure. We have submitted three permutations of our system, as allowed by the task. The first system ‘Aggregation (*Macro*)’ passes a set of 36 features through a random forest classifier. The second system ‘Alignment (*Micro*)’ first aligns the sentences using word-level metrics and then calculates 49 features describing this alignment. Our final system ‘*Hybrid*’ is simply the combination of the former two approaches.

### 4.1 Aggregation (Macro)

In this approach feature sources are used separately, each applied as a sentence similarity measure that is further represented as a single feature.

- *Compositional semantic vectors.* A sentence vector is simply calculated by cumulatively adding its component word vectors. The similarity of a sentence pair is then estimated by the cosine of the angle between the corresponding vectors.
- *Average maximum cosine.* Given a sentence pair of  $(s, t)$  whose number of words are  $m$  and  $n$  respectively, the similarity score is calculated as the average of the maximum cosine similarity of word pairs as follows:

$$\text{score}(s, t) = \frac{\sum_{i=1}^m \max_{j=1}^n \cos(\vec{w}_i, \vec{w}_j)}{\max(m, n)}$$

- *MT metrics.* We apply MT metrics at the sentence level. We used smoothed BLEU-4 and TER implemented within Stanford Phrasal<sup>3</sup> while the METEOR score was provided using techniques from Denkowski and Lavie (2014).
- *Paraphrase DB.* To compute sentence similarity using PPDB, we find the most similar counterpart for each of the words and return an average of obtained similarity scores, weighted by word length.

<sup>3</sup><http://nlp.stanford.edu/phrasal/>

- *Topic modelling metric.* Given that each sentence is represented by a topic-based vector, we can compute a similarity score for a sentence pair using the cosine similarity.

This leads to 36 features, each expected to be positively correlated with sentence similarity.

## 4.2 Alignment (Micro)

In this approach we combine different techniques of assessing relatedness to create a single word similarity measure, use it to align compared sentences, and compute features describing a quality of alignment.

### 4.2.1 Word-level similarity

We employ a machine learning model to create a measure of semantic similarity between words. The model uses four measures:

1. adjusted Levenshtein distance  $x_l$ ,
2. word-vector cosine similarity  $x_{wv}$ ,
3. WordNet Jiang-Conrath similarity  $x_{wn}$ ,
4. paraphrase database score  $x_p$ .

Each measure returns values between 0 (no similarity) and 1 (identical words). As a training set, we have used all the data from the previous year's interpretable subtask (Agirre et al., 2015), which includes pairs of chunks with assigned similarity between 0 and 5. As this set contains pairs of chunks, not words, we extended these measures for multi-word arguments. This has been done by (1) using the whole chunk for Levenshtein distance, (2) finding the best pair for WordNet similarity and (3) using solutions for sentence-level aggregation (described in the previous section) for word vectors and paraphrase database.

Negative examples have been created by selecting unaligned pairs and assigning to them a score equal to 0. In that way we obtain 19,673 training cases, from which the following linear regression model has been deduced:

$$y = -0.3285 + 1.3343 \times x_l + 0.8625 \times x_{wv} + 0.9875 \times x_{wn} + 2.1496 \times x_p$$

The coefficients of this model show that the word vectors and WordNet features have a lower influence on the final score output by the model, whereas

the paraphrase database score has a greater influence. Although the final model was trained on all the data from last year's interpretable similarity sub-task, we performed a separate evaluation on this data in which we partitioned the data into train and test subsets. The resulting correlation on the test subset was 0.8964, which we consider to be very reasonable.

### 4.2.2 Finding alignment

Having a universal similarity measure between words, we can compute an alignment of sentences. To do this, we tokenise each sentence and compute similarity value between every pair of words. Then we find an alignment in a greedy way, by pairing free words in order of decreasing similarity of pairs. This process stops when we reach 1 (in a 0-5 scale, see previous section), which usually leaves some of the words unaligned.

### 4.2.3 Features

The features generated in this approach describe the quality of the alignment of a pair of sentences. The simple measures are: mean similarity between aligned pairs, length of aligned parts as a proportion of sentence length (average from two sentences) and a number of crossings in permutation defined by the alignment, i.e. Kendall's tau (Kendall, 1955). Secondly, we also include sums of lengths of aligned and unaligned words with particular tags, using Stanford CoreNLP (Manning et al., 2014) with slightly simplified Brown tagset (19 tags). This follows our intuition that significance of success or failure of alignment of a particular word is different for different parts of speech (e.g. proper nouns vs. determiners). Finally, we measure the importance of matched and unmatched words by their probability (sum of logarithms) and psycholinguistic metrics – familiarity, concreteness and imagery (sum of values). As a result of this process we get 49 features.

## 4.3 Hybrid

The hybrid approach simply combines outputs from the two feature generation solutions described above. This leads to 85 features, some of which may be redundant.

| Feature                   | Impurity decrease |
|---------------------------|-------------------|
| Paraphrase DB score       | 8082.91           |
| METEOR                    | 4611.94           |
| Average max. cosine       | 2262.56           |
| Compositional sem. cosine | 1895.34           |
| LDA (800 topics)          | 967.74            |
| LDA (675 topics)          | 907.32            |
| LDA (600 topics)          | 852.86            |
| Smoothed BLEU             | 753.78            |
| LDA (525 topics)          | 735.61            |
| Translation Edit Rate     | 706.48            |

**Table 1:** Ten most useful variables from the aggregation approach according to random forest importance measure, i.e. mean decrease in residual sum of squares.

## 5 Learning

Each of the three feature sets described above has been used to create a single regression model. For this purpose we explored different methods available in the R environment (R Core Team, 2013): linear regression, decision trees (Breiman et al., 1984), multivariate adaptive regression splines (Friedman, 1991) and generalised additive models (Hastie and Tibshirani, 1990), but internal evaluation has shown that random forests (Breiman, 2001) perform the best in this task. Since the dimensionality of the task is not very high, we have not performed any feature selection, leaving this to the random forests. They offer a useful measure of variable importance, namely the decrease in residual sum of squares averaged over all trees. Tables 1 and 2 show the ten most useful variables for this purpose from the aggregation and alignment approaches, respectively.

## 6 Evaluation

As explained in previous sections, we have used three features sets to create three classification models, called *Macro* (from aggregation-based features), *Micro* (from alignment-based features) and *Hybrid* (including both feature sets). According to the shared task guidelines, the performance has been measured by computing a correlation between predicted and gold standard (assigned by humans) scores in each data set, and then obtaining their average.

We have performed two main experiments.

| Feature                  | Impurity decrease |
|--------------------------|-------------------|
| Alignment ratio          | 9350.65           |
| Prob. of aligned words   | 4809.45           |
| Mean similarity          | 2361.40           |
| Unaligned nouns          | 1691.97           |
| Prob. of unaligned words | 1576.07           |
| Aligned nouns            | 1258.54           |
| Fam. of aligned words    | 1224.19           |
| Im. of aligned words     | 1073.80           |
| Fam. of unaligned words  | 905.14            |
| Con. of unaligned words  | 874.51            |

**Table 2:** Ten most useful variables from the alignment approach according to random forest importance measure, i.e. mean decrease in residual sum of squares (*Prob.* – probability, *Fam.* – familiarity, *Im.* – imagery, *Con.* – concreteness).

Firstly, we have used the data that have been available for training and testing in the 2015 competition (Agirre et al., 2015) to select the best approach. Then, we have created three final models on all available 2015 data and used them to label the test data provided by the organisers of the 2016 task. Table 3 shows the results of both experiments.

## 7 Discussion

What may seem the most surprising in the results is their diversity – some of the methods achieve correlation well over 0.8 for one data set and below 0.6 for another. In our opinion, that not only shows that there is room for improvement but also reveals a fundamental problem in this task, namely that training and test sets come from different sources. The distribution of features also differs. This situation simulates many real-world scenarios, but also impedes any ML-based approach. In this light, our drop in performance between development (2015) and evaluation (2016) sets seems satisfactorily small.

The data sets related to questions and answers have turned out to cause the most difficulties for our system. We have performed a post-hoc error analysis to understand why. We found that these sets expose weaknesses of our reliance on abstracting from word-level similarity to the sentence-level. For example, consider the following two questions: *What is the difference between Erebor and Moria?* and *What is the difference between splicing and superim-*

| Data set          | Features set |        |               |
|-------------------|--------------|--------|---------------|
|                   | Macro        | Micro  | Hybrid        |
| <b>2015</b>       |              |        |               |
| images            | 0.8022       | 0.8129 | 0.8457        |
| headlines         | 0.7963       | 0.8183 | 0.8263        |
| belief            | 0.7107       | 0.7031 | 0.7455        |

**Table 3:** Correlations of predicted and actual similarity scores measured for datasets available in 2015 and 2016 shared task.

position? As you can see, they have the same structure and a lot of identical words, but the two remaining words create a wholly different meaning. This means that our approach, confirmed by the ranking of features (see table 2), deserves further work.

We may be able to boost our performance on the 2016 task by a few simple measures. Firstly, we could include semantic features from a wider variety of sources. Especially for the word-importance metrics. Secondly, we could consider pre-filtering the sentences for a list of stop-words which typically do not contain much semantic importance to a sentence. Finally, we could attempt to weight our word-level measures based on the semantic importance of each word in a sentence. For example, verbs and nouns are probably more important than adjectives and adverbs, which in turn are likely to be more important than conjunctions.

## Abstract

This paper presents our submissions for semantic textual similarity task in SemEval 2016. Based on several traditional features (i.e., string-based, corpus-based, machine translation similarity and alignment metrics), we leverage word embedding from macro (i.e., first get representation of sentence, then measure the similarity of sentence pair) and micro views (i.e., measure the similarity of word pairs separately) to boost performance. Due to the various domains of training data and test data, we adopt three different strategies: 1) U-SEVEN: an unsupervised model, which utilizes seven straight-forward metrics; 2) S1-All: using all available datasets; 3) S2: selecting the most similar training sets for each test set. Results on test sets show that the unified supervised model (i.e., S1-All) achieves the best averaged performance with a mean correlation of 75.07%.

## 1 Introduction

Estimating the degree of semantic similarity between two sentences is the building block of many Natural Language Processing (NLP) applications, such as question answering, textual entailment, text summarization etc. Therefore, Semantic Textual Similarity (STS) has received an increasing amount of attention in recent years, e.g., the STS tasks in Semantic Evaluation Exercises have been held from 2012 to 2016.

To identify semantic similarity of sentence pairs, most existing works adopt at least one of the following feature types: 1) string based similarity (Bär et

al., 2012; Jimenez et al., 2012) which employs common functions to calculate similarities over string sequences extracted from original strings, e.g., lemma, stem, or  $n$ -grams sequences; 2) corpus based similarity (Šarić et al., 2012) where distributional models such as Latent Semantic Analysis (LSA), are used to derive the distributional vectors of words from a large corpus according to their occurrence patterns, afterwards, similarities of sentence pairs are calculated using these vectors; 3) knowledge based method (Agirre et al., 2015b) which estimates the similarities with the aid of external resources, such as WordNet. Among them, Sultan et al. (2015) leverage different word alignment strategies to bring word-level similarity to sentence-level similarity.

Traditional NLP feature engineering often treat sentence as a bag of words or term frequency, and endeavor to evaluate the similarity according to the co-occurrence of words or other replacement words. For example, Zhao et al. (2014) built a supervised model using ensemble of heterogeneous features and achieved great performance on STS Task 2014. However, it is difficult to evaluate semantic relatedness if all the word in both sentences is unique. For example: *A storm will spread snow over Shanghai*; *The earthquakes have shaken parts of Oklahoma*. These sentences have no words in common, although they convey the similar information.

In this work, we first borrow the aforementioned effective types of similarity measurements including string-based, corpus-based, machine translation similarity and alignment measures to capture the semantic similarity between two sentences. Besides, we also present our highly interpretable and

hyper-parameter free word embedding features from macro and micro views to boost the performance. Then we adopt three different strategies of the usage of training data: 1) U-SEVEN: an unsupervised model, which utilizes seven straight-forward metrics (i.e., longest common sequence, alignment feature, corpus-based feature, and others are all from word embedding features); 2) S1-All: use all available datasets and train a unified regression model after deleting unnecessary features; 3) S2: select the most similar training sets for each test set, according to the source of the dataset, average sentence length, and similarity distance (i.e., word mover’s distance, discussed in Section 2.3).

The rest of this paper is organized as follows. Section 2 describes various similarity measurements used in our systems. Section 3 gives the datasets and system setups. Results on training set and test set will show in Section 4 and 5 respectively, and finally conclusion is given in Section 6.

## 2 Semantic Similarity Measurements

Previous excellent work (Zhao et al., 2014; Sultan et al., 2015) have shown great performance for STS tasks. Following their works, we engineer the traditional widely used features for semantic similarity measurements (i.e., string-based, corpus-based, machine translation similarity and alignment measures). In this work, we also present our highly interpretable and hyper-parameter free word embedding features from macro and micro views to boost the performance.

### 2.1 Preprocessing

Several text preprocessing operations are performed before feature engineering: 1) Converting the contractions to their formal writing, e.g., “*doesn’t*” is rewritten as “*does not*”. 2) The WordNet-based Lemmatizer implemented in Natural Language Toolkit<sup>1</sup> is used to lemmatize all words to their nearest based forms in WordNet, e.g., “*was*” is lemmatized to “*be*”. 3) Stanford CoreNLP (Manning et al., 2014) is adopted to get the Part-Of-Speech (POS) tag and Named Entity Recognition (NER) tag.

---

<sup>1</sup><http://www.nltk.org>

## 2.2 Traditional NLP Feature Engineering

### 2.2.1 String-Based Similarity

**Length Features (len):** We record the length information of given sentence pairs using the following eight measure functions:  $|A|$ ,  $|B|$ ,  $|A - B|$ ,  $|B - A|$ ,  $|A \cup B|$ ,  $|A \cap B|$ ,  $\frac{|A - B|}{|B|}$ ,  $\frac{|B - A|}{|A|}$ , where  $|A|$  stands for the number of non-repeated words in sentence  $A$ .

**Syntactic Features (pos):** Since two sentences with similar syntax structure convey similar meaning, we estimate the similarities of syntax structure. We firstly use Stanford CoreNLP toolkit (Manning et al., 2014) to obtain the POS tags of each sentence. Afterwards, we use eight measure functions mentioned in the Length Features on the sets of POS tags to calculate Syntactic Features.

**Longest Common Sequence (lcs):** In consideration of the different length of sentence pairs, we divide the maximum length of the common subsequence of two sentences by the length of the shorter one.

**$n$ -grams Overlap Features ( $n$ -grams):** We obtain  $n$ -grams at three different level (i.e., the original word level, the lemmatized word level and the character level). Then Jaccard similarity is used for calculating the similarity of these  $n$ -grams pairs. In our experiments,  $n = \{1, 2, 3\}$  are used for the word level whereas  $n = \{2, 3, 4\}$  are used for the character level.

**Named Entities Features (ner):** Besides of the surface similarities between words, we also calculate the relatedness of named entities in two sentences using *lcs* function. Seven types of named entities (i.e., *location*, *organization*, *data*, *money*, *person*, *time*, *percent*), recognized by Stanford CoreNLP toolkit (Manning et al., 2014), are considered.

### 2.2.2 Machine Translation Similarity

Machine Translation (MT) evaluation metrics are designed to assess whether the output of a MT system is semantically equivalent to a set of reference translations. The two given sentences are viewed as one input and one output of a MT system, then we get two MT scores of each MT measure (i.e., *WER*, *TER*, *PER*, *NIST*, *ROUGE-L*, *GTM-1*). Two strategies is employed to get MT similarity features, 1).

average two MT scores in each MT measure; 2). concatenate two MT scores in each MT measure.

### 2.2.3 Corpus-based Features

**WordNet Rank Features (wordnet):** The above semantic similarities only consider the surface similarities rather than their relations in corpus. Hence, we use graph-based lexical relatedness, which performs with a pre-existing Knowledge Base (KB) (i.e., WordNet), to get the relations of words. Then Personalized PageRank is applied on the Lexical Knowledge Base (LKB) to rank the vertices of the LKB. The details of the method are described in Agirre et al. (2015b). It outputs a ranking vector of the sentence over KB nodes and the values of the weights are normalized so that all link weights of particular headword sum to one. Finally, we calculate the Cosine, Manhattan, Euclidean, Jaccard of the two sentence vectors.

**Vector Space Sentence Similarity (lsa):** This measure is motivated by the idea of compositionality of distributional vector (Mitchell and Lapata, 2008). we adopt two distributional word sets released by TakeLab (Šarić et al., 2012), where Latent Semantic Analysis (LSA) was performed on the New York Times Annotated Corpus (NYT)<sup>2</sup> and Wikipedia. Then two strategies are used to convert the distributional meaning of words to sentence level: 1). simply summing up. 2). using  $tf$  to weigh each word vector.

### 2.2.4 Alignment Measures

(Sultan et al., 2015) used delicate word aligner to compute proportion of aligned words across the two input sentences. It aligned words based on their semantic similarity in the two sentences, as well as the similarity between local semantic contexts, which relies on dependencies and surface-form neighbors. The paraphrase Database (PPDB) (Ganitkevitch et al., 2013) was used to identify semantically similar words. Word pairs are aligned with greedy strategy, in descending order of their similarity.

**Global Alignment Features (global):** Given sentences  $S_1$  and  $S_2$ , single proportion over all words is computed over all words:

$$sim(S_1, S_2) = \frac{n_a(S_1) + n_a(S_2)}{n(S_1) + n(S_2)} \quad (1)$$

<sup>2</sup><https://catalog.ldc.upenn.edu/LDC2008T19>

where  $n(S_i)$  is the number of non-repeated words in  $S_i$ , while  $n_a(S_i)$  is the number of aligned content words in  $S_i$ .

### Specific Alignment Features (pos-specific):

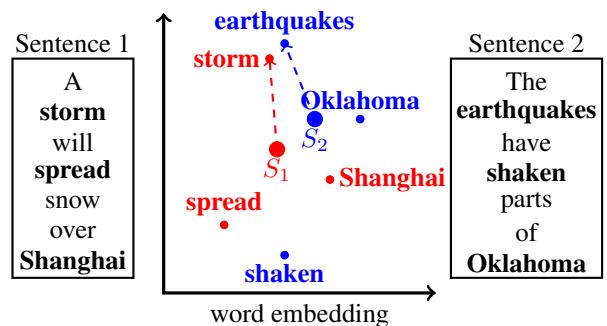

Taking weight of POS tag of aligned words into consideration, score of aligned *noun* word pair is surely higher than the *adjective*. Using this property, we propose the specific alignment feature, to calculate the aligned words proportion specifically according to POS tag (i.e., noun, verb, adjective, adverb).

## 2.3 Word Embedding Feature Engineering

Recently, the distributed representations of words (i.e., word embedding) learned by neural networks over a large raw corpus have been shown that they performed significantly better than Latent Semantic Analysis for preserving linear regularities among words (Mikolov et al., 2013). The training on very large datasets allows the model to learn complex word relationships such as  $vec(Berlin) - vec(Germany) + vec(France) \approx vec(Paris)$  (Mikolov et al., 2013).

As discussed in Section 1, it is very hard to evaluate semantic similarity if no words in the sentence pair in common. Obviously, word embedding features supply the gap. For example, *A storm will spread snow over Shanghai; The earthquakes have shaken parts of Oklahoma.* while *storm* is similar to *earthquake* and *spread* is analogous to *shaken*, *Shanghai* and *Oklahoma* both are locations.

In order to evaluate semantic similarity of a sentence pair, we define the function *INFO* is the semantic information of a word or a sentence carried.

**Figure 1:** An illustration of the word centroid distance. Points in red is the word from sentence 1 (stopwords is ignored), while blue from sentence 2.  $S_i$  is the centroid of points from sentence i.

Thus the semantic similarity of sentence pair can be regarded as the distance between their *INFOs*. In other words, given sentence  $S_1$  and  $S_2$ ,

$$sts(S_1, S_2) = INFO(S_1) - INFO(S_2) \quad (2)$$

where  $INFO(S_i)$  is the semantic information of sentence  $S_i$ . We study the above formula from macro and micro views.

*Macro Information Distance*: From macro view, we first get the *INFO* of each sentence (i.e., semantic information), and then calculate the distance between them. As follows:

$$sts(S_1, S_2) = \text{INFO} \left( f(w_1^{S_1}, w_2^{S_1}, \dots, w_{\text{len}(S_1)}^{S_1}) \right) - \text{INFO} \left( f(w_1^{S_2}, w_2^{S_2}, \dots, w_{\text{len}(S_2)}^{S_2}) \right) \quad (3)$$

where  $w_i^{S_j}$  is the word embedding of word  $i$  in sentence  $j$  and function  $f$  is to obtain the sentence representation from word embeddings, such as sum, average or convolution. Assuming that if two sentences are similar, one word in a sentence should have the similar meaning word with another, we use the centroid of word embedding to symbolise the macro *INFO* of the sentence. As showed in Figure 1,  $S_i$  represents for sentence  $i$ , and the distance between  $S_1$  and  $S_2$  represents for the similarity of the sentence pair. What is more, *storm* and *earthquakes* are the most important word in the sentence pair, we surely should give them more weight. As they are similar, the distance centroid tend to be close (the dashed lines). We use *idf* from datasets to weigh the importance.

*Micro Information Distance:* As for micro view, we first get the *INFO* of each word, and evaluate the distance between the sentence pair according to the

*INFO* of words. The formula is described as Equation 4.

$$\begin{aligned} sts(S_1, S_2) = & INFO(w_1^{S_1}) + INFO(w_2^{S_1}) + \dots + INFO(w_{len(S_1)}^{S_1}) \\ & - INFO(w_1^{S_2}) - INFO(w_2^{S_2}) - \dots - INFO(w_{len(S_2)}^{S_2}) \end{aligned} \quad (4)$$

Our goal is to incorporate the semantic similarity between each word pairs into the micro information distance of sentence. Here, we adopted word mover’s distance (Kusner et al., 2015), the minimum cumulative distance that all word in sentence 1 need to travel to exactly match sentence 2, showed in Figure 2. For more details, see Kusner et al. (2015).

**Word Embedding Features:** Zhao et al. (2014) shows that heterogenous feature outperform a single feature, and we use three embeddings (Turian et al., 2010; Mikolov et al., 2013; Pennington et al., 2014) as our initial word vector input. Incidentally, the distance is substitutable, and we replace it with different measurements (i.e., *cosine distance*, *Manhattan distance*, *Euclidean distance*, *Pearson coefficient*, *Spearman coefficient*, *Kendall tau coefficient*). Specially, because of the high time complexity of word mover’s distance, we only train it on *word2vec* (Mikolov et al., 2013), although other embeddings are also plausible.

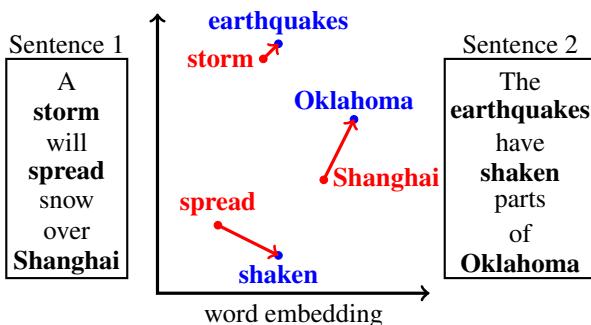

### 3 Experiments

### 3.1 Datasets

We collect all the datasets from 2012 to 2015 as training data. Each dataset consists of a number of sentence pairs and each pair has a human-assigned similarity score in the range [0,5] which increases with similarity. The datasets are collected from different but related domains. We briefly describe data in Table 1, Refer Agirre et al. (2015a) for details. We emphasize dataset with symbol \* for that this dataset appears both in training and test sets, which is very useful to our third submission **S2** (see Section 3.4 for more details).

### **3.2 Evaluation Measurement**

In order to evaluate the performance of different algorithms, we adopt the official evaluation measure, i.e, Pearson correlation coefficient for each individual test set, and a weighted sum of all correlations is used as final evaluation metric. It weights according to the number of gold sentence pairs. The weight of

a test set is equal to the rate of the gold sentences pairs in all the gold sentences.

### 3.3 Learning Algorithm

We conduct a series of experiments using all features discussed in Section 2.2 and 2.3 to obtain the optimized learning algorithm. Three supervised learning methods are explored: Support Vector Regression (SVR), Random Forest (RF) and Gradient Boosting (GB). These supervised learning algorithms are implemented using scikit-learn toolkit (Buitinck et al., 2013). we use all the datasets from STS Task 2015 as development data while others from STS Task 2012 to 2014 as training data.

To configure the parameters in the regression algorithm, i.e., the trade-off parameter  $c$  in SVR, the number of trees  $n_{RF}$  in RF and the number of boosting stages  $n_{GB}$  in GB, we make a grid search for  $c$  in  $[0.01, 0.1, 1, 10]$ ,  $n_{RF}$  from 5 to 100 with step 5 and  $n_{GB}$  from 10 to 300 with step 10.

| RF( $n=40$ )  | 0.7466        | 0.7100           | 0.8200        | 0.8534        | 0.7398         | 0.7816        |
| GB( $n=140$ ) | <b>0.7655</b> | 0.7484           | <b>0.8439</b> | <b>0.8791</b> | <b>0.7469</b>  | <b>0.8080</b> |

**Table 2:** Pearson coefficient of development data using different algorithms with different hyperparameter, as well as top rank results on STS 2015 test data.

Table 2 shows the best result of each algorithm, as well as the top runs on STS 2015 test data. GB( $n=140$ ) outperformed other algorithms on all datasets. We choose GB( $n=140$ ) as our final regression algorithm on our next series experiments. Al-

so, without any specific training dataset selections or choosing suitable features, we achieve the considerable results compare to the top runs on STS 2015 Task. Sultan et al. (2015) has shown that specific training datasets with similar domains and enough data will yield better results than an all-inclusive training datasets. And next we endeavor to select specific training sets and suitable features.

### 3.4 System Setups

We build three different systems according to the usage of training datasets as follows.

**U-SEVEN:** This is an unsupervised system based on the word aligner described in (Sultan et al., 2015) without any training data. We evaluate semantic similarity by adopting straight-forward measurements (i.e., longest common sequence, alignment feature, corpus-based feature, all four features from word embedding features), which are averaged to get the final score. We adopt *cosine distance*, *Pearson coefficient*, *Spearman coefficient* as the distance measurements, which perform better results on our preliminary experiments.

**S1-All:** We use all the training datasets and build a single global regression model regardless of domain information of different test datasets. In order to make better use of these features and improve the performance, we construct feature selection procedure on development set (i.e., test set of STS 2015 Task) and vote for the preserved feature sets. As for feature selection strategy, we adopt *hill climbing*: keep adding one type feature at a time until no further improvement can be achieved.

**S2:** Sultan et al. (2015) has shown that taking all the training datasets into consideration may hurt the performance since training and test sets are from different domains. Hence, for each test set, we select the datasets which are most similar, taking source, average length of sentences and word mover’s distance (discussed in Section 2.3) into consideration. For the data set with symbol \* (i.e., *headlines*), we use all *headlines* pairs. For *answers-answers* and *question-question*, we use *belief*, *deft-forums*, *answers-students*, *answers-forums* pairs. For postediting, we use *SMTeuroparl* and *MSRpar* pairs. For plagiarism, we use *onWN* and *FNWN* pairs.

## 4 Results on Training Data

According to the above preliminary experimental results, we employ GB( $n=140$ ) algorithm as our final regression algorithm. In order to explore the influences of word embedding features and make better use of all the above features, we construct feature selection experiment on development set (i.e., test set of STS 2015 Task) and vote for the preserved feature sets.

| Feature                | belief          | answers -students | headlines     | image         | answers -forums |
|------------------------|-----------------|-------------------|---------------|---------------|-----------------|
| String-based           | len             | -                 | ✓             | ✓             | -               |
|                        | pos             | -                 | ✓             | -             | ✓               |

|                        | glove           | -                 | -             | -             | -               |
|                        | turian's        | ✓                 | ✓             | ✓             | -               |
| Word Embedding (Micro) | wmd             | ✓                 | ✓             | ✓             | ✓               |
| Our Results            | <b>0.7835</b>   | 0.7713            | <b>0.8455</b> | <b>0.8808</b> | <b>0.7636</b>   |
| Best Scores            | 0.7717          | <b>0.7879</b>     | 0.8417        | 0.8713        | 0.7390          |

**Table 3:** Results of feature selection experiments on STS 2015 test data. The last row shows the the best scores of all submitted system on STS 2015 task.

Table 3 shows the results of feature selection experiments on STS 2015 test data. From the table, we find that 1) Word embedding features, the positive complementary of macro perspective and micro perspective, indeed improve results. 2) Specific alignment features can compensate for the weaknesses of global alignment features. 3) Since concatenate MT metrics and glove features does not perform well on all five data sets, we remove them from our feature sets and train our S1-All model with the preserved features.

## 5 Results on Test Data

Table 4 summarizes the results of our submitted runs on test datasets officially released by the organizers, as well as the top runs. In terms of weighted mean of Pearson measurement, system S1-All performs the best while our corpus-specific system **S2** performs the worst. We think the measurement to choose training data from the candidate datesets in main task are ill-suited. It is noteworthy that on plagiarism and postediting, our unsupervised model U-

SEVEN achieves much better results than the supervised model (i.e., S1-All, S2), which indicates the efficiency of the ensemble of similar measurements.

| Dataset           | Runs          |               |               | Best Score |
|-------------------|---------------|---------------|---------------|------------|
|                   | U-SEVEN       | S1-All        | S2            |            |
| answers-answers   | 0.4774        | 0.5697        | <b>0.5715</b> | 0.6923     |
| plagiarism        | <b>0.8301</b> | 0.8250        | 0.7733        | 0.8413     |
| headlines         | 0.7668        | <b>0.8121</b> | 0.7903        | 0.8274     |
| postediting       | <b>0.8423</b> | 0.8234        | 0.7496        | 0.8669     |
| question-question | 0.7191        | <b>0.7311</b> | 0.6763        | 0.7470     |
| weighted mean     | 0.7242        | <b>0.7507</b> | 0.7116        | 0.7780     |

**Table 4:** The results of our three runs on STS 2016 test datasets. The rightmost column shows the best score by any system. The last row shows the value of the officially evaluation metric.

On *answer-answer* set, the gap between top systems and our systems is about 12%. According to our investigations on this set, we find that certain sentence pairs are similar in syntactical structure but express different meanings. For example,

$$\left\{ \begin{array}{l} \text{You should do it.} \\ \text{You can do it, too.} \end{array} \right. \quad \left\{ \begin{array}{l} \text{It's pretty much up to you.} \\ \text{It's much better to ask.} \end{array} \right.$$

Our assumption (i.e., two sentences with similar syntax structure convey similar meaning) does not apply to the above condition.

## 6 Conclusion

We use the traditional NLP features including string-based features, corpus-based features and alignment features for textual similarity estimation, as well as efficient word embedding features. It is also worth pointing out that our word embedding features are highly interpretable and hyper-parameter free, as well as they are straight-forward to measure semantic textual similarity. The difference between top system and our best system is about 2.8%, which means our systems are promising. Noticing the gap between top system and our systems on *answer-answer* set, we will explore to find the central words of sentences in future work.

## Abstract

This paper describes the SAARSHEFF systems that participated in the English Semantic Textual Similarity (STS) task in SemEval-2016. We extend the work on using machine translation (MT) metrics in the STS task by automatically annotating the STS datasets with a variety of MT scores for each pair of text snippets in the STS datasets. We trained our systems using boosted tree ensembles and achieved competitive results that outperforms the median Pearson correlation scores from all participating systems.

## 1 Introduction

Semantic Textual Similarity (STS) is the task of measuring the degree to which two texts have the same meaning (Agirre et al., 2014). For instance, given the two texts, “*the man is slicing the tape from the box.*” and “*a man is cutting open a box.*”, an STS system predicts a real number similarity score on a scale of 0 (no relation) to 5 (semantic equivalence).

This paper presents a collaborative submission between Saarland University and University of Sheffield to the STS English shared task at SemEval-2016. We have submitted three supervised models that predict the similarity scores for the STS task using Machine Translation (MT) evaluation metrics as regression features.

## 2 Related Work

Previous approaches have applied MT evaluation metrics for the STS task with progressively improv-

ing results (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015).

At the pilot English STS-2012 task, Rios et al. (2012) trained a Support Vector Regressor using the lexical overlaps between the surface strings, named entities and semantic role labels and the BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005; Denkowski and Lavie, 2010) scores between the text snippets and their best system scored a Pearson correlation mean of 0.3825. The system underperformed compared to the organizers’ baseline system<sup>1</sup> which scored 0.4356.

For the English STS-2013 task, Barrón-Cedeño et al. (2013) also used a Support Vector Regressor with an larger array of machine translation metrics (BLEU, METEOR, ROUGE (Lin and Och, 2004), NIST (Doddington, 2002), TER (Snover et al., 2006)) with measures that compute similarities of dependency and constituency parses (Liu and Gildea, 2005) and semantic roles, discourse representation and explicit semantic analysis (Gabrilovich and Markovitch, 2007) annotations of the text snippets. These similarity measures are packaged in the Asiya toolkit (Giménez and Márquez, 2010). They scored 0.4037 mean score and performed better than the Takelab baseline (Šarić et al., 2012) at 0.3639.

At the SemEval-2014 Cross-level Semantic Similarity task (Jurgens et al., 2014; Jurgens et al., 2015), participating teams submitted similarity scores for text of different granularity. Huang and Chang (2014) used a linear regressor solely with MT eval-

<sup>1</sup>Refers to the token cosine baseline system (baseline-tokencos) in STS-2012.

ation metrics (BLEU, METEOR, ROUGE) to compute the similarity scores between paragraphs and sentences. They scored 0.792 beating the lowest common substring baseline which scored 0.613.

In the SemEval-2015 English STS and Twitter similarity tasks, Bertero and Fung (2015) trained a neural network classifier using (i) lexical similarity features based on WordNet (Miller, 1995), (ii) neural auto-encoders (Socher et al., 2011), syntactic features based on parse tree edit distance (Zhang and Shasha, 1989; Wan et al., 2006) and (iii) MT evaluation metrics, viz. BLEU, TER, SEPIA (Habash and Elkholy, 2008), BADGER (Parker, 2008) and MEANT (Lo et al., 2012).

For the classic English STS task in SemEval-2015, Tan et al. (2015) used a range of MT evaluation metrics based on lexical (surface  $n$ -gram overlaps), syntactic (shallow parsing similarity) and semantic features (METEOR variants) to train a Bayesian ridge regressor. Their best system achieved 0.7275 mean Pearson correlation outperforming the `token-cos` baseline which scored 0.5871 while the top system (Sultan et al., 2015) achieved 0.8015.

Another notable mention of MT technology in the STS tasks is the use of referential translation machines to predict and derive features instead of using MT evaluation metrics (Biçici and van Genabith, 2013; Biçici and Way, 2014; Bicici, 2015).

### 3 Approach

Following the success of systems that use MT evaluation metrics, we train three regression models using an array of MT metrics based on lexical, syntactic and semantic features.

#### 3.1 Feature Matrix

Machine translation evaluation metrics utilize various degrees of lexical, syntactic and semantic information. Each metric considers several features that compute the translation quality by comparing a translation against one or several reference translations.

We trained our system using the follow feature sets: (i)  $n$ -gram, shallow parsing and named entity overlaps (Asiya), (ii) BEER, (iii) METEOR and (iv) ReVal.

#### 3.1.1 Asiya Features

Gonzàlez et al. (2014) introduced a range of language independent metrics relying on  $n$ -gram overlaps similar to the modified  $n$ -gram precisions of the BLEU metric (Papineni et al., 2002). Different from BLEU, Gonzàlez et al. (2014) computes  $n$ -gram overlaps using similarity coefficients instead of proportions. We use the Asiya toolkit (Giménez and Márquez, 2010) to annotate the dataset with the similarity coefficients of  $n$ -gram overlap features described in this section.

We use 16 features from both cosine similarity and Jaccard Index coefficients of the character-level and token-level  $n$ -grams from the order of bigrams to 5-grams. Additionally, we use the Jaccard similarity of the pseudo-cognates and the ratio of  $n$ -gram length as the 17th and 18th features.

Adding a syntactic dimension to our feature set, we use 52 shallow parsing features described in (Tan et al., 2015); they measure the similarity coefficients from the  $n$ -gram overlaps of the lexicalized shallow parsing (aka chunking) annotations. As for semantics, we use 44 similarity coefficients from Named Entity (NE) annotation overlaps between two texts.

After some feature analysis, we found that 22 out of the 44 NE  $n$ -gram overlap features and 1 of the shallow parsing features have extremely low variance across all sentence pairs in the training data. We removed these features before training our models.

#### 3.1.2 BEER Features

Stanojevic and Simaan (2014) presents an MT evaluation metric that uses character  $n$ -gram overlaps, the Kendall tau distance of the monotonic word order (Isozaki et al., 2010; Birch and Osborne, 2010) and abstract ordering patterns from tree factorization of permutations (Zhang and Gildea, 2007).

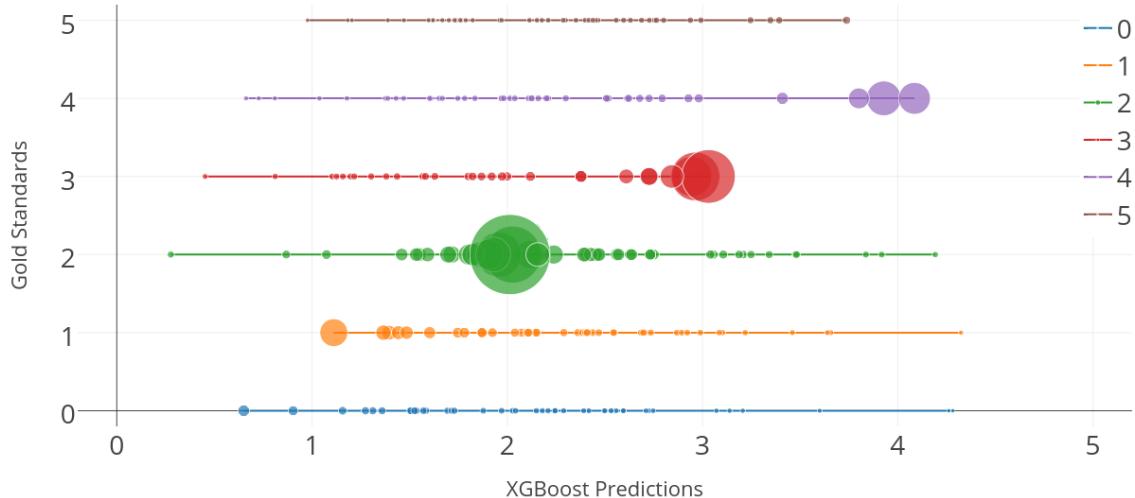

While Asiya features are agnostic to word classes, BEER differentiates between function words and non-function words when calculating its adequacy features.

#### 3.1.3 METEOR Features

METEOR first aligns the translation to its reference, then it uses the unigram mapping to see whether they match based on their surface forms,

|         | answer-answer  | headlines      | plagiarism     | postediting    | question-question | All            |
|---------|----------------|----------------|----------------|----------------|-------------------|----------------|
| Linear  | 0.31539        | 0.76551        | 0.82063        | 0.83329        | 0.73987           | 0.68923        |
| Boosted | 0.37717        | 0.77183        | 0.81529        | 0.84528        | 0.66825           | 0.69259        |
| XGBoost | <b>0.47716</b> | <b>0.78848</b> | <b>0.83212</b> | <b>0.84960</b> | <b>0.69815</b>    | <b>0.72693</b> |
| Median  | 0.48018        | 0.76439        | 0.78949        | 0.81241        | 0.57140           | 0.68923        |
| Best    | 0.69235        | 0.82749        | 0.84138        | 0.86690        | 0.74705           | 0.77807        |

**Table 1:** Pearson Correlation Results for English STS Task at SemEval-2016

**Figure 1:** L1 Error Analysis on the answer-answer domain

word stems, synonyms and paraphrases (Banerjee and Lavie, 2005; Denkowski and Lavie, 2010).

Similar to BEER features, METEOR makes a distinction between content words and function words and its recall mechanism weights them differently. We use all four variants of METEOR: exact, stem, synonym and paraphrase.

### 3.1.4 ReVal Features

ReVal (Gupta et al., 2015) is a deep neural net based metric which uses the cosine similarity score between the Tree-based Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997; Cho et al., 2014; Tai et al., 2015) dense vector space representations of two sentences.

## 3.2 Models

We annotated the STS 2012 to 2015 datasets with the features as described in Section 3.1 and submitted three models to the SemEval-2016 English STS Task using (i) a linear regressor (Linear), (ii) boosted tree regressor (Boosted) (Friedman, 2001) and (iii) eXtreme Gradient Boosted tree re-

gressor (XGBoost) (Chen and He, 2015; Chen and Guestrin, 2015). They were trained using all features described in Section 3.

We have released the MT metrics annotations of the STS data and implementation of systems on <https://github.com/alvations/stasis/blob/master/notebooks/ARMOR.ipynb>

## 4 Results

Table 1 presents the official results for our submissions to the English STS task. The bottom part of the table presents the median and the best correlation results across all participating teams for the respective domains.

Our baseline linear model outperforms the median scores for all domains except the *answer-answer* domain. Our boosted tree model performs better than the linear model and the extreme gradient boosted tree model performs the best of the three. We note that our correlation scores for all three models is lower than the median for the *answer-answer* domain.

Figure 1 shows the bubble chart of the L1 error analysis of our XGBoost model against the gold standard similarity scores for the answer-answer domain. The colored lines correspond to the integer annotations, e.g. the yellow line represents the data points where the gold-standard annotations are 1.0. The span of the line represents the span of predictions our model made for these texts. The size of the bubble represents the effect size of our predictions’ contribution to the Pearson correlation score, i.e. how close our predictions are to the gold standards.

## 5 Discussion

As we see from Figure 1, the centroids of the bubbles represents our model’s best predictions. Our predictions for texts that are annotated at 1 to 4 similarity scores are reasonably close to the gold standards but the model performs poorly for texts annotated with the 0 and 5 similarity scores.

Looking at the texts that are rated 0, we see that there are cases where the *n*-grams within these texts are lexically / syntactically similar but the meaning of the texts are disparate. For example, this pair of text snippets, ‘*You don’t have to know*’ and ‘*You don’t have equipments/facilities*’ are rated 0 in the gold standards but from a machine translation perspective, a translator would have to do little work to change ‘*to know*’ to ‘*equipments/facilities*’.

Because of this, machine translation metrics would rate the texts as being similar and even suitable for post-editing. However, the STS task focuses only on the meaning of the text which corresponds more to the adequacy aspect of the machine translation metrics. Semantic adequacy is often overlooked in machine translation because our mass reliance on BLEU scores to measure the goodness of translation with little considerations for penalizing semantic divergence between the translation and its reference.

On the other end of the spectrum, machine translation metrics remain skeptical when text snippets are annotated with a score of 5 for being semantically analogous but syntactically the texts are expressed in a different form. For example, given the text snippets, ‘*There’s not a lot you can do about that*’ and ‘*I’m afraid there’s not really a lot you can do*’, most machine translation metrics will not al-

locate full similarity scores due to the difference in lexical and stylistic ways in which the sentences are expressed.

Machine translation metrics’ failure to capture similarity score extremes is evident in Figure 1 where there are no 0 and 5.0 predictions.

## 6 Conclusion

In this paper, we have described our submission to the English STS task for SemEval-2016. We have annotated the STS2012-2016 datasets with machine translation (MT) evaluation metric scores and trained a baseline linear regression and two tree ensemble models with the annotated data and achieved competitive results compared to the median pearson correlation scores from all participating systems.

## Acknowledgments

## Abstract

This paper describes the WOLVESAAR systems that participated in the English Semantic Textual Similarity (STS) task in SemEval-2016. We replicated the top systems from the last two editions of the STS task and extended the model using GloVe word embeddings and dense vector space LSTM based sentence representations. We compared the difference in performance of the replicated system and the extended variants. Our variants to the replicated system show improved correlation scores and all of our submissions outperform the median scores from all participating systems.

## 1 Introduction

Semantic Textual Similarity (STS) is the task of assigning a real number score to quantify the semantic likeness of two text snippets. Similarity measures play a crucial role in various areas of text processing and translation technologies ranging from improving information retrieval rankings (Lin and Hovy, 2003; Corley and Mihalcea, 2005) and text summarization to machine translation evaluation and enhancing matches in translation memory and terminologies (Resnik and others, 1999; Ma et al., 2011; Banchs et al., 2015; Vela and Tan, 2015).

The annual SemEval STS task (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015) provides a platform where systems are evaluated on the same data and evaluation criteria.

## 2 DLS System from STS 2014 and 2015

For the past two editions of the STS task, the top performing submissions are from the DLS@CU team (Sultan et al., 2014b; Sultan et al., 2015).

Their STS2014 submission is based on the proportion of overlapping content words between the two sentences treating semantic similarity as a monotonically increasing function of the degree to which two sentences contain semantically similar units and these units occur in similar semantic contexts (Sultan et al., 2014b). Essentially, their semantic metric is based on the proportion of aligned content words between two sentences, formally defined as:

$$prop_{Al}^{(1)} = \frac{|\{i : [\exists j : (i, j) \in Al] \text{ and } w_i^{(1)} \in C\}|}{|\{i : w_i^{(1)} \in C\}|} \quad (1)$$

where  $prop_{Al}^{(1)}$  is the monotonic proportion of the semantic unit alignment from a set of alignments  $Al$  that maps the positions of the words  $(i, j)$  between sentences  $S^{(1)}$  and  $S^{(2)}$ , given that the aligned units belong to a set of content words,  $C$ . Since the proportion is monotonic, the equation above only provides the proportion of semantic unit alignments for  $S^{(1)}$ . The  $Al$  alignments pairs are automatically annotated by a monolingual word aligner (Sultan et al., 2014a) that uses word similarity measures based on contextual evidence from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) and syntactic dependencies.

The same computation needs to be made for  $S^{(2)}$ . An easier formulation of the equation without the formal logic symbols is:

$$prop_{Al}^{(1)} = \frac{\sum(1 \text{ for } w_i, w_j \text{ in } Al^{(1,2)} \text{ if } w_i \text{ in } C)}{\sum(1 \text{ for } w_i \text{ in } S^{(1)} \text{ if } w_i \text{ in } C)} \quad (2)$$

Since the semantic similarity between  $(S^{(1)}, S^{(2)})$  should be a single real number, Sultan et al. (2014b) combined the proportions using harmonic mean:

$$sim(S^{(1)}, S^{(2)}) = \frac{2 * prop_{Al}^{(1)} * prop_{Al}^{(2)}}{prop_{Al}^{(1)} + prop_{Al}^{(2)}} \quad (3)$$

Instead of simply using the alignment proportions, Sultan et al. (2015) extended their hypothesis by leveraging pre-trained neural net embeddings (Baroni et al., 2014). They posited that the semantics of the sentence can be captured by the centroid of its content words<sup>1</sup> computed by the element-wise sum of the content word embeddings normalized by the number of content words in the sentence. Together with the similarity scores from Equation 3 and the cosine similarity between two sentence embeddings, they trained a Bayesian ridge regressor to learn the similarity scores between text snippets.

### 3 Our Replica of DLS for STS 2016

To replicate the success of Sultan et al. (2014b), we use the monolingual word aligner from Sultan et al. (2014a) to annotate the STS-2012 to STS-2015 datasets and computed the alignment proportions as in Equation 1 and 2.

In duplicating Sultan et al. (2015) work, we first have to tokenize and lemmatize text. The details of pre-processing choices was undocumented in their paper, thus we lemmatized the datasets with the NLTK tokenizer (Bird et al., 2009) and PyWSD lemmatizer (Tan, 2014). We use the lemmas to retrieve the word embeddings from the COMPOSES vector space (Baroni et al., 2014). Similar to Equation 2 (changing only the numerator), we sum the sentence embedding's centroid as follows:

$$v(S^{(1)}) = \frac{\sum(v(w_i) \text{ for } w_i \text{ in } S^{(1)} \text{ if } w_i \text{ in } C)}{\sum(1 \text{ for } w_i \text{ in } S^{(1)} \text{ if } w_i \text{ in } C)} \quad (4)$$

---

<sup>1</sup>In the implementation, they have used lemmas instead of words to reduce sparsity when looking up the pre-trained embeddings (personal communication with Arafat Sultan).

where  $v(S^{(1)})$  refers to the dense vector space representation of the sentence  $S^{(1)}$  and  $v(w_i)$  refers to the word embedding of word  $i$  provided by the COMPOSES vector space. The same computation has to be done for  $S^{(2)}$ .

Intuitively, if either of the sentences contains more or less content words than the other, we can see the numerator changing but the denominator changes with it. The difference between  $v(S^{(1)})$  and  $v(S^{(2)})$  contributes to *distributional semantic distance*.

To calculate a real value similarity score between the sentence vectors, we take the dot product between the vectors to compute the cosine similarity between the sentence vectors:

$$sim(S^{(1)}, S^{(2)}) = \frac{v(S^{(1)}) \cdot v(S^{(2)})}{|v(S^{(1)})| |v(S^{(2)})|} \quad (5)$$

There was no clear indication of which vector space Sultan et al. (2015) have chosen to compute the similarity score from Equation 5. Thus we compute two similarity scores using both COMPOSES vector spaces trained with these configurations:

- 5-word context window, 10 negative samples, subsampling, 400 dimensions
- 2-word context window, PMI weighting, no compression, 300K dimensions

In this case, we extracted two similarity features for every sentence pair. With the harmonic proportion feature from Equation 3 and the similarity scores from Equation 5, we trained a boosted tree ensemble on the 3 features using the STS 2012 to 2015 datasets and submitted the outputs from this model as our baseline submission in the English STS Task in SemEval 2016.

#### 3.1 Replacing COMPOSES with GloVe

Pennington et al. (2014) handles semantic regularities (Levy et al., 2014) explicitly by using a global log-bilinear regression model which combines the global matrix factorization and the local context vectors when training word embeddings.

Instead of using the COMPOSES vector space, we experimented with replacing the  $v(w_i)$  com-

ponent in Equation 4 with the GloVe vectors,<sup>2</sup>  $v_{glove}(w_i)$  such that:

$$sim_{glove}(S^{(1)}, S^{(2)}) = \frac{v_{glove}(S^{(1)}) \cdot v_{glove}(S^{(2)})}{|v_{glove}(S^{(1)})| |v_{glove}(S^{(2)})|} \quad (6)$$

The novelty lies in the usage of the global matrix to capture corpus wide phenomena that might not be captured by the local context window. The model leverages on both the non-zero elements in the word-word co-occurrence matrix (not a sparse bag-of-words matrix) and the individual context window vectors similar to the word2vec model (Mikolov et al., 2013).

### 3.2 Similarity Using Tree LSTM

Recurrent Neural Nets (RNNs) allow arbitrarily sized sentence lengths (Elman, 1990) but early work on RNNs suffered from the vanishing/exploding gradients problem (Bengio et al., 1994). Hochreiter and Schmidhuber (1997) introduced multiplicative input and output gate units to solve the vanishing gradients problem. While RNN and LSTM process sentences in a sequential manner, Tree-LSTM extends the LSTM architecture by processing the input sentence through a syntactic structure of the sentence. We use the ReVal metric (Gupta et al., 2015) implementation of Tree-LSTM (Tai et al., 2015) to generate the similarity score.

ReVal represents both sentences ( $h_1, h_2$ ) using Tree-LSTMs and predicts a similarity score  $\hat{y}$  based on a neural network which considers both distance and angle between  $h_1$  and  $h_2$ :

$$\begin{aligned} h_x &= h_1 \odot h_2 \\ h_+ &= |h_1 - h_2| \\ h_s &= \sigma \left( W^{(\times)} h_x + W^{(+)} h_+ + b^{(h)} \right) \quad (7) \\ \hat{p}_\theta &= \text{softmax} \left( W^{(p)} h_s + b^{(p)} \right) \\ \hat{y} &= r^T \hat{p}_\theta \end{aligned}$$

where,  $\sigma$  is a sigmoid function,  $\hat{p}_\theta$  is the estimated probability distribution vector and  $r^T = [1 \ 2 \dots K]$ . The cost function  $J(\theta)$  is defined over probability

---

<sup>2</sup>We use the 300 dimensions vectors from the GloVe model trained on the Commoncrawl Corpus with 840B tokens, 2.2M vocabulary.

distributions  $p$  and  $\hat{p}_\theta$  using regularised Kullback-Leibler (KL) divergence.

$$J(\theta) = \frac{1}{n} \sum_{i=1}^n \text{KL} \left( p^{(i)} \middle\| \hat{p}_\theta^{(i)} \right) + \frac{\lambda}{2} \|\theta\|_2^2 \quad (8)$$

In Equation 8,  $i$  represents the index of each training pair,  $n$  is the number of training pairs and  $p$  is the sparse target distribution such that  $y = r^T p$  is defined as follows:

$$p_j = \begin{cases} y - \lfloor y \rfloor, & j = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & j = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}$$

for  $1 \leq j \leq K$ , where,  $y \in [1, K]$  is the similarity score of a training pair. This gives us a similarity score between [1, K] which is mapped between [0, 1].<sup>3</sup> Please refer to Gupta et al. (2015) for training details.

## 4 Submission

We submitted three models based on the original replication of the Sultan et al. (2014b) and Sultan et al. (2015) system and our variants and extensions of their approach.

Our baseline submission uses the similarity score from Equations 3 and 5 as features to train a linear ridge regression. Our baseline submission achieved an overall 0.69244 Pearson correlation score on all domains.

Extending the baseline implementation, we included the similarity score from Equations 6 and 8 to the feature set and trained a boosted tree ensemble (Friedman, 2001) to produce our Boosted submission. Finally, we use the same feature set to train an eXtreme Boosted tree ensemble (XGBoost) (Chen and He, 2015; Chen and Guestrin, 2015) model.

We annotated the STS 2012 to 2015 datasets with the similarity scores from Equations 2, 3, 5, 6, 8. The annotations and our open source implementation of the system are available at <https://github.com/alvations/stasis/blob/master/notebooks/STRIKE.ipynb>

**Table 1:** Pearson Correlation Results for English STS Task at SemEval-2016

## 5 Results

Table 1 shows the results of our submission to the English STS task in SemEval-2016; the median and best scores are computed across all participating teams in the task. Our baseline system performs reasonably well, outperforming the median scores in most domains.

Our extended variant of the baseline using boosted tree ensemble performs better in the answer-answer, headlines and postediting domains but performed worse in others. Comparatively, it improves the overall correlation score marginally by 0.002.

The system using XGBoost performs the best of the 3 models but it underperforms in the headlines and plagiarism domain when compared to the median scores.

Generally, we did not achieve the outstanding scores in the task as compared to the top performing team DLS@CU in the English STS 2015. Our XGBoost system performs far from the best scores from the top systems. However, overall our correlation scores are higher than the median scores across all submissions for the task.

As a post-hoc test, we have evaluated our baseline system by training on the STS 2012 to 2014 dataset and testing on the STS 2015 dataset and we achieved 0.76141 weighted mean Pearson correlation score on all domains. As compared to Sultan et al. (2015) results of 0.8015 we are 0.04 points short of their results which should technically rank our system at 20th out of 70+ submissions to the STS 2015 task<sup>4</sup>.

Machine Translation (MT) evaluation metrics have shown competitive performance in previous

STS tasks (Barrón-Cedeño et al., 2013; Huang and Chang, 2014; Bertero and Fung, 2015; Tan et al., 2015). Tan et al. (2016) annotated the STS datasets with MT metrics scores for every pair of sentence in the training and evaluation data. We extend our XGBoost model with these MT metric annotations and achieved a higher score for every domain leading to an overall Pearson correlation score of 0.73050 (+Saarsheff in Table 1).

## 6 Conclusion

In this paper, we have presented our findings on replicating the top system in the STS 2014 and 2015 task and evaluated our replica of the system in the English STS task of SemEval-2016. We have introduced variants and extensions to the replica system by using various state-of-art word and sentence embeddings. Our systems trained on (eXtreme) Boosted Tree ensembles outperform the replica system using linear regression. Although our replica of the previous best system did not achieve stellar scores, all our systems outperform the median scores computed across all participating systems.

## Abstract

In this paper we describe our system (DT-Sim) submitted at SemEval-2016 Task 1: Semantic Textual Similarity (STS Core). We developed Support Vector Regression model with various features including the similarity scores calculated using alignment based methods and semantic composition based methods. The correlations between our system output and the human ratings were above 0.8 in three datasets.

## 1 Introduction

The task of measuring the Semantic Textual Similarity (STS) is to quantify the degree of semantic similarity between the given pair of texts. For example, the similarity score of 0 means that the texts are not similar at all and 5 means that they have same meaning (Agirre et al., 2015; Banjade et al., 2015). In this paper, we describe our system DTSim and the submitted three different runs in this year’s SemEval shared task on Semantic Textual Similarity English track (STS Core; Agirre et al. (2016)). We applied Support Vector Regression (SVR) with various features in order to predict the similarity score for the given sentence pairs. The features of the model included semantic similarity scores calculated using individual methods (described in Section 3) and other general features. The pipeline of components in DTSim is shown in Figure 1.

## 2 Preprocessing

Hyphens were replaced with whitespaces if they were not composite verbs (e.g. video-gamed). The

Figure 1: Pipeline of components in DTSim system.

composite verbs were detected based on the POS tag assigned by the POS tagger. Also, the words starting with co-, pre-, meta-, multi-, re-, pro-, al-, anti-, ex-, and non- were left intact. Then, the hyphen-removed texts were tokenized, lemmatized, POS-tagged and annotated with Named Entity tags using Stanford CoreNLP Toolkit (Manning et al., 2014). We also marked each word as whether it was a stop word. We also created chunks using our own Conditional Random Fields (CRF) based chunking tool (Maharjan et al., 2016) which outperforms OpenNLP chunker when evaluated with human annotated chunks provided in interpretable similarity shared task in 2015. We normalized texts using mapping data. For example, *pct* and *%* were changed to *percent*.

## 3 Feature Extraction

We used various features in our regression models including semantic similarity scores generated using individual methods. Before describing those individual methods, we present word similarity methods which were used for sentence similarity calculation.

### 3.1 Word-to-Word Similarity

We used vector based word representation models, PPDB 2.0 database (Pavlick et al., 2015), and WordNet (Miller, 1995) in order to measure the similarity

between words as given below.

$$sim(w_1, w_2, m) = \begin{cases} 1, & \text{if } w_1 \text{ and } w_2 \text{ are synonyms} \\ 0, & \text{if } w_1 \text{ and } w_2 \text{ are antonyms} \\ ppdb(w_1, w_2), & \text{if } m = ppdb \\ \frac{\mathbf{X}_1 \cdot \mathbf{X}_2}{\|\mathbf{X}_1\| \|\mathbf{X}_2\|}, & \text{otherwise} \end{cases}$$

Where  $m \in \{ppdb, LSAwikipedia, word2vec, GloVe\}$ .  $\mathbf{X}_1$  and  $\mathbf{X}_2$  are vector representations of words  $w_1$  and  $w_2$  respectively.

We first checked synonyms and antonyms in WordNet 3.0. If the word pair was neither synonym nor antonym, we calculated the similarity score based on the model selected. The word representation models used are: word2vec (Mikolov et al., 2013)<sup>1</sup>, Glove (Pennington et al., 2014)<sup>2</sup>, and LSA Wiki (Stefanescu et al., 2014a)<sup>3</sup>. The cosine similarity was calculated between the word representation vectors. We also used the similarity score found in PPDB database<sup>4</sup>.

**Handling missing words:** We checked for the representation of word in raw form as well as in base (lemma) form. If neither of them was found, we used vector representation of one of its synonyms in WordNet for the given POS category. The same strategy was used while using PPDB to retrieve similarity score.

## 3.2 Sentence-to-Sentence Similarity

### 3.2.1 Word Alignment Based Method

In this approach, all the content words (in lemma form) in two sentences ( $S_1$  and  $S_2$ ) were aligned optimally ( $OA$ ) using Hungarian algorithm (Kuhn, 1955) as described in (Rus and Lintean, 2012) and implemented in SEMILAR Toolkit (Rus et al., 2013). The process is same as finding the maximum weight matching in a weighted bipartite graph. The nodes are words and the weights are the similarity scores between the word pairs. The sentence similarity is calculated as:

$$sim(S_1, S_2) = 2 * \frac{\sum_{(w_1, w_2) \in OA} sim(w_1, w_2)}{|S_1| + |S_2|}$$

<sup>1</sup><https://code.google.com/archive/p/word2vec/>

<sup>2</sup><http://nlp.stanford.edu/projects/glove/>

<sup>3</sup><http://semanticsimilarity.org>

<sup>4</sup><http://paraphrase.org/>

In order to avoid the noisy alignments, we reset the similarity score below 0.5 (empirically set threshold) to 0.

### 3.2.2 Chunk Alignment Based Method

We chunked texts (see Section 2) and aligned chunks optimally as described in (Ştefanescu et al., 2014b). The difference is that the chunks containing Named Entities were aligned using rules: (a) the chunks were treated as equivalent if both were named entities and at least one of the content words was matching, (b) they were treated as equivalent if one was the acronym of another. In other cases, chunk-to-chunk similarity was calculated using optimal word alignment method. The process is same as word alignment based method. First, the words in chunks were aligned to calculate chunk-to-chunk similarity. Finally, chunks in two sentences were aligned optimally for sentence level similarity. In order to avoid noisy alignments, we set similarity score to 0 below 0.5 for word alignment and 0.6 for chunk alignment. These thresholds were set empirically.

### 3.2.3 Interpretable Feature Based Method

We aligned chunks from one sentence to another and assigned semantic relations and similarity scores for each alignment. The semantic labels were EQUI, OPPO, SIMI, REL, SPE1, SPE2, and NOALI. For example, the semantic relation EQUI was assigned if the given two chunks were equivalent. The similarity score range from 0 (no similarity) to 5 (equivalent). We aligned chunks and assigned labels as described in (Maharjan et al., 2016). Once the chunks were aligned and semantic relation types and similarity scores were assigned, sentence level scores were calculated for each relation type as well as an overall score was calculated using all alignment types as shown next.

$$\begin{aligned} & Norm\_count(alignment-type) \\ &= \frac{(\# \text{ alignments with type} = \text{alignment-type})}{\text{Total \# alignments including NOALI}} \end{aligned}$$

$$\begin{aligned} & Similarity(S_1, S_2) \\ &= \frac{\sum_{(c_1, c_2) \in Alignments} sim(c_1, c_2)}{5 * (\text{Total \# alignments including NOALI})} \end{aligned}$$

Where  $c_1 \in \{S_1 \text{ chunks}\}$ ,  $c_2 \in \{S_2 \text{ chunks}\}$ , and  $\text{alignment-type} \in$

$\{EQUI, OPPO, SIMI, REL, SPE1, SPE2, NOALI\}$ .

### 3.2.4 Vector Algebra Based Method

In this approach, we combined vector based word representations to obtain sentence level representations through vector algebra as:

$$RV(S) = \sum_{w \in W} V_w$$

Where  $W$  is the set of content words in sentence  $S$  and  $V_w$  is the vector representation for word  $w$ . The cosine similarity was calculated between the resultant vectors -  $RV(S1)$  and  $RV(S2)$ . Word representations from LSA Wiki, word2vec and GloVe models were used.

### 3.2.5 Similarity Matrix Based Method

The approach is similar to the word alignment based method and similarity scores for all pairs of words from given two sentences are calculated. However, a key difference is that all word-to-word similarities are taken into account, not just the maximally aligned word similarities as described in (Fernando and Stevenson, 2008).

## 3.3 Features

All or subset of the following features was used for three different runs as described in Section 4. We used word2vec representation and WordNet antonym and synonym for word similarity unless anything else is mentioned specifically.

1. Similarity scores generated using word alignment based methods where word-to-word similarity was calculated using methods described in Section 3.1.
2. Similarity score using optimal alignment of chunks where word-to-word similarity scores were calculated using representation from word2vec model.
3. Similarity scores using similarity matrix based methods. The similarities between words were calculated using different word similarity methods discussed in Section 3.1.
4. Similarity scores using chunk alignment types and alignment scores (interpretable features).

| Data set        | Count       | Release time |
|-----------------|-------------|--------------|
| SMTnews         | 351         | STS2012-Test |

Table 1: Summary of training data.

5. Similarity scores using the resultant vector based method using word representations from word2vec, GloVe, and LSA Wiki models.
6. Noun-Noun, Adjective-Adjective, Adverb-Adverb, and Verb-Verb similarity scores and similarity score for other types of words using word alignment based method.
7. Multiplication of noun-noun similarity scores and verb-verb similarity scores.
8.  $\frac{|C_{i1} - C_{i2}|}{C_{i1} + C_{i2}}$  where  $C_{i1}$  and  $C_{i2}$  are the counts of  $i \in \{\text{all tokens, adjectives, adverbs, nouns, and verbs}\}$  for sentence 1 and 2 respectively.
9. Presence of adjectives and adverbs in first sentence, and in the second sentence.
10. Unigram overlap with synonym check, bigram overlap and BLEU score.
11. Number of EQUI, OPPO, REL, SIMI, and SPE relations in aligning chunks between texts relative to the total number of alignments.
12. Presence of antonym pair among all word pairs between given two sentences.

## 4 Building Models

**Training Data:** For building models, we used data released in previous shared tasks (summarized in Table 1). We selected datasets that included texts from different genres. However, some others, such as Tweet-news and MSRPar were not included. For instance, Tweet-news data were quite different from most other texts.

**Models and Runs:** Using the combination of features described in Section 3.3, we built three different Support Vector Regression (SVR) models corresponding to three runs (R1-3) submitted. In Run 1 (i.e. R1), all of the features except chunk alignment based features were used. The XL version of PPDB 2.0 was used. In Run 2, we selected the features using Weka’s correlation based feature selection tool (Hall and Smith, 1998) which also included chunk alignment based similarity score. In Run 3, we took the representative features from all of the features described in Section 3.3. For example, alignment based similarity scores generated using word2vec model were selected as it performed relatively better in training set compared to GloVe and LSA Wiki models. Also, we used XXXL version of the PPDB 2.0 database (the precision maybe lower but the coverage is higher as compared to the smaller version of the database).

We used LibSVM library (Chang and Lin, 2011) in Weka 3.6.8<sup>5</sup> to develop SVR models. We evaluated our models in training data using 10-fold cross validation approach. The correlation scores in training set were 0.791, 0.773 and 0.800 for R1, R2, and R3 respectively. The best results in training set was obtained using RBF kernel. All other parameters were set to Weka’s default.

## 5 Results

The test data contained 1186 sentence pairs as: Headlines (249), Plagiarism (230), Postediting (244), Question-question (209), and Answer-Answer (254). The further details about the test data can be found in (Agirre et al., 2016).

Table 2 shows the correlation (Pearson) of our system outputs with human ratings. The correlation scores of all three runs are 0.8 or above for three datasets - Headlines, Plagiarism, and Postediting. However, the correlations are comparatively lower for Question-question and Answer-answer datasets. One of the reasons is that these two datasets are quite different from the texts we used for the training (we could not include them as such type of datasets were not available during model building). For example, the question pair (#24 in Question-question dataset): *How to select a workout plan?* and *How to create a*

| Data set          | R1    | R2    | R3    |
|-------------------|-------|-------|-------|
| Headlines         | 0.815 | 0.795 | 0.812 |
| Plagiarism        | 0.837 | 0.828 | 0.832 |
| Postediting       | 0.823 | 0.815 | 0.815 |
| Question-Question | 0.614 | 0.608 | 0.591 |
| Answer-Answer     | 0.578 | 0.550 | 0.562 |
| Weighted Mean     | 0.735 | 0.720 | 0.724 |

**Table 2:** Results of our submitted runs on test data.

*workout plan?* have high lexical overlap but they are asking very different things. Analyzing the focus of the questions may be needed in order to distinguish the questions, i.e. the similarity between such pairs may need to be modeled differently. With the release of this type of dataset will foster the development of similarity models where the text pair consists of questions. It should to be noted that we used a single set of training data in all models without tailoring our models to specific test data.

Another interesting observation is that the results of three different runs are similar to each other. The most predictive feature was the word alignment based similarity using word2vec model. The correlation in full training set was 0.725. It is not surprising considering that the alignment based systems were top performing systems in the past shared tasks as well (Han et al., 2013; Sultan et al., 2015; Agirre et al., 2015). Selecting smaller set of features that best predict the similarity scores should be considered in the future which will reduce the complexity of the model and potential of overfitting.

## 6 Conclusion

This paper presented the DTSim system and three different runs submitted at SemEval 2016 task on STS English track. We developed support vector regression models with various features in order to predict the similarity score for the given pair of texts. The correlation of our system output were up to 0.83. However, the relatively lower scores for two datasets which were of new types (such as question-question) indicate that different datasets may need to be treated differently.

## **Abstract**

This paper describes our system developed for English Monolingual subtask (STS Core) of SemEval-2016 Task 1: “Semantic Textual Similarity: A Unified Framework for Semantic Processing and Evaluation”. We measure the similarity between two sentences using three different types of features, including word alignment-based similarity, sentence vector-based similarity and sentence constituent similarity. The best performance of our submitted runs is a mean 0.69996 Pearson correlation which outperforms the median score from all participating systems.

## **1 Introduction**

Semantic Textual Similarity (STS) is the task of measuring the degree of semantic equivalence of a sentence pair (Agirre et al., 2012). STS was first held in SemEval 2012 and has drawn considerable attention in recent years. STS has been widely used in a lot of natural language processing tasks such as information retrieval, machine translation, question answering, text summarization, and so on.

Previous methods for this task could be roughly divided into three categories: alignment approaches, vector space approaches and machine learning approaches (Häig et al., 2015). Alignment approaches align words or phrases in a sentence pair, and then take the quality or coverage of alignments as similarity measure (Sultan et al., 2014). Vector space approaches represent sentences as bag-of-words vectors and take vector similarity as their similarity measure (Meadow et al., 1992).

Machine learning approaches combine different similarity measures and features using supervised machine learning models (Bär et al., 2012).

In our system, we measure semantic text similarity by combining evidence from all above three categories. Specifically, we extract alignment-based similarity features, vector-based similarity features and sentence constituent similarity features from sentence pairs, and produce similarity scores between two sentences by combining these feature through a Support Vector Regression (SVR) model.

## **2 System Overview**

To measure the similarity between two sentences, we first extract a series of features, including alignment-based similarity features, vector-based similarity features and sentence constituent similarity features. Then we combine all these features and get an overall similarity using a Support Vector Regression (SVR). In following we first describe how to extract different types of features. Then we describe how to train the SVR model.

### **2.1 Alignment-based Similarity Features**

Sultan aligner is an open source unsupervised word alignment tool<sup>1</sup> whose core algorithm is described in (Sultan et al., 2014).

This aligner aligns related words in two sentences based on the following two properties of the words: firstly, whether they are semantically similar; secondly, whether they occur in similar semantic contexts in the respective sentences. As to the

---

<sup>1</sup> <https://github.com/ma-sultan/monolingual-word-aligner/>

former one, it mainly utilizes information provided by the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) to make decisions. In the case of the latter, contextual similarity for a word pair is computed as the sum of the word similarities for each pair of words in the context of them. The system based on Sultan aligner achieved the best performance at the SemEval 2014 STS task. And then at the SemEval 2015 English STS task, they constructed a top-performing system combining output of Sultan aligner and another vector-based feature.

In our system, we use the output result of Sultan aligner as follows:

- Given two input sentences, we compute their similarity score based on the produced word alignments, using a similarity function the same as the one described in (Sultan et al., 2015).
- The word aligner is used as the basis of subsequent feature extraction. Specifically, we use the word aligner to determine sentence major constituent similarity, named entity similarity and keyword similarity.

## 2.2 Vector-based similarity Features

In our system, we extract two vector-based similarity features based on two different types of word vectors. Given two sentences, we first generate two vector representations, and then compute a cosine similarity between these vectors as their similarity score.

The first type of word vectors used in our system comes from Baroni et al. (2014), which were learned by Skip-Gram framework in word2vec toolkit (Mikolov et al., 2013) from a corpus of about 2.8 billion tokens. Details on their approach can be found in (Baroni et al., 2014). We get the vector representation of a sentence by combining all the vectors of words in this sentence via element-wise addition.

The second type of word vectors we used is the multi-prototype word vectors come from (Liu Y et al., 2015). They assume that a word in different topic express different meanings. In our work, we employ Latent Dirichlet Allocation (LDA) (Ng and Jordan., 2003) framework to infer the topic distribution of text, and collapsed Gibbs sampling algorithm (Griffiths and Steyvers., 2004) to assign a

topic to each word in the corpus. In our work, we use Wikipedia English Dump (2012.12 Version) to learn the LDA model and TWE-2 framework, which consider each word-topic pair  $\langle w_i, z_i \rangle$  as pseudo word to learn. To get the representation of a sentence, we first use LDA and collapsed Gibbs sampling algorithm to get the topic assignment for each word in this sentence, and combine these vectors by the same way as the first type of vectors.

## 2.3 Sentence constituent similarity Features

In our system, we extract the following sentence constituent similarity features:

- **Subject similarity:** If the subjects of two sentences are the same, we assign a subject similarity 1, otherwise 0.
- **Predicate similarity:** If the predicates of two sentences are the same, we assign a predicate similarity 1, otherwise 0.
- **Object similarity:** If the objects of two sentences are the same, we assign an object similarity 1, otherwise 0.
- **Complement similarity:** If the complements of two sentences are the same, we assign a complement similarity 1, otherwise 0.
- **Named entity similarity:** We extract three similarity features based on whether there are aligned time pairs, location pairs or person pairs between compared sentences. For instance, given two sentences, if there exist locations that could be aligned between them, we will assign a 1 to the according named entity similarity, otherwise 0.
- **Keyword similarity:** Given two sentences, we acquire a keyword set for each one from the output of the Stanford CoreNLP tools<sup>2</sup> (Manning, Christopher D. et al., 2014). And then find out the keyword pairs that appear in the result of Sultan aligner. Finally, we get a real number between 0 and 1 as keyword similarity based on the proportion of aligned keywords in the above two sets.

---

<sup>2</sup> <http://stanfordnlp.github.io/CoreNLP/>

Generally speaking, different words in a sentence belonging to different sentence constituents may have different contributions to the semantic of the whole sentence. Based on this assumption, we extract four features to capture the similarities between the four major constituents of two sentences, including subject, predicate, object and complement. In our implementation, we extract the above constituents from the syntactic parsing result of the Stanford CoreNLP tools, and then we use the alignment result provided by Sultan aligner to judge whether they could be aligned.

In some specific domains, named entities play important roles in sentence semantic similarity. For instance, two headlines usually will be regarded to have little similarity when some named entities such as times and locations are different, although the rest parts may be quite similar. Based on the above observation, we extract three named entity similarity features for our system, according to whether there exist aligned time pairs, location pairs or person pairs between compared sentences. Concretely, if there exist aligned named entities of the above three types between two sentences, we set their corresponding similarity to 1, otherwise set it to 0. When extracting these features, we take outputs of the Stanford CoreNLP tools and the Sultan aligner as input.

Finally, we also extract an additional feature based on the keyword sets outputted by the Stanford CoreNLP tools. It is obtained by measuring the overlap between the two keyword sets of the sentence pair. In detail, given two sentences  $S^{(1)}$  and  $S^{(2)}$ , the keyword similarity feature is a real number between 0 and 1, which is computed as the following formula,

$$Sim_{key} = \frac{2 * N_{Ak}}{N_k^1 + N_k^2}$$

where  $N_{Ak}$  is the number of aligned keywords,  $N_k^i$  is the size of keyword set of  $S^{(i)}$ .

## 2.4 Support Vector Regression Model

Finally, we combine all the above features using a support vector regression model which is implemented in Scikit-learn (Pedregosa et al., 2011). We use its default SVR parameter settings( $C=1.0$ ,  $cache\_size=200$ ,  $coef0=0.0$ ,  $degree=3$ ,  $\epsilonpsilonion=0.1$ ,  $gamma='auto'$ ,  $kernel='rbf'$ ,  $max\_iter=-1$ ,

$shrinking=True$ ,  $tol=0.001$ ,  $verbose=False$ ) without further optimization.

## 3 Data

There are five test date sets in English Monolingual subtask (STS Core) of SemEval-2016 Task 1, which are Q&A Answer-Answer data set, Headlines data set, Plagiarism Detection data set, Post-Edited Machine Translations data set and Q&A Question-Question data set.

We trained our supervised systems using data from the past four years (2012-2015) of SemEval English STS task. For headlines we used all Headlines (2013), Headlines (2014), Deftnews(2014), SMTnews (2012) and Headlines (2015) sentence pairs. For the other four domains, we used all past annotation data.

## 4 Evaluation

We submitted three runs named S1, S2 and S3 before the deadline, but S3 is identical to S1 by mistake. So in this paper, we just discuss S1 and S2.

Table 1 lists the settings of run S1 and run S2. For run S1, we used all the features described in this paper. For run S2, we just used word alignment-based and sentence vector-based features.

| Run | Settings   |
|-----|--|
| S1  | Use all three different types of features                                    |
| S2  | Use alignment-based similarity features and vector-based similarity features |

**Table 1:** Settings of our submitted runs for SemEval 2016

| Data Set          | Runs          |               |
|-------------------|---------------|---------------|
|                   | S1            | S2            |
| Answer-Answer     | 0.4937        | <b>0.4965</b> |
| Headlines         | <b>0.7976</b> | 0.7904        |
| Plagiarism        | <b>0.8193</b> | 0.8121        |
| Post-Edited       | <b>0.8118</b> | 0.8118        |
| Question-Question | <b>0.5721</b> | 0.5718        |
| All               | 0.6999        | 0.6975        |

**Table 2:** Performances on STS 2016 test data. Each number in rows 1-5 is the correlation between system output and human annotations for the corresponding data set. The last row shows the values of the comprehensive results of each run.

Performances of our two runs on each of the STS 2016 test sets are shown in Table 2. Each bold number represents the best score on the corresponding test set. The weighted mean of correlations for each run is also shown. The results show that S1 performs equally or better than S2 in all the data sets but Answer-Answer.

| Data Set          | Align-Sim | Vector-Sim1 | Vector-Sim2 | S1     |
|-------------------|-----------|-------------|-------------|--------|
| Answer-Answer     | 0.4776    | 0.1247      | 0.2339      | 0.4937 |
| headlines         | 0.7938    | 0.6931      | 0.5785      | 0.7976 |
| Plagiarism        | 0.8185    | 0.7919      | 0.6774      | 0.8193 |
| Post-Edited       | 0.8179    | 0.8183      | 0.7740      | 0.8118 |
| Question-Question | 0.5696    | 0.6816      | 0.2287      | 0.5721 |

**Table 3:** Performance of three individual feature and our best run (S1) on STS 2016 test sets.

Table 3 shows the performance of our best run S1 and other three runs which only use one specific kind of features. *Align-Sim* uses only word alignment information, *Vector-Sim1* uses only sentence vector information and word vectors comes from (Baroni et al., 2014), *Vector-Sim2* uses only sentence vector information and word vectors comes from (Liu Y et al., 2015 ).

Results in table 3 show that our approach can achieve best performance by combining different types of features.

## 5 Conclusions and Future Work

At SemEval 2016, we present a supervised system for English Monolingual subtask of task1 using multiple features including alignment-based similarity features, vector-based similarity features and sentence constituent similarity features. Experimental results show that our approach can achieve better performance by combining more features.

For future work, we want to better measure the similarity between the major constituents of two sentences, rather than simply use 1 or 0 as their similarity values. We also want to get better sentence vector representation by developing better word composition models.

## Abstract

We describe an attention-based convolutional neural network for the English semantic textual similarity (STS) task in the SemEval-2016 competition (Agirre et al., 2016). We develop an attention-based input interaction layer and incorporate it into our multi-perspective convolutional neural network (He et al., 2015), using the PARAGRAM-PHRASE word embeddings (Wieting et al., 2016) trained on paraphrase pairs. Without using any sparse features, our final model outperforms the winning entry in STS2015 when evaluated on the STS2015 data.

## 1 Introduction

Measuring the semantic textual similarity (STS) of two pieces of text remains a fundamental problem in language research. It lies at the core of many language processing tasks, including paraphrase detection (Xu et al., 2014), question answering (Lin, 2007), and query ranking (Duh, 2009).

The STS problem can be formalized as: given a query sentence  $S_1$  and a comparison sentence  $S_2$ , the task is to compute their semantic similarity in terms of a similarity score  $sim(S_1, S_2)$ . The SemEval Semantic Textual Similarity tasks (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015; Agirre et al., 2016) are a popular evaluation venue for the STS problem. Over the years the competitions have made more than 15,000 human annotated sentence pairs publicly available, and have evaluated over 300 system runs.

Traditional approaches are based on hand-crafted feature engineering (Wan et al., 2006; Madnani et

al., 2012; Fellbaum, 1998; Fern and Stevenson, 2008; Das and Smith, 2009; Guo and Diab, 2012; Sultan et al., 2014; Kashyap et al., 2014; Lynam et al., 2014). Competitive systems in recent years are mostly based on neural networks (He et al., 2015; Tai et al., 2015; Yin and Schütze, 2015; He and Lin, 2016), which can alleviate data sparseness with pre-training and distributed representations.

In this paper, we extend the multi-perspective convolutional neural network (MPCNN) of He et al. (2015). Most previous neural network models, including the MPCNN, treat input sentences separately, and largely ignore context-sensitive interactions between the input sentences. We address this problem by utilizing an attention mechanism (Bahdanau et al., 2014) to develop an attention-based input interaction layer (Sec. 3). It converts the two independent input sentences into an inter-related sentence pair, which can help the model identify important input words for improved similarity measurement. We also use the strongly-performing PARAGRAM-PHRASE word embeddings (Wieting et al., 2016) (Sec. 4) trained on phrase pairs from the Paraphrase Database (Ganitkevitch et al., 2013).

These components comprise our submission to the SemEval-2016 STS competition (shown in Figure 1): an attention-based multi-perspective convolutional neural network augmented with PARAGRAM-PHRASE word embeddings. We provide details of each component in the following sections. Unlike much previous work in the SemEval competitions (Šarić et al., 2012; Sultan et al., 2014), we do not use sparse features, syntactic parsers, or external resources like WordNet.

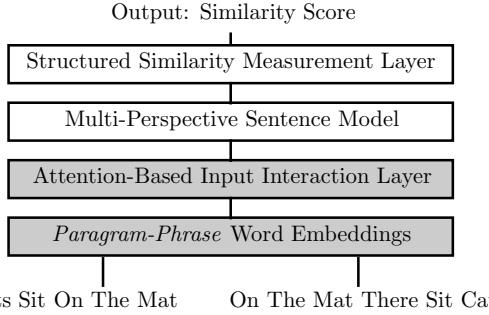

Figure 1: Model overview. Input sentences are processed by the attention-based input interaction layer and multi-perspective convolutional sentence model, then compared by the structured similarity measurement layer. The shaded components are our additions to the MPCNN model for the competition.

## 2 Base Model: Multi-Perspective Convolutional Neural Networks

We use the recently-proposed multi-perspective convolutional neural network model (MPCNN) of He et al. (2015) due to its competitive performance.<sup>1</sup> It consists of two major components:

1. **A multi-perspective sentence model** for converting a sentence into a representation. A convolutional neural network captures different granularities of information in each sentence using multiple types of convolutional filters, types of pooling, and window sizes.
2. **A structured similarity measurement layer** with multiple similarity metrics for comparing local regions of sentence representations.

The MPCNN model has a *Siamese* structure (Bromley et al., 1993), with a multi-perspective sentence model for each of the two input sentences.

**Multiple Convolutional Filters.** The MPCNN model applies two types of convolutional filters: 1-d per-dimension filters and 2-d holistic filters. The holistic filters operate over sliding windows while considering the full dimensionality of the word embeddings, like typical *temporal* convolutional filters. The per-dimension filters focus on information at a finer granularity and operate over sliding windows of each dimension of the word embeddings. Per-dimension filters can find and extract information

from individual dimensions, while holistic filters can discover broader patterns of contextual information. We use both kinds of filters for a richer representation of the input.

**Multiple Window Sizes.** The window size denotes how many words are matched by a filter. The MPCNN model uses filters with different window sizes  $ws$  in order to capture information at different  $n$ -gram lengths. We use filters with  $ws$  selected from  $\{1, 2, 3\}$ , so our filters can find unigrams, bigrams, and trigrams in the input sentences. In addition, to retain the raw information in the input,  $ws$  is also set to  $\infty$  where pooling layers are directly applied over the entire sentence embedding matrix without the use of convolution layers in-between.

**Multiple Pooling Types.** For each output vector of a convolutional filter, the MPCNN model converts it to a scalar via a pooling layer. Pooling helps a convolutional model retain the most prominent and prevalent features, which is helpful for robustness across examples. One widely adopted pooling layer is *max pooling*, which applies a max operation over the input vector and returns the maximum value. In addition to max pooling, The MPCNN model uses two other types of pooling, min and mean, to extract different aspects of the filter matches.

**Similarity Measurement Layer.** After the sentence models produce representations for each sentence, we use a module that performs comparisons between the two sentence representations to output a final similarity score. One simple way to do this would be to flatten each sentence representation into a vector and then apply a similarity function such as cosine similarity. However, this discards important information because particular regions of the sentence representations come from different underlying sources. Therefore, the MPCNN model performs structured similarity measurements over particular local regions of the sentence representations.

The MPCNN model uses rules to identify local regions whose underlying components are related. These rules consider whether the local regions are: (1) from the same filter type; (2) from the convolutional filter with the same window size  $ws$ ; (3) from the same pooling type; (4) from the same specific filter of the underlying convolution filter type.

<sup>1</sup><https://github.com/hohoCode>

Only feature vectors that share at least two of the above are compared. There are two algorithms using three similarity metrics to compare local regions: one works on the output of holistic filters only, while the other uses the outputs of both the holistic and per-dimension filters.

On top of the structured similarity measurement layer, we stack two linear layers with a tanh activation layer in between, followed by a log-softmax layer. More details are provided in He et al. (2015).

### 3 Attention-Based Input Interaction Layer

The MPCNN model treats input sentences separately with two neural networks in parallel, which ignores the input contextual interaction information. We instead utilize an attention mechanism (Bahdanau et al., 2014) and develop an attention-based interaction layer that converts the two independent input sentences into an inter-related sentence pair.

We incorporate this into the base MPCNN model as the first layer of our system. It is applied over raw word embeddings of input sentences to generate re-weighted word embeddings. The attention-based re-weightings can guide the *focus* of the MPCNN model onto important input words. That is, words in one sentence that are more relevant to the other sentence receive higher weights.

We first define input sentence representation  $S^i \in \mathbb{R}^{\ell_i \times d}$  ( $i \in \{0, 1\}$ ) to be a sequence of  $\ell_i$  words, each with a  $d$ -dimensional word embedding vector.  $S^i[a]$  denotes the embedding vector of the  $a$ -th word in  $S^i$ . We then define an *attention matrix*  $D \in \mathbb{R}^{\ell_0 \times \ell_1}$ . Entry  $(a, b)$  in the matrix  $D$  represents the pairwise word similarity score between the  $a$ -th word embedding of  $S^0$  and the  $b$ -th word embedding of  $S^1$ . The similarity score uses cosine distance:

$$D[a][b] = \text{cosine}(S^0[a], S^1[b])$$

Given the attention matrix  $D$ , we generate the attention weight vector  $A^i \in \mathbb{R}^{\ell_i}$  for input sentence  $S^i$  ( $i \in \{0, 1\}$ ). Each entry  $A^i[a]$  of the attention weight vector can be viewed as an attention-based relevance score of one word embedding  $S^i[a]$  with respect to all word embeddings of the other sentence  $S^{1-i}[:, :]$ . Attention weights  $A^i[:, :]$  sum to one due to

the *softmax* normalization:

$$\begin{aligned} E^0[a] &= \sum_b D[a][b] \\ E^1[b] &= \sum_a D[a][b] \\ A^i &= \text{softmax}(E^i) \end{aligned}$$

We finally define updated embeddings  $\text{attenEmb} \in \mathbb{R}^{2d}$  for each word as a concatenation of the original and attention-reweighted word embeddings:

$$\text{attenEmb}^i[a] = \text{concat}(S^i[a], A^i[a] \odot S^i[a])$$

where  $\odot$  represents element-wise multiplication.

Our input interaction layer is inspired by recent work that incorporates attention mechanisms into neural networks (Bahdanau et al., 2014; Rush et al., 2015; Yin et al., 2015; Rocktäschel et al., 2016). Many of these add parameters and computational complexity to the model. However, our attention-based input layer is simpler and more efficient. Moreover, we do not introduce any additional parameters, as we simply use cosine distance to create the attention weights. Nevertheless, adding this attention layer improves performance, as we show in Section 5.

### 4 Word Embeddings

We compare several types of word embeddings to represent the initial sentence matrices ( $S^i$ ). We use the PARAGRAM-SL999 embeddings from Wieting et al. (2015) and the PARAGRAM-PHRASE embeddings from Wieting et al. (2016). These were both constructed from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) by training on *noisy* paraphrase pairs using a hinge-based loss with negative sampling. However, they were trained on two different types of data.

The PARAGRAM-SL999 embeddings were trained on the lexical section of PPDB, which consists of word pairs only. The PARAGRAM-PHRASE embeddings were trained on the phrasal section of PPDB, which consists of phrase pairs. The representations for the phrases were created by simply averaging word embeddings, which was found to outperform more complicated compositional architectures like LSTMs (Hochreiter and Schmidhuber, 1997)

when evaluated on out-of-domain data.<sup>2</sup> The resulting word embeddings yield sentence embeddings (via simple averaging) that perform well across STS tasks without task-specific tuning. Their performance is thought to be due in part to how the vectors for less important words have smaller norms than those for information-bearing words.

## 5 Experiments and Results

**Datasets.** The test data of the SemEval-2016 English STS competition consists of five datasets from different domains. We tokenize all data using Stanford CoreNLP (Manning et al., 2014). Each pair has a similarity score  $\in [0, 5]$  which increases with similarity. We use training data from previous STS competitions (2012 to 2015). Table 1 provides a brief description.

**Experimental Settings.** We largely follow the same experimental settings as He et al. (2015), e.g., we perform optimization with stochastic gradient descent using a fixed learning rate of 0.01. We use the 300-dimensional PARAGRAM-PHRASE XXL word embeddings ( $d = 300$ ).

**Results on STS2016.** We provide results of three runs in Table 2. The three runs are from the same system, but with models of different training epochs.

**Ablation Study on STS2015.** Table 3 shows an ablation study on the STS2015 test sets which consist of 3,000 sentence pairs from five domains. Our training data for the ablation study is from previous test sets in STS2012-2014 following the rules of the STS2015 competition (Agirre et al., 2015). We remove or replace one component at a time from the full system and perform re-training and re-testing.

<sup>2</sup>For in-domain evaluation, LSTMs outperformed averaging.

| - Replace PARAGRAM-PHRASE with GloVe (Sec. 4) | 0.7622                          |
| - Replace PARAGRAM-PHRASE with PARAGRAM-SL999 | 0.7721                          |
| Winning System of STS2015                     | 0.8015                          |

Table 3: Ablation study on STS2015 test data.

We observe a significant drop when the attention-based input interaction layer (Sec. 3) is removed. We also find that the PARAGRAM-PHRASE word embeddings are highly beneficial, outperforming both GloVe word embeddings (Pennington et al., 2014) and the PARAGRAM-SL999 embeddings of Wieting et al. (2015). Our full system performs favorably compared to the winning system (Sultan et al., 2015) at the STS2015 SemEval competition.

## 6 Conclusion

Our submission to the SemEval-2016 STS competition uses our multi-perspective convolutional neural network model as the base model. We develop an attention-based input interaction layer to guide the convolutional neural network to focus on the most important input words. We further improve performance by using the PARAGRAM-PHRASE word embeddings, yielding a result on the 2015 test data that surpasses that of the top system from STS2015.

## Abstract

We describe a set of systems submitted to the SemEval-2016 English Semantic Textual Similarity (STS) task. Given two English sentences, the task is to compute the degree of their semantic similarity. Each of our systems uses the SemEval 2012–2015 STS datasets to train a ridge regression model that combines different measures of similarity. Our best system demonstrates 73.6% correlation with average human annotations across five test sets.

## 1 Introduction

Identification of short-text semantic similarity is an important research problem with application in a multitude of NLP tasks: question answering (Yao et al., 2013; Severyn and Moschitti, 2013), short answer grading (Mohler et al., 2011; Ramachandran et al., 2015), text summarization (Dasgupta et al., 2013; Wang et al., 2013), evaluation of machine translation (Chan and Ng, 2008; Liu et al., 2011), and so on. The SemEval Semantic Textual Similarity (STS) task series (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015) is a core platform for the task: a publicly available corpus of more than 14,000 sentence pairs have been developed over a span of four years with human annotations of similarity for each pair; and about 300 system runs have been evaluated.

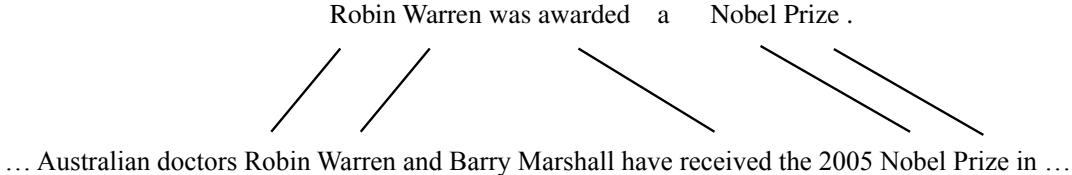

In this article, we describe a set of systems that participated in the SemEval-2016 English Semantic Textual Similarity (STS) task. Given two English sentences, the objective is to compute their semantic similarity in the range [0, 5], where the

score increases with similarity (i.e., 0 indicates no similarity and 5 indicates identical meanings). The official evaluation metric is the Pearson product-moment correlation coefficient with human annotations. Our systems leverage different measures of sentence similarity and train ridge regression models that learn to combine predictions from these different sources using past SemEval data. The best of our three system runs achieves 73.6% with human annotations among all submitted systems on five test sets (containing a total of 1186 test pairs).

Early work in sentence similarity (Mihalcea et al., 2006; Li et al., 2006; Islam and Inkpen, 2008) established the basic procedural framework under which most modern algorithms operate: computing sentence similarity as a mean of word similarities across the two input sentences. With no human annotated STS dataset available, these algorithms are unsupervised and were evaluated extrinsically on tasks like paraphrase detection and textual entailment recognition. The SemEval STS task series has made an important contribution through the large annotated dataset, enabling intrinsic evaluation of STS systems and making supervised STS systems a reality.

At SemEval 2012–2015, most of the top-performing STS systems used a regression algorithm to combine different measures of similarity (Bär et al., 2012; Šarić et al., 2012; Wu et al., 2013; Lynam et al., 2014; Sultan et al., 2015), with the notable exception of a couple of unsupervised systems that relied primarily on alignment of related words in the two sentences (Han et al., 2013; Sultan et al., 2014b).

Our models are based on the successful linear re-

**Figure 1:** Words aligned by our aligner across two sentences taken from the MSR alignment corpus (Brockett, 2007). (We show only part of the second sentence.) Besides exact word/lemma matches, it identifies and aligns semantically similar word pairs using PPDB (*awarded* ↔ *received* in this example).

gression architecture of past SemEval systems in general, and the winning system of SemEval-2015 (Sultan et al., 2015) in particular. We use the features in the latter system unchanged in one of our runs and augment them with simple word and character  $n$ -gram overlap features in the other two runs.

## 2 System Description

Our system employs a ridge regression model (linear regression with  $L_2$  error and  $L_2$  regularization) to combine a set of similarity measures. The model is trained on SemEval 2012–2015 data. Our three runs differ in the subset of features drawn from the feature pool. We describe the feature set in this section; the individual runs will be discussed in Section 4.

### 2.1 Features

**Word Alignment Proportion.** This feature operationalizes the hypothesis that highly semantically similar sentences should also have a high degree of conceptual alignment between their semantic units, i.e., words and phrases. To that end, we apply the monolingual word aligner developed by Sultan et al. (2014a) to input sentence pairs.<sup>1</sup>

This aligner aligns words based on their semantic similarity and the similarity between their local semantic contexts in the two sentences. It uses the paraphrase database PPDB (Ganitkevitch et al., 2013) to identify semantically similar words, and relies on dependencies and surface-form neighbors of the two words to determine their contextual similarity. Word pairs are aligned in decreasing order of a weighted sum of their semantic and contextual similarity. Figure 1 shows an example set of alignments.

<sup>1</sup><https://github.com/ma-sultan/monolingual-word-aligner>

For more details, see (Sultan et al., 2014a).

Additionally, we also consider a Levenshtein distance<sup>2</sup> of 1 between a misspelled word and a correctly spelled word (of length  $> 2$ ) to be a match.

Given sentences  $S^{(1)}$  and  $S^{(2)}$ , the alignment-based similarity measure is computed as follows:

$$\text{sim}(S^{(1)}, S^{(2)}) = \frac{n_c^a(S^{(1)}) + n_c^a(S^{(2)})}{n_c(S^{(1)}) + n_c(S^{(2)})}$$

where  $n_c(S^{(i)})$  and  $n_c^a(S^{(i)})$  are the number of content words and the number of aligned content words in  $S^{(i)}$ , respectively.

**Sentence Embedding.** A fundamental limitation of the above feature is that it only relies on PPDB to identify semantically similar words; consequently, similar word pairs are limited to only lexical paraphrases. Hence it fails to utilize semantic similarity or relatedness between non-paraphrase word pairs (e.g., *sister* and *related*). In the current feature, we leverage neural word embeddings to overcome this limitation. We use the 400-dimensional vectors<sup>3</sup> developed by Baroni et al. (2014). They used the word2vec toolkit<sup>4</sup> to extract these vectors from a corpus of about 2.8 billion tokens. These vectors perform well across different word similarity datasets in their experiments. Details on their approach and findings can be found in (Baroni et al., 2014).

Instead of comparing word vectors across the two input sentences, we adopt a simple vector composition scheme to construct a vector representation of

<sup>2</sup>The minimum number of single-character edits needed to change one word into the other, where an edit is an insertion, a deletion or a substitution.

<sup>3</sup><http://clic.cimec.unitn.it/composes/semantic-vectors.html>

Table 1: Test sets at SemEval STS 2016.

each input sentence and then take the cosine similarity between the two sentence vectors as our second feature for this run. The vector representing a sentence is simply the sum of its content lemma vectors.

**Word  $n$ -gram Overlap.** This feature computes the proportion of word  $n$ -grams (lemmatized) that are in both  $S^{(1)}$  and  $S^{(2)}$ . We employ separate instances of this feature for  $n = 1, 2, 3$ . The goal is to identify high local similarities in the two snippets and learn the influence that such local similarities might have on human judgment of sentence similarity.

**Character  $n$ -gram Overlap.** This feature computes the proportion of character  $n$ -grams that are in both  $S^{(1)}$  and  $S^{(2)}$  in their surface form. We employ separate instances of this feature for  $n = 3, 4$ . The goal is to identify and correct for spelling errors as well as incorrect lemmatizations.

**Soft Cardinality.** Soft Cardinality (Jimenez et al., 2012) is a measure of set cardinality where similar items in a set contribute less to its cardinality than dissimilar items. Jimenez et al. (2012) propose a parameterized measure of semantic similarity based on soft cardinality that computes sentence similarity from word similarity and the latter from character  $n$ -gram similarity. This measure was highly successful at SemEval-2012 (Agirre et al., 2012). We employ this measure with untuned parameter values as a feature for our model:  $p = 1$ ,  $bias = 0$ ,  $\alpha = 0.5$ ,  $bias_{sim} = 0$ ,  $\alpha_{sim} = 0.5$ ,  $q_1 = 2$ , and  $q_2 = 4$ . (Please see the original article for a detailed description of these parameters as well as the similarity measure.)

### 3 Data

The 1186 test sentence pairs at SemEval-2016 are divided into five sets, each consisting of pairs from a particular domain. Each pair is assigned a similarity score in the range [0, 5] by human annotators (0: no similarity, 5: identically). Test sets are discussed

briefly in Table 1.

We train our supervised systems using data from the past four years of SemEval STS (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). The selections vary by test set, which we discuss in the next section.

## 4 Runs

We submit three runs at SemEval-2016. Each run employs a ridge regression model; we use Scikit-learn (Pedregosa et al., 2011) for model implementation. Different training data from SemEval 2012–2015 are used for different test sets. For *headlines*, we train the model on *headlines* (2013, 2014, 2015), *deft-news* (2014), *tweet-news* (2014), and *smtnews* (2012) pairs. For *postediting*, the model is trained on *smt* (2013), *smteuroparl* (2012) and *smtnews* (2012) pairs. These selections are based on the similarity between the source and the target domains—news data for *headlines*, machine translation data for *postediting*. For the other three test sets, all past annotations (except those for *fnwn* (2013)) are used, as we did not find any close matches for these test sets in the SemEval 2012–2015 data.

### 4.1 Run 1

Run 1 is a ridge regression model based only on the first two features—alignment and embeddings. The regularization strength parameter  $\alpha$  is set using cross-validation on training data.

### 4.2 Run 2

Run 2 employs a model similar to the run 1 model, but uses the entire feature set described in Section 2.1. The same training sets are used for each test set and the model parameter  $\alpha$  is again set using cross-validation on training data.

### 4.3 Run 3

Run 3 is identical to run 2, except that it assigns a lower value to the regularization parameter  $\alpha$  (100 as opposed to 500 in run 2).

## 5 Evaluation

Table 2 shows the performances of the three runs (measured by Pearson’s  $r$ , the official evaluation metric at SemEval STS) alongside the score for the

| Dataset                  | Runs  |       |       | Best Score |
|--------------------------|-------|-------|-------|------------|
|                          | 1     | 2     | 3     |            |
| <b>answer-answer</b>     | .5523 | .5599 | .5453 | .6924      |
| <b>headlines</b>         | .8008 | .8033 | .8033 | .8275      |
| <b>plagiarism</b>        | .8229 | .8123 | .8195 | .8414      |
| <b>postediting</b>       | .8426 | .8442 | .8442 | .8669      |
| <b>question-question</b> | .6599 | .6423 | .6666 | .7471      |
| <b>Weighted Mean</b>     | .7356 | .7330 | .7355 | .7781      |

**Table 2:** Performance on STS 2016 data. Each number in rows 1–5 is the correlation (Pearson’s  $r$ ) between system output and human annotations for the corresponding test set. The rightmost column shows the best score by any system. The last row shows the value of the final evaluation metric for each run as well as the top-performing system.

best performing system for each test set. The last row shows the official evaluation metric that computes a weighted sum of correlations over all test sets, where the weight of a test set is proportional to the number of sentence pairs it contains.

Runs 1 and 3 have very similar overall performances, slightly better than that of run 2. Among the different test sets, the models perform well on news headlines, plagiarism and machine translation data, but poorly on the Q&A forums data.

### 5.1 Ablation Study

From the overall performances in Table 2, it is clear that the three new features added to the Sultan et al. (2015) model do not improve performance. Therefore, we run a feature ablation study only on the run 1 model. Table 3 shows the results. Similar to the findings reported in (Sultan et al., 2015), the alignment-based feature performs better across test sets. However, the addition of the embedding feature improves performance on almost all test sets.

### 5.2 Relation between the Runs

We compute pairwise correlations between the predictions of our three runs to see how different they are. As Table 4 shows, the predictions are highly correlated, which is expected given the results in Table 2.

## 6 Conclusions and Future Work

We present three supervised models of sentence similarity based on the winning system at SemEval-2015 (Sultan et al., 2015). Our additional features

| Data Set                 | Run 1 | Alignment | Embedding |
|--------------------------|-------|-----------|-----------|

do not improve performance and results show similar influences of alignment and embedding features as in SemEval-2015.

Besides high performance, the run 1 model has the key advantage of simplicity and high replicability. All the major design components are also available for free download (links provided in Section 2).

A key limitation of the system is its inability to model semantics of units larger than words (phrasal verbs, idioms, and so on). This is an important future direction not only for our system but also for STS and text comparison tasks in general. Incorporation of stop word semantics is key to identifying similarities and differences in subtle aspects of sentential semantics like polarity and modality. Domain-specific learning of the word vectors can also improve results.

## Abstract

We experiment with learning word representations designed to be combined into sentence-level semantic representations, using an objective function which does not directly make use of the supervised scores provided with the training data, instead opting for a simpler objective which encourages similar phrases to be close together in the embedding space. This simple objective lets us start with high-quality embeddings trained using the Paraphrase Database (PPDB) (Wieting et al., 2015; Ganitkevitch et al., 2013), and then tune these embeddings using the official STS task training data, as well as synthetic paraphrases for each test dataset, obtained by pivoting through machine translation.

Our submissions include runs which only compare the similarity of phrases in the embedding space, directly using the similarity score to produce predictions, as well as a run which uses vector similarity in addition to a suite of features we investigated for our 2015 Semeval submission.

For the crosslingual task, we simply translate the Spanish sentences to English, and use the same system we designed for the monolingual task.

## 1 Introduction

We describe the work carried out by the DCU-SEManiacs team on the Semantic Textual Similarity (STS) task at SemEval-2016 (Agirre et al., 2013; Agirre et al., 2014; Nakov et al., 2015).

The main ideas we investigate in our systems are:

1. Using a margin-based objective function to train high-quality sentence embeddings without using supervised scores
2. Creating new synthetic training data using machine translation to generate artificial paraphrases
3. Using ensemble models to combine features generated by our embedding networks with features obtained from other sources

### 1.1 Task Description

The Semeval Semantic Textual Similarity (STS) task provides participants with training data consisting of pairs of sentences annotated with gold-standard semantic similarity scores. The crowd-sourced similarity scores are given on a scale from 0 (no relation) to 5 (semantic equivalence). Thus, our aim is to use the training data to learn a model which predicts a score between 0 and 5 for unseen input pairs (Nakov et al., 2015). The monolingual STS task has been organized each year since 2012, and most approaches have viewed the learning task as a regression problem, where real-valued model output is clipped to be  $0 \leq \hat{y} \leq 5$  (Agirre et al., 2013; Agirre et al., 2014; Nakov et al., 2015).

For two of our three STS systems, we take a novel approach to this task, and directly use the similarity scores produced by the embedding networks as the predicted score. When training the embedding networks, we use the gold scores only to *reduce* the task-internal data to segments with a high-semantic similarity – embeddings are then learned using a simplified training objective which only makes use

of training pairs which are “perfect” paraphrases (see section 2.1). Interestingly, these models perform very well without access to the gold standard scores.

The 2016 edition of the STS task also introduced a pilot crosslingual STS task in addition to the monolingual STS task. The crosslingual task is similar to monolingual STS, except either member of each sentence pair may be in Spanish (language identification is *not* provided with the data). In order to use our monolingual STS system in the crosslingual task, we first automatically identify sentences which are probably in Spanish, use machine translation to translate Spanish sentences to English, then approach the crosslingual task as another monolingual task.

Although our systems performed well in both the crosslingual and monolingual STS tasks, we also discuss some possible shortcomings of our approach, and opportunities for improvement.

The rest of the paper is organized as follows: section 2 discusses the main novelties of our submissions, and presents the task-internal and external datasets we leverage for training our systems, section 3 gives a detailed discussion of each of our submitted systems, including information on hyperparameters and training configuration, section 4 gives a summary of experimental results, and section 5 discusses the advantages and disadvantages of our approach, and proposes avenues for future work.

## 2 Methodology

### 2.1 Paragraph Vectors and PPDB

Wieting (2015) introduced Paragraph-phrase embeddings, which use a novel training objective designed to learn robust sentence-level embeddings which are simple bag-of-words averages of the embeddings in each sequence. Wieting discusses several possible means of encoding a sequence into a vector using shallow and deep feedforward and recurrent networks. Surprisingly, the best performing model is a single-layer word embedding matrix, where sentence vectors are constructed by taking the mean of the token embeddings (equation 1).

In our preliminary experiments, we also experimented with deeper feedforward models, as well as mono-directional and bi-directional Long Short-

Term Memory (LSTM) recurrent models (Hochreiter and Schmidhuber, 1997) in place of the simple averaging approach; however, we did not observe an improvement in performance, which supports the results presented by Wieting (2015).

We also experimented with objective functions that are more representative of the task objective, such as Kullback-Leibler Divergence (Tai et al., 2015; Wieting et al., 2015); however, we found that the simple margin-based training objective outperforms cost-functions which take the score into account. We hypothesize that this is because the notion of “partial-similarity” is mostly captured by the bag-of-words averaging of all token embeddings to compose the vector representation of a sequence, and because the semantic similarity scores for the STS task are sufficiently coarse that the bulk of their semantic content can be efficiently captured even when all structural information has been discarded.

Equation 2 shows the objective function for the Paragraph-phrase model. This function pushes similar examples together, and dissimilar examples apart, driven by the margin  $\delta$ .  $g(x)$  is some differentiable function which transforms a sequence of tokens into a fixed-size vector. This model is simple to implement, and very fast to train<sup>1</sup>. An additional advantage of the margin-based objective function is that the model can learn from any dataset containing pairs of phrases which are semantically equivalent, enabling the use of unsupervised paraphrase data during training. We exploit this flexibility to greatly improve the performance of our models by tuning the Paragraph vectors with new data (section 3.2).

$$\text{embedding}(x) = \frac{1}{n} \sum_i^n W_{word}^{x^i} \quad (1)$$

The word embeddings are the only parameters of this network. Intuitively, tokens whose embeddings have a high L2 norm in this space contribute more to the semantics of a sentence than those whose norm is low. This simple parameterization has the added advantage that it is very fast to train, relative to other possible architectures, such as mono- or bi-directional LSTMs or Gated Recurrent Units (GRUs) (Chung et al., 2015). However, the main

| <b>ALL</b> | .743           | .754          | <b>.766</b>          |

**Table 1:** Using the 2015 STS data as development data, a comparison of our 2015 model with raw results from paragraph vectors trained on PPDB, and an ensemble system of our 2015 model with the paragraph similarity included as a feature.

advantage of this objective function for our work is that models can now be trained with any dataset consisting of pairs of sequences which are semantically equivalent. Thus datasets such as PPDB can be used to train high-quality embeddings.

We start by using the 300-dimensional vectors provided by Wieting (2015). These vectors were trained using the XXL version of PPDB (Ganitkevitch et al., 2013). The sentence embeddings obtained by averaging the raw paragraph vectors are used as the development baseline for our systems, and we look for ways to tune the model for the STS task without changing the training objective.

This training objective assumes that each pair is “sufficiently similar” – there is no explicit way to represent partial similarity, since the  $\delta$  margin dictates that the model should predict a score of at least  $\delta$  for positive training examples. Therefore, we filter the Semeval STS 2012-2014 training data to contain only those pairs whose similarity is  $>= 3.8^2$ .

### 3 System Descriptions

#### 3.1 Generating Negative Examples

Wieting (2015) discusses two ways of selecting negative examples for the paragraph vector training objective. The first is to compute the similarity of  $x_1$

<sup>2</sup>This cutoff parameter was tuned between 3-4.5 with increments of 0.1, note that lowering this threshold results in more training data, but also lowers the quality of the paraphrases, since more partially-similar pairs are included

and  $x_2$  with every segment in the training minibatch, choosing the most similar segment  $t_1$  to  $x_1$  and the most similar segment  $t_2$  to  $x_2$  that are *not* members of the current pair  $(x_1, x_2)$ , and to use these as the negative training examples for the pair. The second is to alternate between choosing a random negative example and choosing the most similar phrase. Although the approach of choosing the most similar negative example is theoretically satisfying, there are heavy computational costs: this requires at least  $N$  vector comparisons for each example in each pair, where  $N$  is the size of the minibatch, and the comparisons must be repeated for each training epoch, since the most similar segment may have changed since the previous epoch. Due to the computational overhead associated with computing the most similar example for each example in each minibatch, we opt instead to use randomly chosen segments as the negative examples. Because the random negative examples are re-selected for each epoch, the model also views more data – each time a training pair is seen, the negative examples  $t_1$  and  $t_2$  selected for  $x_1$  and  $x_2$  are different. Intuitively, this should positively contribute to desirable invariance in the learned semantic embeddings; however, we did not validate this empirically.

#### 3.2 Synthetic Data Generation

We believe that the requirement for human annotation is the major bottleneck for producing more training data for the STS task. Inspired by the

| <b>Dataset</b>    | <b>task-internal</b> | <b>synthetic</b> | <b>fusion</b> | <i>Median</i> | <i>Best System</i> |

| Mean*          | .832                 | <b>.846</b>      | .863               |

**Table 3:** Crosslingual STS results by run, with best scores for reference. Our best performing systems are bolded.

methodology used to create PPDB (Ganitkevitch et al., 2013), we propose a novel means of producing paraphrases which combines domain-adaptation with paraphrase generation using two or more MT systems. For the experiments presented here, we translate every test sentence into Spanish, then back into English, and add the resulting “pseudo-instance” to the data provided by the task organizers. This method has the additional advantage that we can generate new paraphrases targeted at the sentences in the test data, allowing unsupervised domain adaptation of the model to the test datasets.

This approach is obviously dependent upon the quality of the machine translation output; however, if translation from  $e \rightarrow f \rightarrow \hat{e}$  outputs exactly the input  $e$ , the new synthetic training example would be of little use. Therefore, the MT systems used for synthetic generation should ideally produce fluent output  $\hat{e}$  which paraphrases the original input  $e$ , but is diverse with respect to the gold-standard reference translations.

In order to validate that adding synthetic data actually improves performance, we generated synthetic paraphrases for the 2015 Images dataset, and compared performance with respect to the Paragraph baseline, and with respect to a model trained with only the task-internal data. These experiments confirmed that synthetic data generation can significantly improve performance. During development, we did not test performance on all of the 2015 data because the process of generating paraphrases is

time-consuming, and because we wanted to keep our usage of the Google Translate API within the free credit allocated for test usage of the API, to ensure that our results can be easily replicated.

### 3.3 Semantic Textual Similarity

We submit three systems to the monolingual STS task. The first system is an ensemble of features from our 2015 submission, together with two features produced by the embedding systems. The second system uses the task-internal data from Semeval 2012-2015 to tune the Paragraph embeddings for the STS task. The third system includes one synthetic paraphrase for each sentence in each test dataset, generated by first translating the sentence into Spanish, then back into English. Note that, due to time constraints we did not tune a separate model for each test dataset, instead we used one model trained with all synthetic paraphrases from all test datasets. We believe that training a separate model for each test dataset with synthetic data for only that dataset would improve performance somewhat. Because the scores of the embedding models are in the range 0–1, we scale the outputs by a factor of 5 to match the Semeval scoring system.

### 3.4 Ensemble Model

In order to test the use of embedding model similarity scores as downstream features, we train an ensemble system with all features from our 2015 submission along with the similarity scores generated

| Feature     | Gini Coefficient | Description                              |
|-------------|------------------|--|
| paraphrase1 | 0.337            | Vector similarity                        |
| paraphrase2 | 0.073            | Vector similarity with synthetic data    |
| cosine icf  | 0.054            | Normalized cosine similarity             |
| f15         | 0.049            | Weighted Word Match                      |
| f14         | 0.042            | WordNet match                            |
| f20         | 0.038            | Relative length difference               |
| product     | 0.036            | Word2Vec based sentence similarity score |
| f2          | 0.033            | F1-score of number match                 |
| nn1         | 0.028            | Comparing only nouns using Word2Vec      |

**Table 4:** Ensemble model top 10 features in decreasing order

by both the task-internal and synthetic models. This ensemble, which we call “fusion” was our best system overall (see table 2). We used gradient boosting regressor<sup>3</sup> model trained over combined set of previous year’s Semeval STS data sets from 2012-2015. The details of this system are described in (Arora et al., 2015).

### 3.5 Cross-lingual

For our submission to the cross-lingual STS task, we leverage the Google translate API<sup>4</sup> in three ways: the language identification API is used to detect which segments are in Spanish, the translation API is used to translate Spanish sentences into English, and the pivoting method for generating synthetic paraphrases discussed in section 3.2 is used to generate one new paraphrase for each segment in each test instance. We then apply our monolingual embedding methodology to the translated text with no modification.

### 3.6 Training Configuration

For the final systems, we use all existing task-internal training data from the Semeval STS task from 2012-2015. The 2015 datasets were used as validation data to find the best system settings, and then included in the training data for the final systems.  $\delta$  from equation 2 is set to 0.8 for all of our experiments. Embedding dimensionality is 300. We use a minibatch size of 100, and use AdaDelta (Zeiler, 2012) as the gradient update

<sup>3</sup><http://scikit-learn.org/stable/modules/generated/sklearn.ensemble.GradientBoostingRegressor.html>

<sup>4</sup><https://cloud.google.com/translate/>

method. The regularization weight  $\lambda$  is set to  $10^{-5}$  for all models.

| Dataset           | % Unknown |
|-------------------|-----------|
| question-question | 3.2       |
| plagiarism        | 4.9       |
| post-editing      | 4.2       |
| headlines         | 4.86      |
| answer-answer     | 0.81      |

**Table 5:** Total % unknown for each 2016 dataset

The pretrained paragram vectors have a size of 42091; we do not add any new tokens to the index. Table 5 gives the total percentage of each 2016 test dataset which is unknown with respect to our index. Because the baseline paragram vector index does not contain a special “UNKNOWN” token, we randomly choose a low-frequency token to assign as unknown. Some experimentation showed that using a rare token instead of a stopword results in a small performance improvement.

## 4 Results

Our monolingual STS systems all performed better than the median system, with the fusion system slightly outperforming the embedding model trained with synthetic data (see tables 2 and 3).

For all systems in both the monolingual and crosslingual STS tasks, we observe an overall improvement over the Paragram baseline when using task-internal training data, and a further improvement when we incorporate synthetic training examples. This result validates the utility of synthetic paraphrases generated by machine translation, and encourages us to explore this avenue further.

For our ensemble based approach, we analyzed the features using Gini importance<sup>5</sup> (Singh et al., 2010). Table 4 shows the importance of the top 10 features in our ensemble model. The relative impact of our two paraphrase features is very high, confirming the utility of the paragraph embedding model for the STS task.

| Our Features   |
|--|
| task-internal paraphrases, synthetic paraphrases, cosine_icf, product_w2v, nn_w2v, vb_w2v, cosine, sum_w2v, det_1, det_2             |
| TakeLab (Šarić et al., 2012) features  |
| weighted_word_match, wn_sim_match, relative_len_difference, number_features, weighted_dist_sim, case_matches, relative_ic_difference |

**Table 6:** Important features.

## 5 Conclusions

We have presented a method of fine-tuning Paragraph-phrase vectors for the STS task using both task-internal and synthetic paraphrases. Our embedding models achieve surprisingly good performance on the STS task without directly taking advantage of the gold-standard scores during training. We have also introduced a novel method of generating synthetic paraphrases for test instances using machine translation. Finally we have shown that a combination of traditional features with the similarity score learned by our embedding models outperforms each individual system.

Future work will focus on increasing the diversity of the synthetic data, and on incorporating multiple objective functions into different stages of the training process.

## Abstract

This paper describes *iUBC*, a neural network based approach that achieves competitive results on the interpretable STS task (iSTS 2016). Actually, it achieves top performance in one of the three datasets. iUBC makes use of a jointly trained classifier and regressor, and both models work on top of a recurrent neural network. Through the paper we provide detailed description of the approach, as well as the results obtained in iSTS 2015 test, iSTS 2016 training and iSTS 2016 test.

## 1 Introduction

*Semantic Textual Similarity* (STS) aims to catch the degree of equivalence between a pair of text nuggets. *Interpretable STS* (iSTS) is beyond STS in that it adds fine-grained information when evaluating the equivalence between text snippets. This explanatory layer is achieved by **aligning text segments** pertaining to one sentence with the segments pertaining to the second sentence, and, for each alignment, indicating a **relation label** and a **similarity score**.

In sum, alignments consist of a similarity score and a relation label that are defined as follows. On the one hand, the relation label has to be chosen from a set of categorical values (*equivalence, opposition, specialization, similarity and other kind of relation*). On the other hand, the similarity score has to be a real number bounded by (0,5]. Apart from this, there is an extra label to handle *not aligned* text segments.

The present paper describes *iUBC* and its participation in the *International Workshop on Semantic Evaluation* (SemEval-2016) task 2: Interpretable

Semantic Textual Similarity. To check the task in full detail please refer to Agirre et al. (2016). Note that some of the authors participated in the organization of the task. Organizers prevented developers from access to the test dataset, and only allowed to access the same data as the rest of participants.

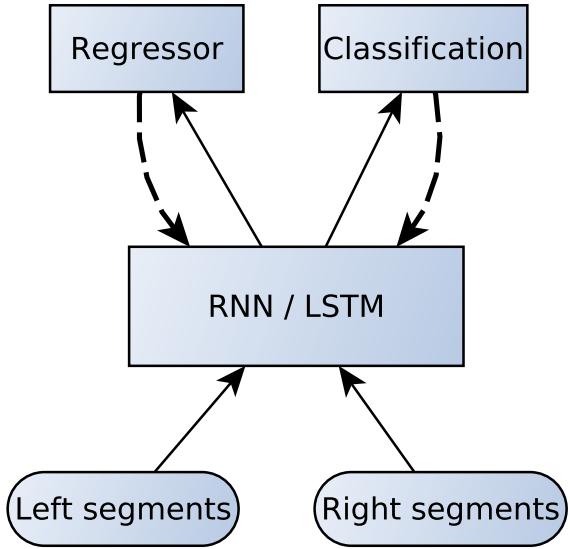

The paper is organized as follows. Section 2 describes iUBC's components, section 3 describes development performance and run configurations, section 4 shows the results obtained in the iSTS 2016 task, and, finally, section 5 mentions the conclusions and future work directions.

## 2 System Description

iUBC is composed of **three components**. The first component, *Input handling and chunking* (section 2.1), is responsible for reading the input and identifying segments over sentences; the second component, *Alignment* (section 2.2), takes care of aligning segments; and, finally, the third component, *Joint classification and scoring* (section 2.3), handles the assignment of similarity scores and relation labels. The main contribution of this architecture resides in the third component, in which a classifier and a regressor have been **trained jointly** on top of a recurrent artificial neural network (ANN).

### 2.1 Input handling and chunking

The iSTS task offers *two different scenarios* as regards the input: the scenario known as *System chunks* (syschunks), where participant systems are responsible for identifying the segments contained in the raw sentence pairs; and the *Gold chunks* scenario (goldchunks), where participants are provided

**Figure 1:** Joint model diagram. In the forward propagation (normal arrow) left and right segments are processed by a recurrent ANN producing as output a d-dimensional vector for each input segment. Features computed out of these vectors are then fed to both a regressor and a classifier that produce the similarity score and the relation label. In the backward propagation (stripped arrow) weights are adjusted in the recurrent ANN combining the gradients that propagate from the above models.

with gold standard segment marks over raw sentence pairs. The current component is only used in the syschunks scenario.

To identify and segment raw input sentences we use *python’s NLTK library* (Bird, 2006) and the *ixa-pipes-chunker* (Agerri et al., 2014). Once the chunks are marked we use regular expressions to tune them according to the task’s chunk definition. We developed four rules to optimize how conjunctions, punctuations and prepositions are handled. These rules aim to merge consequent chunks to form new chunks<sup>1</sup>.

The output of the component are the same sentence pairs as the ones provided as input, but incorporating chunk marks to denote the start and end of segments.

<sup>1</sup>We found significant improvement if prepositional phrases followed by a nominal phrase are unified as a single chunk. The other three rules unify nominal phrases separated by punctuations, conjunctions, or a combination of them. The four rules are coded as regular expressions in Python.

## 2.2 Alignment

The alignment component focuses on making optimal segment connections for each sentence pair. The algorithm is as follows.

To begin with, the module constructs a token-token matrix in which each element  $(i,j)$  determines that there exists a connection between token  $i$  and token  $j$ <sup>2</sup>. The token-token matrix is populated using the weighted sum of the following metrics: lower-cased token overlap, stemmed or lemmatized token overlap, cosine similarity between Mikolov’s pre-trained word vectors (Mikolov et al., 2013) and the alignment prediction provided by the monolingual word aligner described in Sultan et al. (2014).

Once the token-token matrix is built, the alignment component makes use of segment regions to group individual tokens. The strength of each segment connection is proportional to the weights of the interconnected tokens. By carrying out this operation over all segments in the pair the module obtains the chunk-chunk matrix<sup>3</sup>. Once the chunk-chunk matrix has been computed, the last step is to use the Hungarian-Munkres algorithm (Clapper, 2009) to discover the segments  $(x,y)$  that maximize the connection weights.

The alignment is done as follows: the segments that maximize the alignment strength are taken as *alignment main nodes*. Once the process is finished, the segments that are connected with lower weights to either one or the other of the main nodes are incorporated as *satellite nodes*. No many-to-many alignments are produced as we considered further analysis is necessary in order to obtain significant improvement.

## 2.3 Joint classification and scoring

iUBC uses a classification model and a regressor to predict the relation label and the similarity score for aligned segments.

The main picture of this component can be described as a **two layer architecture**, in which, a

<sup>2</sup>Token  $i$  being a token from the first sentence and token  $j$  being a token from the second sentence. Thus, the token-token matrix has a dimensionality of (#sentence1tokens x #sentence2tokens).

<sup>3</sup>This operation can be seen as pooling the token-token matrix by collapsing weights. The chunk-chunk matrix has a dimensionality of (#sentence1segments x #sentence2segments).

classifier and a regressor **work on top of a recurrent ANN**. While the models on the top layer are trained to produce scores and labels, the underlying recurrent net tries to capture the semantic representation of input segments and feed it upwards.

Both models on the top layer are trained in a supervised manner at the same time, and the delta error messages computed on them are used to train the net of the bottom layer. That is, **the gradient propagating from both models on the top layer** is used to train the weights of the ANN (Figure 1). A similar architecture with one top layer propagating gradients to an ANN has previously been used in Tai et al. (2015), which we use as motivation for our work.

The whole model works as follows: the ANN from the bottom layer processes segment words one at a time until there are no more words left. At each time step the net updates its *internal memory state* so that it keeps on capturing the *semantic representation of the segment*. Once the two segments have been processed the net outputs both segment representation d-dimensional vectors. These vectors are used to compute features for the models in the top layer.

Element wise *distance* ( $|\vec{S1}^d - \vec{S2}^d|$ ) and *angle* ( $\vec{S1}^d * \vec{S2}^d$ ) are computed as features, as proposed in Tai et al. (2015). The distance and angle concatenation yields a  $2 * d$ -dimensional vector. This resulting vector is used as input in top layer models.

As regards the top layer models, feedforward neural networks are used for both. All the parameters of the models are summarized in Table 1. The scientific computing framework *Torch* has been used to build the whole component (Collobert et al., 2011). Note that this component doesn't use any type of lexicalized or domain specific feature but Pennington et al. (2014) word embeddings.

### 3 Development

Initial experiments (section 3.2) have been carried out using the official train and test splits from iSTS 2015 (Agirre et al., 2015). The 2016 interpretable STS task released three train datasets: *Images*, *Headlines* and *Answer-Students*. These datasets have been used to train the models using 10-fold cross-validation.

In Section 3.1 we describe in detail the set up of

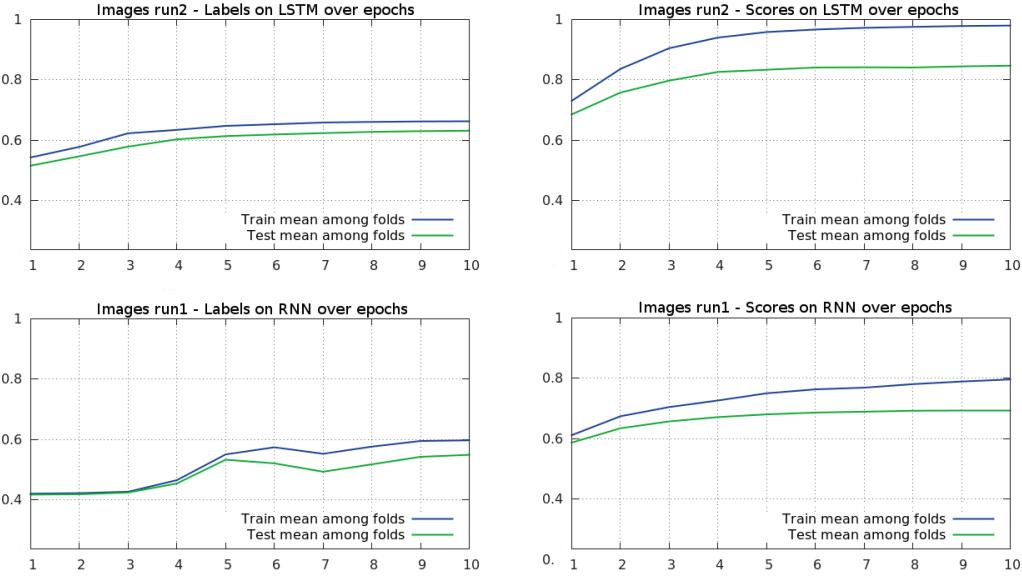

| Bottom layer ANN: RNN or LSTM    |                         |

**Table 1:** All parameters used in the Joint classification and scoring component.

iUBC for each run, Section 3.2 presents the results on iSTS 2015 data, and in Section 3.3 we present the training results from iSTS 2016.

### 3.1 Selection of runs

We developed three runs with the following specific settings: **iUBC\_run1**, the simplest run, uses a 1-layer RNN trained separately on each dataset; **iUBC\_run2**, is the same as run1 but instead of using a 1-layer RNN it employs a 1-layer LSTM; **iUBC\_run3**, is the same as run2 but the datasets are perturbed so they include segments that are not part of the gold standard. To produce this perturbation or noise we combine the gold standard alignments with the system alignments. The aim of doing so is to incorporate some noise in the training data, which we think would be useful to prevent overfitting. Both ANN models (RNN and LSTM) are coded following the equations of Tai et al. (2015).

**Figure 2:** Cross-validation results for the *Joint classification and scoring* component over the iSTS 2015 training data. Figure describes run1 (RNN) and run2 (LSTM) results on the Images dataset. Micro F-score is used to evaluate labels and Pearson correlation coefficient is used to evaluate scores.

**Table 2:** iSTS 2015 test results in Headlines and Images on both scenarios. Baseline, AVG and Max participants rows are taken from iSTS 2015. *F*, *+T*, *+S* and *+TS* stand for the official evaluation metrics F1 Alignment, F1 Type, F1 Score and F1 Type+Score.

### 3.2 Results on iSTS 2015 test

Results obtained using the described runs on iSTS 2015 test data are shown in Table 2. Comparing our runs to the published results, we think they perform competitively. According to the *F* evaluation metric, in both datasets we obtain equal or higher results than the maximum score among participants,

moreover, our second run also obtains the highest results on the *+S* evaluation metric. The *+T* and *+TS* evaluation metrics are the ones in which our runs don't outperform best published results. Yet, they are above participants average in all scenarios, in some cases by large margin.

As regards our runs, we conclude that run2 and run3 outperform run1, but they both perform quite similarly. It seems that the noise added in the third run helps very slightly in the *Images* dataset. We also noticed that the hardest scenario for our runs turns to be the *Headlines* syschunks, where we almost obtain the same results for all runs.

As the majority of the systems participating in the iSTS 2015 task used lexicalized and task specific features or rules, we think iUBC is rather a different approach. It contributes to the task by being a system that doesn't make use of domain specific features but word embeddings while remaining competitive. We also think that results on the iSTS 2016 task will be reasonable as the training data for the iSTS 2016 task duplicates the one of the 2015. Actually, the reduced size of the training data is a matter that worried us. Due to this, for iSTS 2016 we decided not to divide the training data in train and development splits but to use cross-validation.

### 3.3 Results on iSTS 2016 train

Figure 2 shows cross-validation results for the *Joint classification and scoring* component over the *Images* dataset. Due to space constraint we have only included figures for the first and second run.

Comparing the RNN (Figure 2 bottom images) with the LSTM (Figure 2 top images) we can observe that the LSTM is able to fit the dataset with better results in fewer iterations. Actually, the evolution over epochs for the LSTM is smoother than the evolution of the RNN, especially for the labeling task. It seems that the RNN needs more epochs than the LSTM to fit the dataset.

It is also observable the high fitting of the LSTM to the scores of the training data, which is almost reaching the 100% correctness. Yet, this over-fitting seems not to contribute badly towards test results, which are noticeably higher than the RNN’s. On the contrary, for relation labels the fitting is not that high for neither of the networks, even the LSTM outperforms the RNN.

## 4 Results on iSTS 2016 test

Table 3 shows the results obtained by distinct runs respectively in *Headlines*, *Images* and *Answer-Students* datasets.

Overall, iUBC performs competitively being *Headlines* the most difficult dataset to fit in and *Answer-Students* the best. In addition, we can see that both run2 and run3 outperform run1 by a large margin. Actually, the results scored by run1 are not that good as it scores below the participants’ average. The main conclusion drawn from these result tables as regards run1 is that RNNs are not able to fit these datasets as well as LSTMs do.

Concerning run2 and run3 we expected run3 to outperform run2 on *syschunk* scenarios because of the noise it has been trained with. Nevertheless, this behavior can only be observed in *Headlines*, as in *images* run2 scores better than run3 and in *Answer-Students* they both score equally. The noise also seems not to affect *gschunks* scenarios very badly as in *Headlines* and *Anser-students* both runs score equally. Even though, run3’s performance worsens 3 points in *Images* dataset on this scenario.

As pointed out in section 3.2 the *F* evaluation metric and the *+S* evaluation metric continue to be the

**Table 3:** iSTS 2016 test results in Headlines, Images and Answers-Students on both scenarios. Baseline, AVG and Max participants rows are taken from iSTS 2016. *F*, *+T*, *+S* and *+TS* stand for the official evaluation metrics F1 Alignment, F1 Type, F1 Score and F1 Type+Score.

ones in which iUBC scores best. Being sometimes (primarily on *gschunks* scenario) the top performing system above the participants’ maximum. On the contrary, it is harder for the system to perform on the *+T* evaluation metric. This is related to what have been described in section 3.3. That is, the system finds it more difficult to fit the dataset labels than the scores. The main conclusion drawn from here could be that not only word embeddings, but also lexicalized features may be necessary in order to continue improving performance. Similar conclusions are achieved in Yin et al. (2015) regarding to the concatenation of word embedding based features and other kind of features.

## 5 Conclusions and Future Work

Throughout this paper we have described *iUBC*: a RNN and LSTM based system that has achieved reasonable results on the interpretable STS 2016 task. We have seen how the system works by **jointly training** a classifier and a regressor to produce the

relation labels and the similarity scores. We have also described how the error gradient from this top layer propagates to the bottom recurrent net, which aims to capture the semantic representation of input sentences into d-dimensional vectors.

We have shown performance of the system in the iSTS 2016 test data and described that iUBC **performs especially well** in the *Answer-Students dataset*. In addition, we have mentioned that the RNN based run is not able to perform as well as **LSTMs based runs**. Moreover, we have seen that including **noise in the training** data helps improve performance in the *Headlines* dataset on the *syschunks* scenario. But, worsens results in the *Images* dataset on the *gschunks* scenario.

We have also discussed that the model is more suitable to produce **similarity scores** than relation labels. This could be a consequence of the reduced size of the training data and labeling being a more demanding task. As regards this issue, we have mentioned that further features might be necessary in order to continue improving the system’s results. In any case, this will require some more analysis.

All in all, we can conclude by saying that the interpretable STS task is an **interesting challenge** whose aim is to share knowledge about building NLP systems able to provide valuable feedback.

## Abstract

We present the description of our submission to SemEval-2016 Task 2, for the sub-task of aligning pre-annotated chunks between sentence pairs and providing similarity and relatedness labels for the alignment. The objective of the task is to provide interpretable semantic textual similarity assessments by adding an explanatory layer to aligned chunks. We analysed the provided datasets, considering lexical overlap, the part of speech tags and the synonyms of the words in the chunks, and developed a rule-based system reflecting that analysis. Our system performance indicates that when sentence pairs are similar, alignment of chunks can be performed fairly well using lexical information alone without syntactic or semantic analysis. The advantage of our system is that we can easily trace when chunks are aligned.

## 1 Introduction

We developed a system for SemEval-2016 Task 2: “Interpretable Semantic Textual Similarity” (Agirre et al., 2016), which requires the development of a system that labels aligned chunks of a sentence pair, in terms of their similarity or relatedness. Our approach is based on a detailed analysis of the provided annotation guidelines for the task and the annotated training data.

The annotation guidelines for the task indicate how to align the chunks of two sentence pairs and how to label the similarity or relatedness types and assign scores. Annotations are provided for three different training sets: headlines, images and student

responses to questions. Chunks consist of a word or contiguous words. The training sets come in the form of sentence pairs, pre-annotated chunks with their alignment and alignment labels.

The number of sentence pairs for the training and test sets supplied is, respectively: headlines – 726 and 375; images – 750 and 375; and student answers – 330 and 344. The test sets come with the pre-annotated chunks but without alignments or labels. Participants of the sub-task are required to align the pre-annotated chunks and provide the similarity and relatedness assessment for the alignment, which is considered as an explanatory layer that enriches measurement of similarity between the sentence pairs.

The alignment types are semantically equivalent (EQUI), opposite in meaning (OPPO), similar in meaning but specific to the chunk in the first sentence (SPE1), similar in meaning but specific to the chunk in second sentence (SPE2), similar in meaning (SIMI) and related in meaning (REL). Additional types, are factuality (FACT) and polarity (POL). For chunks with no alignment, the label is NOALI. The similarity and relatedness scores are 5 for equivalent (i.e. EQUI//5), [4, 3] for very similar or closely related, [2, 1] for slightly similar or somehow related and 0 for completely unrelated (i.e. NOALI//0).

In order to demonstrate that the relationship between chunks are based on lexical selection, Abney (1991) uses context-free grammar to describe the structure of chunks, providing a definition of a chunk from a linguistic perspective, which he hypothesizes is closer to how humans parse texts. His

definition provided room for computational implementation. Thus, for this SemEval sub-task, we attempt to understand how lexical overlap, syntactic (more precisely, Part of Speech (PoS) categories), and word synonyms can be used to align chunks, as this information is not provided. Even though string, substring and approximate string matching have been well studied (Yu et al., 2006; Chang and Lawler, 1990; Cole and Hariharan, 2002; Gusfield, 1997), there have been fewer attempts to assess similarity based on not only lexical/character-level overlap but also incorporating other linguistic characteristics. Therefore we attempt to explore the use of this more linguistic information in chunk alignment. We manually examined the annotation guidelines and training set supplied to understand how the chunks are aligned and how the similarity and relatedness labels may be assigned based on this information. Our objective is to develop rules for an automatic system that can effectively align and label the chunks between sentence pairs.

## 2 Data Analysis

We perform manual data analysis considering lexical matches, part of speech (PoS) categories and synonyms on the headlines training set and derived the rules based on our observation. Through an iterative process, we observed how well the rules derived generalise to the other two training sets (i.e., images and student-answers) and refined the rules. Due to time constraints, the rules were derived mostly from headlines training set and tested on the other two datasets with limited rule refinement iterations from the other two datasets. We summarise our rules below according to the type of lexical match, noting how they correspond to alignment label and score.

**[Punctuations]**, such as full stop and comma, which are pre-annotated as individual chunks, do not align.

**[Identical string]** Two identical chunks align directly, and indicate equivalence with relatedness of 5. For example, injured  $\iff$  injured; in Iraq  $\iff$  in Iraq. Although the label EQUI//5 is provided, its interpretation as direct lexical matching is confirmed.

**[Sub-string]** Lexical overlap where the chunk from

one sentence is a proper sub-string of another generally results in alignment to create similar meaning, with one chunk being more specific than the other (SPE1 or SPE2). For example: SPE1//gay marriage bill  $\iff$  gay marriage; SPE2//airstrike  $\iff$  new airstrike.

The following generalisations are also made:

- [Verb and verb agreement] If the PoS tag for the words in the chunks is a verb, direct matching with an addition of ‘s’ on any of the chunks will produce alignment of EQUI//5. For example: kill  $\iff$  kills; recognizes  $\iff$  recognize. This captures the situation that not all EQUI//5 cases are direct matching; in this case the verb is aligned and the variation reflects only verb agreement.
- [Plural and singular] If the PoS for the words in both the chunks is a noun, direct lexical overlap, with an addition of ‘s’ on each side will produce alignment SIMI//4. For example: Suicide bomber  $\iff$  Suicide Bombers; despite concession  $\iff$  despite concessions. This occurs when the chunks are the same noun, but plural/singular variants.
- [Syntactic function ‘to’] Direct matching of ‘to’ on either side of the chunks will create alignment of EQUI//5. For example: to vote  $\iff$  vote; to NZ same-sex marriage  $\iff$  New Zealand same-sex marriage

**[Number]** For chunks containing numbers, several subcases apply.

- [Same value]. Two chunks containing the same number results in EQUI//5. For example: at 91  $\iff$  aged 91; Boeing 787 Dreamliner  $\iff$  on 787 Dreamliner
- Otherwise, chunks with digits are aligned to produce alignment label of SIMI. The Relatedness score depends on the differences of the digits extracted from the chunks. We have identified the following heuristics:

- If the difference is greater than 100, alignment will produce Relatedness of 1 (e.g., to 35 years  $\leftrightarrow$  to 1,000 years)
- If the difference is between 30 and 100, assign Relatedness 2 (e.g., At least 45  $\leftrightarrow$  At least 13)
- If the difference is between 7 and 10, assign Relatedness 3 (e.g., 17  $\leftrightarrow$  10)
- if the difference is less than 7, assign Relatedness 4 (e.g., 17  $\leftrightarrow$  15)

**[Single word match]** Generally, if a single word in a chunk is string equivalent to a word in another multi-word chunk, they will align. For example: in bus accident  $\leftrightarrow$  in road accident. The following related generalisations are also made:

- [Synonymous] If the two chunks contain a synonymous word rather than an identical word, the chunks are aligned and given labels of EQUI//5. For example: China stocks  $\leftrightarrow$  Chinese stocks; From Soccer  $\leftrightarrow$  from football.
- [PP - modifier to head noun] If the words in the chunks are prepositional phrases (PP) with the same head noun but different modifiers, the chunks are aligned with a label of SIMI//4. For example: as legitimate representative  $\leftrightarrow$  as sole representative.
- [NP - different head noun] If both the words in the chunks are noun phrases (NP) and the matching word is an adjective, the chunks are aligned as REL. For example: economic traps  $\leftrightarrow$  economic growth; French train  $\leftrightarrow$  French train passengers.

Through stemming, individual words in the chunks are converted to root word.

**[Same root word]** Chunks that can be converted to same root word, are aligned as EQUI//5. For example: detained  $\leftrightarrow$  detains; summoned  $\leftrightarrow$  summons.

**[Synonymous root word]** If the root words are synonymous, aligned as EQUI//5 (for example: to permit  $\leftrightarrow$  Allowed)

**[Misc]** A few recurrent cases appeared in training set like OPPO//5 (e.g.: higher  $\leftrightarrow$  lower) and OPPO//4 (e.g.: close  $\leftrightarrow$  open); these chunks are matched as antonyms.

### 3 Methodology

In order to understand the effect of lexical overlap in aligning chunks between sentences, we developed two separate systems: LexiM and Rev, although we only submitted one run for this sub-task, which is the Rev system. Both systems are implemented in Java and strictly rule-based systems. LexiM, a system purely based on lexical overlap contained 13 rules. The rules are based on string or sub-string matches, which follow the category of our data analysis but excluding cases that considers PoS or word synonym, or the rules that require conversion to root word. We performed error analysis on the other training sets but the overall performance is compared to the baseline approach supplied by the organiser (Table 1).

Rev extends LexiM by adopting the rules of LexiM as outlined in Section 2 (excluding the Misc rule), with addition of string distance and semantic similarity-based strategies. LexiM works to align chunks which have lexical overlap, while string similarity and semantic distance work in two ways. The first way is to align chunks that cannot be handled with those rules and follow by assigning labels to the aligned chunks. The second way is for the chunks that are aligned through LexiM, the string distance and semantic similarity rule will provide similarity and relatedness labels. There are existing tools which perform tasks such as string distance measurement like SecondString (Cohen et al., 2003) and stringmetric (Madden, 2013), PoS taggers like Stanford Parser (Klein and Manning, 2003), and dictionary for synonymous words like WordNet (Fellbaum, 1998). Cohen et al. (2003) shows that Jaro-Winkler is an effective string distance metric for name matching task. Liu et al. (2010) has shown that TESLA, a similarity metric that considers both PoS tags and semantic equivalence (based on WordNet synsets), is effective in the task of auto-

matic evaluation of machine translation in English language. We used Jaro-Winkler proximity (SecondString implementation) for string distance measurement, and TESLA for semantic similarity measurement.

We analyzed the chunks in terms of their string distance and semantic similarity scores, relating the scores to the similarity and relatedness types and scores in the annotated data. We identified the lowest, average and highest values for the string distance and semantic similarity measures for each association type and score, for example: REL//1 corresponds to {string distance: 0.0, 0.19, 0.43} and {semantic similarity: 0.04, 0.18, 0.5}. Subsequently, we developed rules for alignment using string distance and semantic similarity where both ranges must be satisfied in order for the rules to be applied. Chunks that do not fulfill any of the rules or similarity criteria will be assigned as NOALI//0.

## 4 Results and Discussion

The evaluation method determined by the organiser is  $F_1$ -score (Powers, 2011). As shown in our results tables (Table 1 and 2),  $F_1$ -score is calculated separately for the aligned chunks (Ali), the alignment type (Type), the similarity and relatedness score (Score) and combination of alignment type and score (Typ+Sco).

The performance of LexiM helps to understand the effect of lexical overlap and sub-string matches in aligning chunks between sentence pairs. We compared the results to the baseline approach (Agerri et al., 2014) provided (Table 1, the Student-Answers baseline is not provided (NS)). The baseline approach is a multilingual Natural Language Processing (NLP) tool that can perform tokenization and segmentation, statistical POS tagging and lemmatization, Named Entity Recognition tagger, probabilistic chunker and constituent parser for several languages, including English. LexiM, although consists of lexical overlap and sub-string matches rules, outperformed the baseline (Table 1). This demonstrates that alignment of chunks can be performed purely using lexical matching; the lexical information was useful for identifying overlaps between the chunks, especially in the case of similar sentences.

Some of the examples where LexiM produces

| Dataset         | Baseline     | LexiM        | Rev          |

correct alignment with the wrong type and score: a baby  $\Leftrightarrow$  holding a baby; sitting  $\Leftrightarrow$  sit; is not connected  $\Leftrightarrow$  are not connected; at the negative connection.  $\Leftrightarrow$  the battery. There are cases where the alignment by LexiM is interpretable. For example in the images dataset, LexiM produced SPE1//4//in front of yellow flowers  $\Leftrightarrow$  in a field, while gold standard labels is SIMI//2. Another case, LexiM produced SPE2//4//sheep  $\Leftrightarrow$  A sheep while the standard labels are EQUI//5. Even if only two sentences with the chunks are provided, the system is able to produce a reasonable alignment of the chunks.

We observed slight improvement in  $F_1$ -scores between LexiM and Rev. The difference between LexiM and Rev is additional lexical information like PoS and synonym. We performed error analysis on the output of LexiM and Rev with comparison to the baseline approach which uses probabilistic approach. We performed error analysis to understand this better: Rev produced correct alignment and labels EQUI//5//sleeps  $\Leftrightarrow$  asleep considering the both words are synonymous, while LexiM is able to align the chunks lexically with wrong labels and the baseline approach fails to align the chunks; Rev is able to align standing  $\Leftrightarrow$  grazing but with wrong labels, while LexiM and the baseline approach fails to align the chunks. This shows that adding additional information like PoS and syn-

**Table 2:** Official Results

onym can assist in alignment and labelling of the aligned chunks.

The overall performance of Rev using the test sets is presented in Table 2. As stated previously, the rules are derived mostly from the headlines dataset. Therefore it is unsurprising that Rev exhibits the best performance over the headlines test set. Indeed, it performs slightly better on the headlines test set than on the corresponding training set; although the reasons for this are unclear, it suggests that the rules captured in Rev have indeed captured reasonable generalizations.

Unfortunately, Rev did not perform well for the other two datasets because the rules are too specific to the headlines dataset. There are many more other potential rules which could be derived from the other datasets; more targeted effort in rule development for those data sets would improve the performance of Rev. It is also clear from the results that the current rules in Rev are quite brittle; they did not perform well in comparison to other submissions for the task.

Using the chunk alignments produced by Rev, we can easily provide an explanation for the alignment by highlighting the rule that facilitated the alignment. Here are some examples of this, concentrating on cases without direct lexical matching:

[Synonymous root word] a set of stairs  
 $\iff$  steps.

[Synonymous root word] jumps  $\iff$  leaps.

[Number] 22 Dead  $\iff$  89 dead.

[Plural and singular] The dog  $\iff$  Three dogs.

The weakness of Rev is that the rules are limited

to the direct observations of the training set, and only consider a narrow set of linguistic characteristics. Clearly, other linguistic rules could be incorporated. For instance, an antonym dictionary could be consulted; this would directly benefit the OPPO label included in the task.

## 5 Conclusion

Based on the observation that pairs of chunks that align are often lexically very similar, we have concentrated on alignment using a lexical approach. Although deriving and iteratively refining rules manually is a time consuming process, this process is helpful to build an interpretable semantic textual similarity system.

As future work, we plan to directly include an indication of the rule that produced the alignment as an additional explanation in the output, beyond the similarity and relatedness scores and types alone. There are many other types of linguistic analysis that can be performed and we will consider incorporating these as future enhancements to our system.

## Abstract

In this paper we present our system developed for the SemEval 2016 Task 2 - Interpretable Semantic Textual Similarity along with the results obtained for our submitted runs. Our system participated in the subtasks predicting chunk similarity alignments for gold chunks as well as for predicted chunks. The Inspire system extends the basic ideas from last years participant NeRoSim, however we realize the rules in logic programming and obtain the result with an Answer Set Solver. To prepare the input for the logic program, we use the PunktTokenizer, Word2Vec, and WordNet APIs of NLTK, and the POS- and NER-taggers from Stanford CoreNLP. For chunking we use a joint POS-tagger and dependency parser and based on that determine chunks with an Answer Set Program. Our system ranked third place overall and first place in the Headlines gold chunk subtask.

## 1 Introduction

Semantic Textual Similarity (STS), refers to the degree of semantic equivalence between a pair of texts. This helps in explaining how some texts are related or unrelated. In Interpretable STS (iSTS) systems, further explanation is provided as to why the two texts are related or unrelated. Finding these detailed explanations helps in gathering a meaningful representation of their similarities.

The competition at SemEval 2016 was run on three different datasets: Headlines, Images and

Student-Answers. Each dataset included two files containing pairs of sentences and two files containing pairs of gold-chunked sentences. Either the gold chunks provided by the organizers or chunks obtained from the given texts would be used as input to the system. The expected outputs of the system are m:n chunk-chunk alignments, corresponding similarity scores between 0 (unrelated) and 5(equivalent), and a label indicating the type of semantic relation. Possible semantic relations are EQUI (semantically equal), OPPO (opposite), SPE1/SPE2 (chunk 1/2 is more specific than chunk 2/1), SIMI (similar but none of the relations above), REL (related but none of the relations above), and NOALI (not aligned, e.g., punctuation). All relations shall be considered in the given context. For details see the companion paper (Agirre et al., 2016).

Similarity alignment in the Inspire system is based on ideas of previous year's NeRoSim (Banjade et al., 2015) entry, however we reimplemented the system and realize the rule engine in Answer Set Programming (ASP) (Lifschitz, 2008; Brewka et al., 2011) which gives us flexibility for reordering rules or applying them in parallel. To account for differences in datasets we detect the type of input with a Naive Bayes classifier and use different parameter sets for each of the datasets.

Chunking in the Inspire system is based on a joint POS-tagger and dependency parser (Bohnet et al., 2013) and an ASP program that determines chunk boundaries.

In Section 2 we give preliminaries of ASP, Section 3 describes how we represented semantic alignment in ASP, in Section 5 we explain parameter sets used for different datasets, Section 4 briefly outlines our chunking approach, and we give evaluation results in Section 6.

## 2 Answer Set Programming (ASP)

Answer Set Programming (ASP) (Lifschitz, 2008; Brewka et al., 2011) is a logic programming paradigm based on rules of the form:

$$a \leftarrow b_1, \dots, b_m, \text{not } b_{m+1}, \dots, \text{not } b_n$$

where  $a$ ,  $b_i$  are atoms from a first-order language,  $a$  is the head and  $b_1, \dots, \text{not } b_n$  is the body of the rule, and **not** is negation as failure. Variables start with capital letters, facts (rules without body condition) are written as ‘ $a.$ ’ instead of ‘ $a \leftarrow$ ’. Intuitively  $a$  is true if all positive body atoms are true and no negative body atom is true. ASP is declarative, i.e., the order of rules and the order of body atoms in rules does not matter (different from Prolog), a popular usage pattern of ASP is to create three program modules called Generate, Define, and Test, which (i) generate a space of potential solutions, (ii) define auxiliary concepts, and (iii) eliminate invalid solutions using constraints, respectively. ASP allows encoding of nondeterministic polynomial time (NP)-hard problems, solver tools usually first instantiate the given program and then find solutions of the variable-free theory using adapted Satisfiability (SAT) solvers. Apart from normal atoms and rules, ASP supports aggregates and other constructions, for details we refer to the ASP-Core-2 standard (Calimeri et al., 2012). In this work we use the ASP solvers Gringo and Clasp (Gebser et al., 2011) as a Python library.

## 3 Alignment based on ASP

For each sentence pair, we align chunks in the following architecture:

- Chunked input sentence pairs are preprocessed (POS, NER, Word2Vec, WordNet) and represented as a set of ASP facts (3.1).
- A generic set of rules represents how alignments can be defined and changed (3.2).

- We represent alignments based on the description of the NeRoSim engine (3.3).
- We evaluate the above components in an ASP solver, obtaining answers sets containing a representation of alignments. From this we create the system output file (3.4).

### 3.1 Preprocessing

In this step we create facts that represent the input, including lemmatization via NLTK (Bird, 2006), POS- and NER-tagging from Stanford CoreNLP (Manning et al., 2014), lookups in WordNet (Miller, 1995), and similarity values obtained using Word2Vec (Mikolov et al., 2013).

We explain the input representation of the following sentence pair:

```
[ A tan puppy ] [ being petted ] [ . ]
[ A tan puppy ] [ being held and petted ] [ . ]
```

We first represent sentences, chunks, and words in chunks with POS-tags, NER-tags, and lowercase versions of words as follows:

```
sentence(1).
chunk(sc(1, 0)).
chunk(sc(1, 1)).
chunk(sc(1, 2)).
mword(cw(sc(1, 0), 1), "A", "a", "DT", "O").
mword(cw(sc(1, 0), 2), "tan",
      "tan", "NN", "O").
mword(cw(sc(1, 0), 3), "puppy",
      "puppy", "NN", "O").
...
sentence(2).
chunk(sc(2, 0)).
...
```

Intuitively a sentence ID is an integer, a chunk ID is a composite  $sc(sentenceID, chunkIdx)$ , and a word ID is a composite  $cw(chunkID, wordIdx)$ .

We detect punctuation, cardinal numbers, and dates/times using regular expressions and represent this as facts  $punct(\cdot)$ ,  $cardinalnumber(\cdot)$ , and  $datetime(\cdot)$ , resp., e.g.,

```
punct(cw(sc(1, 2), 0)).
```

We lookup synonyms, hypernyms, and antonyms in WordNet and add the respective facts.

```

synonym("a", "a").
synonym("a", "vitamin a").
synonym("tan", "burn").
hypernym("puppy", "dog").
hypernym("puppy", "domestic_dog").
hypernym("puppy", "canis_familiaris").
...

```

We use distributional similarity with the Word2Vec tool (Mikolov et al., 2013) trained on the One Billion Word<sup>1</sup> benchmark (Chelba et al., 2014) with SkipGram context representation, window size 10, vector dimension 200, and pruning below frequency 50. Word-word similarity  $sim(v, w)$  is computed using cosine similarity from scikit-learn (Pedregosa et al., 2011), between vectors of words  $v$  and  $w$ . We compute chunk-chunk similarity as

$$\frac{best(1, 2) + best(2, 1)}{2 \min(n_1, n_2)}, \text{ where} \quad (1)$$

$$best(x, y) = \sum_{i=1}^{n_x} \max_{j=1}^{n_y} sim(w_i^x, w_j^y)$$

with  $n_x$  the number of words in chunk  $x$  and  $w_b^x$  the word of index  $b$  in chunk  $x$ . This is based on (Banjade et al., 2015, Section 2.2.2).

We represent chunk-chunk similarity as atoms  $chunksimilarity(chunk1Id, chunk2Id, S)$ . In our example this creates, e.g., the following facts.

```

chunksimilarity(sc(1, 0), sc(2, 0), 101).
chunksimilarity(sc(1, 0), sc(2, 1), 22).
chunksimilarity(sc(1, 0), sc(2, 2), 2).
chunksimilarity(sc(1, 1), sc(2, 0), 34).
...

```

Note that similarity can be above 100 due to dividing by the shorter chunk length.

### 3.2 Rule Engine

To make POS, NER, word, and lowercase words more accessible, we project them to new facts

---

<sup>1</sup><http://www.statmt.org/lm-benchmark/>

with the following rules

```

word(Id, W) ← mword(Id, W, __, __, __).
lword(Id, L) ← mword(Id, __, L, __, __).
pos(Id, P) ← mword(Id, __, __, P, __).
ner(Id, N) ← mword(Id, __, __, __, N).

```

where the arguments of  $mword$  are word ID, word, lowercase word, POS and NER tag.

Variables of the form ‘ $\underline{\ }$ ’ are anonymous, intuitively these values are projected away before applying the rule.

We interpret POS and NER tags, and mark nouns, verbs, contentwords, proper nouns, cardinal numbers and locations based on tags from the Penn Treebank (Marcus et al., 1993).

```

noun(Id) ← pos(Id, "NNS").
noun(Id) ← pos(Id, "NNP").
verb(Id) ← pos(Id, "VB").
verb(Id) ← pos(Id, "VBD").
...
location(Id) ← ner(Id, "LOCATION").

```

We ensure symmetry of chunk similarity, synonyms and antonyms, and transitivity of the synonym relation.

```

chunksimilarity(C2, C1, S) ←
    chunksimilarity(C1, C2, S).
synonym(W, W') ← synonym(W', W).
antonym(W, W') ← antonym(W', W).
synonym(W1, W3) ← synonym(W1, W2),
    synonym(W2, W3).

```

We define pairs of chunks that can be matched together with their sentence indices. This is useful because this way we can define conditions on potential alignments without specifying the direction of alignment (1 to 2 vs. 2 to 1).

```

chpair(S1, S2, sc(S1, C1), sc(S2, C2)) ←
    chunk(sc(S1, C1)), chunk(sc(S2, C2)), S1 ≠ S2.

```

We represent alignments as follows:

- (i) alignment happens in steps that have an order defined by atoms  $nextStep(S, S')$  which indicates that  $S$  happens before  $S'$ ,

- (ii) a chunk can be aligned to one or more chunks only within one step, afterwards alignment cannot be changed,
- (iii) program modules can define atoms of form  $chalign(C_1, R, Sc, C_2, St)$  which indicates that chunks  $C_1$  and  $C_2$  should be aligned with label  $R$  (e.g., "EQUI") and score  $Sc$  (e.g., 5) in step  $St$ .

Defining an alignment is possible if the chunks are not yet aligned, it marks both involved chunks as aligned, and they stay aligned.

```

aligned(C, S') ← not aligned(C, S),
  chalign(C, __, __, __, S), nextStep(S, S').

aligned(C, S') ← not aligned(C, S),
  chalign(__, __, __, C, S), nextStep(S, S').

aligned(C, S') ← aligned(C, S), nextStep(S, S').

```

Final alignments (that are interpreted by Python) are represented using predicate *final*, these atoms include raw chunk similarity (for experimenting with other ways to define the similarity score). Moreover only steps that are used (in *nextStep*( $\cdot, \cdot$ )) are included.

```

usedStep(S) ← nextStep(S, __).
usedStep(S') ← nextStep(__, S').
final(C1, Rel, Score, C2, S, Simi) ←
  chalign(C1, Rel, Score, C2, S),
  not aligned(C1, S), not aligned(C2, S),
  usedStep(S), chunksimilarity(C1, C2, Simi).

```

This system gives us flexibility for configuring the usage and application of the order of rules by defining *nextStep* accordingly (see Section 5).

### 3.3 NeRoSim Rules

All that remains is to realize the NeRoSim rules, labeled with individual steps, and add them to the program.

In the following we give an example of how we realize NeRoSim's condition  $C_1$  (one chunk has a conjunction and other does not).

```

cond1(C1, C2) ← chpair(__, __, C1, C2),
#count{W1 : conjunction(cw(C1, W1))} = 0,
#count{W2 : conjunction(cw(C2, W2))} ≥ 1.

```

Intuitively, the  $\#count$  aggregates become true if the appropriate number of atoms in the set becomes true.

As a second example, our adaptation of rule  $SP_1$  for SPE1/SPE2 alignments defines  $sp1(C_1, C_2)$  if  $cond_1$  holds between  $C_2$  and  $C_1$  and if  $C_1$  contains all content words of  $C_2$ . Note that  $contentword\_subset(A, B)$  is defined separately for chunks  $A, B$  if  $B$  contains all content words of  $A$ .

```

sp1(C1, C2) ← chpair(__, __, C1, C2),
  cond1(C2, C1), contentword_subset(C2, C1).

```

We use  $sp1$  in our stepwise alignment engine by defining *chalign* with SPE1 and SPE2 according to which *sentence* is more specific.

```

chalign(C1, "SPE1", 4, C2, sp1) ←
  chpair(1, 2, C1, C2), sp1(C1, C2).

chalign(C1, "SPE2", 4, C2, sp1) ←
  chpair(1, 2, C1, C2), sp1(C2, C1).

```

For reasons of space we are unable to list all NeRoSim rules and their ASP realization. For the description of rules NOALIC, EQUI(1–5), OPPO, SPE1/2(1–3), SIMI(1–5), REL, we refer to (Banjade et al., 2015).

The full ASP code is publicly available.<sup>2</sup>

### 3.4 Interpretation of Answer Sets

After the evaluation of the above rules with the facts that describe the input sentences (Section 3.1) the solver returns a set of answer sets (in our case a single answer set). This answer set contains all true atoms and we are interested only in the *final* predicates.

```

word(cw(sc(1, 1), 4), "being").
word(cw(sc(1, 1), 5), "petted").
word(cw(sc(2, 1), 4), "being").
word(cw(sc(2, 1), 5), "held").
word(cw(sc(2, 1), 6), "and").
...
final(sc(1, 0), "EQUI", 5, sc(2, 0), equi1, 101).

```

---

<sup>2</sup><https://bitbucket.org/snippets/knowlp/yrjqr>

*final(sc(1, 1), "SPE2", 4, sc(2, 1), sp1, 106).*

From these predicates we create the required output which is a single continuous line of the following form:

```
4 5 6 <==> 4 5 6 7 // SPE2 // 4 //
being petted <==> being held and petted
```

#### 4 Chunking based on ASP

For this subtrack, the system has to identify chunks and align them. The Inspire system realizes chunking as a preprocessing step: sentences are tokenized and processed by a joint POS-tagger and parser (Bohnet et al., 2013). Tokens, POS-tags, and dependency relations are represented as ASP facts and processed by a program that roughly encodes the following:

- chunks extend to child tokens until another chunk starts, and
- chunks start at (i) prepositions, except ‘of’ in ‘in front of’; (ii) determiners, unless after a preposition; (iii) punctuations (where they immediately end); (iv) adverbs; (v) nodes in an appositive relation; and (vi) nodes having a subject.

These rules were created manually to obtain a result close to (Abney, 1991).

#### 5 Experiments and Parameters

Our system does not require training, so we tested and optimized it on the training data for Headlines (H), Images (I), and Student-Answers (S) datasets. As a criteria for accuracy the competition used the F1 score based on alignments (A), alignments and alignment type (AT), alignments and alignment score (AS), and full consideration of alignment, type, and score (ATS).

Our optimization experiments showed us, that there are significant differences in annotations between datasets. In particular S contains spelling mistakes, verbs are often singleton chunks in H, and ‘to’ and ‘s’ often start a new chunk in H, while they are annotated as part of the previous chunk in I and S.

Therefore we decided to configure our system differently for each dataset, based on a Multinomial Naive Bayes Classifier trained on input

unigrams and bigrams implemented using scikit-learn (Pedregosa et al., 2011). F1-score obtained on training data with 10-fold cross-validation was 0.99.

Our dataset configuration is as follows: we exclude stopwords from the calculation of similarity (1) for datasets H and I by using the NLTK corpus of stopwords; we remove non-singleton punctuation for dataset S; and we add rules to handle verb types (VBP, VBZ) as punctuation and ‘s’ as a preposition in chunking.

We optimized parameters for 3 runs according to different criteria.

**Run 1** is optimized for the full label (ATS). We used our implementation of NeRoSim rules in the same order, except SI4, SI5, and RE1, which we excluded. In ASP this is configured by defining facts for *nextStep(s, s')* where

$$(s, s') \in \{(noalic, equi1), (equi1, equi2), \\ (equi2, equi3), (equi3, equi4), (equi4, equi5), \\ (equi5, oppo), (oppo, sp1), (sp1, sp2), (sp2, sp3), \\ (sp3, simi1), (simi1, simi2), (simi2, simi3), \\ (simi3, result)\}.$$

**Run 2** is optimized for prediction of alignment (A), this is done by using all NeRoSim rules in their original order: we define *nextStep(s, s')* for

$$(s, s') \in \{(noalic, equi1), (equi1, equi2), \\ (equi2, equi3), (equi3, equi4), (equi4, equi5), \\ (equi5, oppo), (oppo, sp1), (sp1, sp2), (sp2, sp3), \\ (sp3, simi1), (simi1, simi2), (simi2, simi3), \\ (simi3, simi4), (simi4, simi5), (simi5, rel1), \\ (rel1, result)\}.$$

In addition, for dataset S we perform automated spelling correction using Enchant.<sup>3</sup>

**Run 3** is based the observation, that the scorer tool does not severely punish overlapping alignments in the F1-score of A. Hence we allow SIMI4, SIMI5, and REL1 to be applied simultaneously by defining *nextStep(s, s')* for

$$(s, s') \in \{(noalic, equi1), (equi1, equi2),$$

---

<sup>3</sup><http://www.abisource.com/projects/enchant/>

$(equi2, equi3), (equi3, equi4), (equi4, equi5),$   
 $(equi5, oppo), (oppo, sp1), (sp1, sp2), (sp2, sp3),$   
 $(sp3, simi1), (simi1, simi2), (simi2, simi3),$   
 $(simi3, simi4), (simi3, simi5), (simi3, rel1),$   
 $(simi4, result), (simi5, result), (rel1, result)\}.$

Accordingly, we expected Run 1 to perform best with respect to the ATS (and AT) metric, Run 2 to perform best with respect to A (and AS) metrics, and Run 3 to sometimes perform above other runs. These expectations were confirmed by the results shown in the next section.

## 6 Results and Conclusion

The results of the competition, obtained with the above parameter sets, are shown in Table 1.

The Inspire system made use of a rule-based approach using Answer Set Programming for determining chunk boundaries (based on a representation obtained from a dependency parser) and for aligning chunks and assigning alignment type and score (based on a representation obtained from POS, NER, and distributed similarity tagging). In team ranking, our system is among the top three systems for Headlines and Images datasets, and in overall ranking (both for system and gold chunks). In terms of runs (each team could submit three runs), our system obtains first and second place for Headlines with gold standard chunks. For Student-Answers dataset our system performs worst. The configuration of Run 1 performs best in all categories.

In future work we want to represent semantic knowledge in ASP externals (Eiter et al., 2015), and use ASP guesses, constraints, and optimization as outlined in (Lierler and Schüller, 2013).

## Abstract

We present the system developed at FBK for the SemEval 2016 Shared Task 2 "Interpretable Semantic Textual Similarity" as well as the results of the submitted runs. We use a single neural network classification model for predicting the alignment at chunk level, the relation type of the alignment and the similarity scores. Our best run was ranked as first in one the subtracks (i.e. raw input data, Student Answers), among 12 runs submitted, and the approach proved to be very robust across the different datasets.

## 1 Introduction

The Semantic Textual Similarity (STS) task measures the degree of equivalence between the meaning of two texts, usually sentences. In the Interpretable STS (iSTS) (Agirre et al., 2016) the similarity is calculated at chunk level, and systems are asked to provide the type of the relationship between two chunks, as an interpretation of the similarity. Given an input pair of sentences, participant systems were asked to: (i) identify the chunks in each sentence; (ii) align chunks across the two sentences; (iii) indicate the relation between the aligned chunks and (iv) specify the similarity score of each alignment.

The iSTS task has already been the object of an evaluation campaign in 2015, as a subtask of the SemEval-2015 Task 2: Semantic Textual Similarity (Agirre et al., 2015). More in general, shared tasks for the identification and measurement of STS were organized in 2012 (Agirre et al., 2012), 2013 (Agirre et al., 2013) and 2014 (Agirre et al., 2014).

Data provided to participants include three datasets: image captions (Images), pairs of sentences from news headlines (Headlines), and a question-answer dataset collected and annotated during the evaluation of the BEETLE II tutorial dialogue system (Student Answers) (Agirre et al., 2015). For each dataset, two subtracks were released: the first with raw input data (SYS), the second with data split in gold standard chunks (GS). Given these input data, participants were required to identify the chunks in each sentence (for the first subtrack only), align chunks across the two sentences, specify the semantic relation of the alignment - selecting one of the following: EQUI for equivalent, OPPO for opposite, SPE1 and SPE2 if chunk in sentence1 is more specific than chunk in sentence2 and vice versa, SIMI for similar meanings, REL for chunks that have related meanings, and NOALI for chunk has no corresponding chunk in the other sentence (Agirre et al., 2015)-, and provide a similarity score for each alignment, from 5 (maximum similarity/relatedness) to 0 (no relation at all). In addition, an optional tag for alignments showing factuality (FACT) or polarity (POL) phenomena, can be specified. The evaluation is based on (Melamed, 1998), which uses the F1 of precision and recall of token alignments.

We participate in the iSTS shared task with a system that combines different features - including word embedding and chunk similarity - using a Multilayer Perceptrons (MLP). Our main contribution was focused on the optimization of a Neural Network setting (i.e. topology, activation function, multi-task training) for the iSTS task. We show that

even with a relatively small and unbalanced training dataset, a neural network classifier can be built that achieves results very close to the best system. Particularly, our system makes use of a single model for the different training sets of the task, proving to be very robust to domain differences.

The paper is organized as follows. Section 2 presents the system we built; Section 3 reports the results we obtained and an evaluation of our system. Finally, Section 4 provides some conclusions.

## 2 System Description

Our system is built combining different linguistic features in a classification model for predicting chunk-to-chunk alignment, relation type and STS score. We decide to use the same features for all these three subtasks and to use a unique multitask MLP with shared layers for all the subtasks. The system is expandable and scalable for adopting more useful features aiming at improving the accuracy.

In this Section, we describe the pre-processing of the data, the features we used, the MLP structure, its training, its output and, finally, the difference between the three submitted runs.

### 2.1 Data Pre-processing

The input data undergo a data pre-processing in which we use a Python implementation of MBSP (Daelemans and Van den Bosch, 2005), a library providing tools for tokenization, sentence splitting, part of speech tagging, chunking, lemmatization and prepositional phrase attachment. The MBSP chunker is used in the SYS subtrack, which requires participants to identify the chunks in each sentence. For both subtracks, we pre-processed the initial datasets of sentence pairs by pairing all the chunks in the first sentence with all the chunks in the second sentence. Henceforth, we will refer to the two chunks in each of the obtained pairs as *chunk1* and *chunk2*, being *chunk1* a chunk of the first sentence and *chunk2* a chunk of the second sentence.

### 2.2 Feature Selection

To compute the chunk-to-chunk alignment, the relation type and the STS score we use a total of 245 features.

**Chunk tags.** A total of 18 features (9 for *chunk1* and 9 for *chunk2*) are related to chunk tags (e.g. noun phrase, prepositional phrase, verb phrase).

For each chunk in the SYS datasets -chunked with MBSP- the system takes into consideration the chunk tags as identified by that library.<sup>1</sup>

For the GS datasets -already chunked datasets- the system first re-chunks the datasets with MBSP and than evaluates if chunks in the GS corresponds to chunks as identified in MBSP. If this is the case, chunk tag is extracted; otherwise the systems does the same operation (i.e. re-chunking and tag extraction) using *pattern.en* (De Smedt and Daelemans, 2012), a regular expressions-based shallow parser for English that uses a part-of-speech tagger extended with a tokenizer, lemmatizer and chunker.<sup>2</sup>

If no corresponding chunk is found, no chunk tag is assigned.

**Token and lemma overlap.** Four further features are related to tokens and lemmas overlap between a pair of chunks. In particular, the system considers the percentage of (i) tokens and (ii) lemmas in *chunks1* that are present also in *chunk2* and viceversa (iii - iv).

**WordNet based features.** Another group of features concerns lexical and semantic relations between words extracted from WordNet 3.0 (Fellbaum, 1998). As such, we evaluate the type of relation between chunks by considering all the lemmas in the two chunks and checking whether a lemma in *chunk1* is a synonym, antonym, hyponym, hyperonym, meronym or holonym of a lemma in *chunk2*. The relations between all the combinations of the lemmas in the two chunks are extracted. The presence or absence of a relation is consider a feature at chunk level (for a total of 6 features for *chunk1* and 6 features for *chunk2*).

Furthermore, we consider as a feature the synset similarity existing in the WordNet hierarchy between each lemma in the two chunks, as calculated

---

<sup>1</sup>The chunk tags are the following: noun phrase (NP), prepositional phrase (PP), verb phrase (VP), adverb phrase (ADVP), adjective phrase (ADJP), subordinating conjunction (SBAR), particle (PRT), interjection (INTJ), prepositional noun phrase (PNP).

<sup>2</sup>The two chunkers use the same set of chunk tags.

by *pattern.en*. We calculate the average of the best alignments for each lemma in the two chunks. For example, consider the chunk pair: *chunk1* "the animal" and *chunk2* "the sweet dog". For each lemma in *chunk1*, for which a synset can be retrieved from WordNet, ("animal"), we calculate the maximum similarity with lemmas in *chunk2*. Thus, for this pair of chunks the resulting maximum similarity is between "animal-dog" = 0.299 (being equal to 0.264 for "animal-sweet"). The chunk similarity score is 0.299. With the same strategy we calculate similarity between lemmas in *chunk2* towards *chunk1*, i.e. "sweet-animal" = 0.264, "dog-animal" = 0.299 resulting in a chunk similarity score of  $[(0.264 + 0.299)/ 2] = 0.281$ . If lemmas were not found in WordNet, the synset similarity is considered 0.

**Word embedding.** We use a distributional representation of the chunk for a total of 200 features (100 for *chunk1* and 100 for *chunk2*) by first calculating word embedding and then combining the vectors of the words in the chunk (i.e. by calculating the element wise mean of each vector). We use Mikolov word2vec (Mikolov et al., 2013) with 100 dimensions using ukWaC, GigaWords (NYT), Europarl V.7, Training Set (JRC) corpora.

The system computes the chunk-to-chunk similarity by calculating the cosine similarity between the two chunk vectors with three different models: the first uses the already described vectors (one feature); the second uses vectors representations extracted with a different corpus and a different parametres -i.e. Google News, with 300 dimensions of the vectors- (one feature); the third uses GloVe vectors (Pennington et al., 2014) with 300 dimensions (one feature).

**Baseline feature.** The baseline output - provided by the organizers (Agirre et al., 2016) - was also exploited, i.e. we consider if the chunks are evaluated as aligned, if *chunk1* is not aligned, if *chunk2* is not aligned (3 features).

**Composition of the input data.** The last three features refer to the datasets. The system takes into consideration if the chunks are extracted from Headline, Images, or Student Answers dataset.

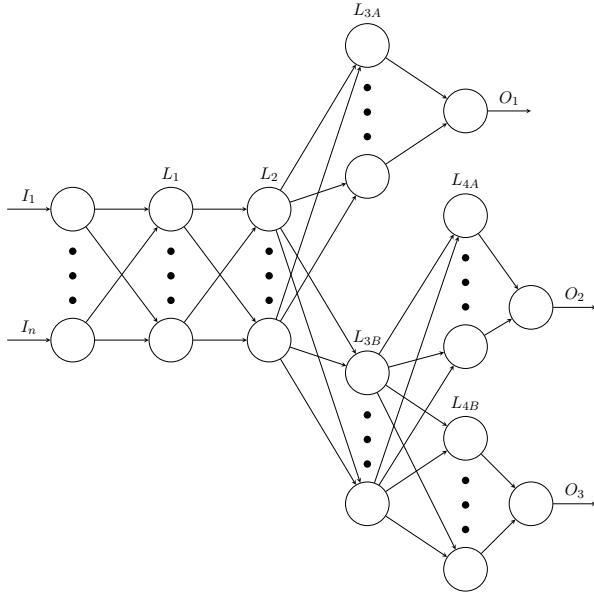

|                                  | #features |
|----------------------------------|-----------|

| Total                            | 245       |

**Table 1:** Feature Selection.

### 2.3 Neural Network

We use a multitask MLP (see Figure 1) to classify chunk pairs, implemented with the TensorFlow library (Abadi et al., 2015). The system uses three classifiers: one for the chunk alignment, one for alignment type, one for STS score. The input layer has 245 entities, so we use fully connected hidden layers with 250 nodes. During the test we observed that smaller (200 nodes) or bigger (300 nodes) layers reduce the performances. The system is composed by two layers (i.e. L1 and L2) shared between the three classifiers. On the top of them there are other two layers: the former (L3a) used only for the alignment classifier and the latter (L3b) shared among the score classifier and the type classifier. At the very end of L3b, there are other two layers one for the score (L4a) and one for the type (L4b). In synthesis for alignment there are three hidden layers, two shared (L1 and L2) and one private (L3a), for STS score there are four hidden layers, three shared (L1, L2, L3b) and one private (L4a) and the same for the type labeling (L1, L2, L3b + L4b). Every output layers is a softmax; during the training the system has a dropout layer that remove nodes from the layer with a probability of 50% to avoid overfitting.

We use sigmoid as activation function as it results the best one during the development test among all the activation function available in the library. Finally, we train our MLP using three different optimizers; each of them reduces the softmax error on a subtasks (i.e. alignment, type labeling or STS score). For the optimization we use the Adam algorithm (Kingma and Ba, 2014) with different learning rates: 0.00006 for the first classifier and 0.00004 for

**Figure 1:** Multitask learning Neural Network.

the other ones.

We train the classifiers for three cycles. This training strategy is driven by learning curves analysis: we keep training the classifiers until the learning curves keep growing. We notice that the alignment classifier stops learning earlier, followed by the relation type classifier, and, at the end, the STS score classifier. Under these findings, to train all the classifiers in the same way overfits the training data. Furthermore, the training data are very unbalanced (most of the pairs are not aligned); thus, we use random mini-batches with a fix proportion between aligned pairs and unaligned pairs. To do so, we use the unaligned pairs more than once in a single training epoch. In particular, first we train the alignment classifier with the following proportion: 2/5 of aligned examples and 3/5 of not aligned pairs, for 8 training epochs (i.e. every aligned pair is used as training data at least 8 times). The second training cycle optimizes relation type labeling and STS score, with the proportion of 9/10 aligned and 1/10 not aligned for other 8 training epochs. Finally, in the third training cycle, we train only for STS score with a proportion of 9/10 aligned and 1/10 not aligned pairs.

## 2.4 Output

We combine the output of the three classifiers (alignment, relation type and similarity score) organized

in a pipeline. First, we label as "not aligned" all the punctuation chunks (i.e. those defined as "not alignable" by the baseline); then we label as "aligned" all the chunks aligned by the first classifier, allowing multiple alignments for each chunk. For every aligned chunk pair we add the type label and the STS score. We do not take into consideration chunk pairs classified as "not aligned" by the first classifier even if they are classified with a label different from NOTALI or with an STS score higher than 0.

## 2.5 Submitted Runs

We submitted three runs, with different training settings. In the first run we use all the training data with a mini-batch of 150 elements. In the second run we train and evaluate separately each dataset with a mini-batch of 150 elements. Finally, in the third run we use all the training data with a mini-batch of 200 elements. We choose these settings in order to evaluate how in-domain data and different sizes of the mini-batch influence the classification results.

## 3 Results and Evaluation

Table 2 compares the results of our runs with the baseline and the best system for each subtrack of the three datasets, showing:

- F1 on alignment classification (F);
- F1 on alignment classification plus relation alignment type (+T);
- F1 on alignment classification plus STS score (+S);
- F1 on alignment classification plus relation alignment type and STS score (+TS);
- Ranked position over the runs submitted: i.e. 13 runs for Images and Headlines SYS, 12 for Student Answer SYS, 20 for Images and Headlines GS and 19 for Student Answer GS (RANK)

Table 2 shows that for all the six subtracks run1 and run3 register better results. In particular, for what concerns GS subtasks (with already chunked sentences), run2 is ranked at least two positions lower with respect to the other two runs. Since the difference between run2 and the other runs lays on the data used for training, these results seem to

|                       | IMAGES SYS          |               |               |               |          | IMAGE GS           |        |               |        |      |

| BestSystem            |                     |               |               |               |          | 0.8684             | 0.6511 | 0.8245        | 0.6385 | 1    |

**Table 2:** Results for the Baseline, Our System three runs and the Best System for the two subtracks split in the three datasets.

suggest that the system takes advantage of a bigger training set with different domain data. Instead, the size of the mini-batch (that is the difference between run1 and run3) does not seem to have a clear influence on the system performance, since in some cases run1 is higher ranked while in other cases run3 is higher ranked.

Furthermore, Table 2 shows that results for Alignment classification (F) and for Alignment plus STS score (+S) frequently approach the Best System (being the major deficit for F equal to 0.0393 in Headline SYS for run3 and equal to 0.0349 for +S in Student Answer GS dataset for run3) and in a few cases outperform it (e.g. in Headlines GS for F results and in Images SYS for +S results). On the other hand, when also relation type classification is considered (i.e. +T and +TS) we register worse performances, being the minimum difference with the Best System equals to 0.0371 for +T results and of 0.0368 for +TS results (both in Headlines SYS) and

the maximum difference equals to 0.1437 for +T and to 0.1458 for +TS (both in Images GS). This indicates that type labelling is the hardest subtask for our system, probably because the subtask requires to identify a higher number of classes (i.e. 7 types).

By comparing the rank of the two subtracks SYS and GS, we notice that our system performs much better in the SYS subtrack (being the worst ranking 8 out of 13 for SYS and 18 out of 20 for GS). This fact indicates that our system does not benefit from having already chunked sentence pairs.

Table 3 presents the final rank calculated by considering the mean of +TS results for the three datasets. As previously mentioned, our system performs relatively better when chunk identification is required. Also, it evidences again that run2 performs worse and that run1 and run3 are similar. Overall our system ranked second among 4 systems (+1 by the authors) in the SYS subtrack.

|            | SYS            |      | GS             |      |
|------------|----------------|------|----------------|------|
|            | MEAN<br>F + TS | RANK | MEAN<br>F + TS | RANK |
| Baseline   | 0.428433       |      | 0.527533       |      |
| Run1       | 0.533133       | 4    | 0.571266       | 11   |
| Run2       | 0.5134         | 6    | 0.5506         | 17   |
| Run3       | 0.531733       | 5    | 0.5722         | 10   |
| BestSystem | 0.6095         | 1    | 0.637733       | 1    |

**Table 3:** Mean of the F+TS results in the two subtracks for the Baseline, Our System three runs and the Best System and final rank.

## 4 Conclusion and Further Work

Considering the obtained results, in particular the difference between the runs, we expect our system to be robust also in situation where data from different domains are provided (e.g. training data from several domains and test data on one of them). In fact, for domain adaptation our system seems to require few data of the target domain.

In any case, the system perform better with more training data, independently on the domains involved. As such, further work may include the use of silver data extracted from other datasets, e.g. SICK dataset (Marelli et al., 2014).

In addition, we believe that a deep analysis of the distribution of the type labels and of the STS scores can improve significantly the performance of the system.

Finally, an ablation test can be helpful in identifying the most salient features for the systems, helping to reduce the complexity of the MLP or to develop better topologies.

Indian Institute of Science, Bangalore, India

## Abstract

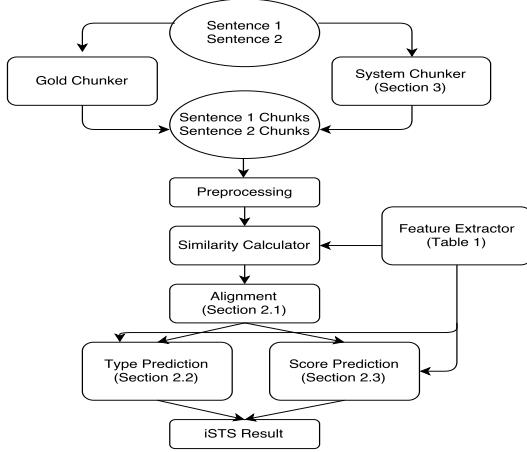

Interpretable semantic textual similarity (iSTS) task adds a crucial explanatory layer to pairwise sentence similarity. We address various components of this task: chunk level semantic alignment along with assignment of similarity type and score for aligned chunks with a novel system presented in this paper. We propose an algorithm, iMATCH, for the alignment of multiple non-contiguous chunks based on Integer Linear Programming (ILP). Similarity type and score assignment for pairs of chunks is done using a supervised multiclass classification technique based on Random Forrest Classifier. Results show that our algorithm iMATCH has low execution time and outperforms most other participating systems in terms of alignment score. Of the three datasets, we are top ranked for answer-students dataset in terms of overall score and have top alignment score for headlines dataset in the gold chunks track.

## 1 Introduction and Related Work

Semantic Textual Similarity (STS) refers to measuring the degree of equivalence in underlying semantics(meaning) of a pair of text snippets. It finds applications in information retrieval, question answering and other natural language processing tasks. Interpretable STS (iSTS) adds an explanatory layer, by measuring similarity across chunks of segmented text, leading to an improved interpretability. It involves aligning multiple chunks across sentences with similar meaning along with similarity score(0-5) and type assignment.

Interpretable STS task was first introduced as a pilot task in 2015 Semeval STS task. Several approaches were proposed including NeRoSim (Banjade et al., 2015), UBC-Cubes (Agirre et al., 2015) and Exb-Thermis (Häning et al., 2015). For the task of alignment, these submissions used approaches based on monolingual aligner using word similarity and contextual features (Md Arafat Sultan and Summer, 2014), JACANA that uses phrase based semi-markov CRFs (Yao and Durme, 2015) and Hungarian Munkers algorithm (Kuhn and Yaw, 1955). Other popular approaches for mono-lingual alignment include two-stage logistic-regression based aligner (Md Arafat Sultan and Summer, 2015), techniques based on edit rate computation such as (lien Maxe Anne Vilnat, 2011) and TER-Plus (Snover et al., 2009). (Bodrumlu et al., 2009) used ILP for word alignment problem. The iSTS task in 2016 introduced problem of many-to-many chunk alignment, where multiple non-contiguous chunks of the source can align with multiple-non-contiguous chunks of the target sentence, that previous monolingual alignment techniques cannot handle. We propose iMATCH, a new technique for monolingual alignment for many-to-many alignment at the chunk level, that can combine non-contiguous chunks based on integer linear programming (ILP). We also explore several features to define a similarity score between chunks to define the objective function for our optimization problem, similarity type and score classification modules. To summarize our contributions:

- We propose a novel algorithm for monolingual alignment : iMATCH that handles many-to-

**Figure 1:** Flow diagram of proposed iSTS system

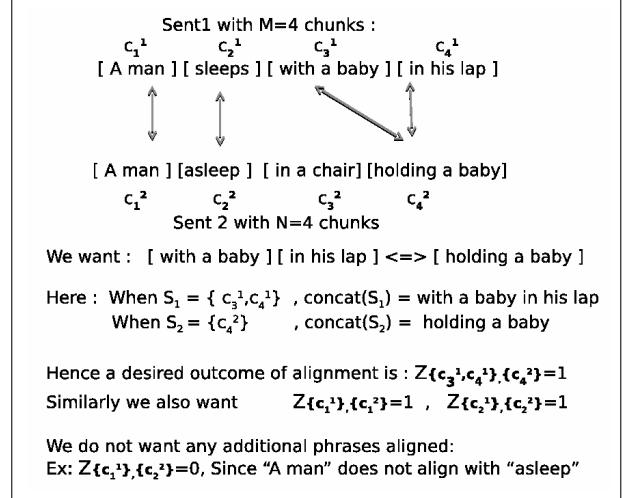

many chunk level alignment, based on Integer Linear Programming.

- We propose a system for Interpretable Semantic Textual Similarity: In the Gold-chunks track, our system is the top performer for the students-dataset and our alignment score is in that of the best two teams for all datasets.

## 2 System for Interpretable STS

Our system comprises of (a) alignment module, iMATCH (section 2.1), (2) Type prediction module (section 2.2) and (3) Score prediction module (section 2.3). In the case of system chunks, there is an additional chunking module for segmenting input sentences into chunks. Figure 1 shows the block diagram of proposed system.

**Problem Formulation:** Following is the formal definition of our problem. Consider source sentence ( $Sent_1$ ) with M chunks and target sentence ( $Sent_2$ ) with N chunks. Consider sets  $C^1 = \{c_1^1, \dots, c_M^1\}$ , the chunks of sentence  $Sent_1$  and  $C^2 = \{c_1^2, \dots, c_N^2\}$ , the chunks of sentence  $Sent_2$ . Consider sets  $\mathcal{S}_1 \subset PowerSet(C^1) - \phi$  and  $\mathcal{S}_2 \subset PowerSet(C^2) - \phi$ . Note that  $\mathcal{S}_1$  and  $\mathcal{S}_2$  are subsets of the power set (set of all possible combinations of sentence chunks) of  $C^1$  and  $C^2$  respectively. Consider sets  $S_1 \in \mathcal{S}_1$  and  $S_2 \in \mathcal{S}_2$ , which denotes a specific subset of chunks that are likely to be combined during alignment. Let  $concat(S_1)$  denote the phrase resulting from concatenation of chunks in  $S_1$  and  $concat(S_2)$  denote the phrase resulting from concatenation of chunks of  $S_2$ . Consider a binary

**Figure 2:** iMatch: An example illustrating notation

variable  $Z_{S_1, S_2}$  that takes value 1 if  $concat(S_1)$  is aligned with  $concat(S_2)$  and 0 otherwise.

The goal of *alignment module* is to determine the decision variables ( $Z_{S_1, S_2}$ ), which are non-zero.  $S_1$  and  $S_2$  can have more than one chunk (multiple alignment), that are not necessarily contiguous. Aligned chunks are further classified using Type classifier and Score classifier. *Type prediction module* identifies a pair of aligned chunks ( $(concat(S_1), concat(S_2))$ ) with a relation type like EQUI (equivalent), OPPO (opposite) etc. *Score classifier module* assigns a similarity score ranging between 0-5 for a pair of chunks. For the system chunks track, the *chunking module*, converts sentences  $Sent_1, Sent_2$  to sentence chunks  $C_1, C_2$ .

### 2.1 iMATCH: ILP based Monolingual Aligner for Multiple-Alignment at the Chunk Level

We approach the problem of multiple alignment (permitting non-contiguous chunk combinations) by formulating it as an Integer Linear Programming (ILP) optimization problem. We construct the objective function as the sum of all  $Z_{S_1, S_2}, \forall S_1, S_2$  weighed by the similarity between  $concat(S_1)$  and  $concat(S_2)$ , subject to constraints to ensure that each chunk is aligned only a single time with any other chunk. This leads to the following optimization problem based on Integer linear programming

(Nemhauser and Wolsey, 1988):

$$\begin{aligned} \max_Z & \sum_{S_1 \in \mathcal{S}_1, S_2 \in \mathcal{S}_2} Z_{S_1, S_2} \alpha(S_1, S_2) \text{Sim}(S_1, S_2) \\ \text{S.T.} & \sum_{\bar{S}_1 = \{S: c^1 \in S, S \in \mathcal{S}_1\}, S_2 \in \mathcal{S}_2} Z_{S_1, S_2} \leq 1, \forall 1 \leq c^1 \leq M \\ & \sum_{S_1 \in \mathcal{S}_1, \bar{S}_2 = \{S: c^2 \in S, S \in \mathcal{S}_2\}} Z_{S_1, S_2} \leq 1, \forall 1 \leq c^2 \leq N \\ & Z_{S_1, S_2} \in \{0, 1\}, \forall S_1 \in \mathcal{S}_1, S_2 \in \mathcal{S}_2 \end{aligned}$$

Optimization constraints ensure that a particular chunk  $c$  appears in an alignment a single time with any subset of chunks in the other sentence. Therefore, one chunk can be part of alignment only once. We note that all possible multiple alignments are explored by this optimization problem when  $\mathcal{S}_1 = \text{PowerSet}(C^1) - \phi$  and  $\mathcal{S}_2 = \text{PowerSet}(C^2) - \phi$ . However, this leads to a very high number of decision variables  $Z_{S_1, S_2}$ , not suitable for realistic use. Hence we consider a restricted usecase

$$\mathcal{S}_1 = \{C_1^1\}, \dots, \{C_M^1\} \cup \{\{C_i^1, C_j^1\} : 1 \leq i < j \leq M\}$$

$$\mathcal{S}_2 = \{C_1^2\}, \dots, \{C_N^2\} \cup \{\{C_i^2, C_j^2\} : 1 \leq i < j \leq N\}$$

This leads to many-to-many alignment where at most two chunks are combined to align with two other chunks. For iSTS task submission, we restrict our experiments to this setting (since this worked well for the iSTS task), but can relax sets  $S_1$  and  $S_2$  to cover combinations of 3 or more chunks. For efficiency, it should be possible to consider a subset of chunks based on adjacency information, existence of a dependency using dependency parsing techniques.  $\text{Sim}(S_1, S_2)$ , the similarity score, that measures desirability of aligning  $\text{concat}(S_1)$  with  $\text{concat}(S_2)$ , plays an important role in finding the optimal solution for the monolingual alignment task. We compute this similarity score by taking the maximum of similarity scores obtained from a subset of features F1, F2, F3, F8, F10 and F11 given in Table 1 as follows:  $\max(F1, F2, F3, F8, F10, F11)$ . During implementation, the weighting term,  $\alpha(S_1, S_2)$  is set as a function of the cardinality of  $S_1$  and cardinality of  $S_2$  to ensure aligning fewer individual chunks (for instance, single alignment tends to increase objective function value more due to more aligned pairs, since similarity scores are normalized to lie between

-1 and 1) does not get an undue advantage over multiple alignment. This is a hyper-parameter whose value is set using simple grid search. We solve the actual ILP optimization problem using PuLP (Mitchell et al., 2011), a python toolkit for linear programming. Our system achieved the best alignment score for headlines datasets in the gold chunks track.

## 2.2 Type Prediction Module

We use a supervised approach for multiclass classification based on the training data of 2016 and that of previous years (for some submitted runs) to learn the similarity type between aligned pair of chunks based on various features derived from the chunk text. We train a one-vs-rest random forest classifier (Pedregosa et al., 2011) with various features mentioned in Table 1. We perform normalization on the input phrases as a preprocessing step before extracting features for classification. Normalisation step includes various heuristic steps to convert similar words to the same form, for example ‘USA’ and ‘US’ were mapped to ‘U.S.A’. Empirical results suggested that features F1, F2, F3, F5, F7, F8, F9, F12 along with unigram and bigram features give good accuracy with decision tree classifier. Feature vector normalisation is done before training and prediction. We note that our type classification module performed well for the answer-students dataset, while it did not generalize as well for the headlines and images. We are exploring other features to improve performance on these datasets as future work.

## 2.3 Score Prediction Module

Similar to type classifier, we designed the Score classifier to do multiclass classification using one-vs-rest random forest classifier (Pedregosa et al., 2011). Each score 1-5 is considered as a class. ‘0’ score is assigned by default for ‘not-aligned’ chunks. Word normalization (US, USA, U.S.A are mapped to U.S.A string) is performed as a preprocessing step. Features F1, F2, F3, F5, F7, F8, F9, F12 along with unigram and bigram features (refer Table 1) were used in training the multi-class classifier. Feature normalization was performed to improve results. Our score classifier works well on all datasets. The system achieved highest score on the gold-chunks track for answer-students dataset and

**Table 1:** Feature Extraction as used in various modules of iSTS system

| No. | Feature Name                   | Description  |
|-----|--------------------------------|--|
| F1  | Common Word Count              | $v1\_words = \{words1 \text{ from sentence 1}\}$<br>$v2\_words = \{words2 \text{ from sentence 2}\}$<br>$\text{feature value} = \frac{\{ v1\_words \cap v2\_words \}}{0.5 * (sentence1.length + sentence2.length)}$  |

headlines dataset and is within 2% of the top score for all other datasets.

#### 2.4 System Chunks Track: Chunking Module

When gold chunks are not given, we perform an additional chunking step. We use two methods for chunking: (1) With OpenNLP Chunker(Apache, 2010) (2) With stanford-core-nlp (Manning et al., 2014) API for generating parse trees and using the chunklink (Buchholz, 2000) tool for chunking based on the parse trees.

For chunking, we do preprocessing to remove punctuations unless the punctuation is space separated (therefore constitutes an independent word). We also convert unicode characters to ascii characters. Output of chunker is further post-processed to combine each single preposition phrase with the preceding phrase. We noted that the OpenNLP chunker ignored last word of a sentence, in which case,

we concatenated the last word as a separate chunk. In the case of chunking based on stanford-core-nlp parser, we noted that in several instances, particularly in the student answer dataset, a conjunction such as ‘and’ was consistently being separated into an independent chunk in most cases, and therefore improved chunking can be realized by potentially combining chunks around a conjunction. These processing heuristics are based on observations from gold chunks data. We observe that quality of chunking has a huge impact on the overall score in system chunks track. As future work, we are exploring ways to improve the chunking with custom algorithms.

### 3 Experimental Results

In this section, we present our results, in both the gold standard and the system chunks tracks. We submitted 3 runs for each track. In *gold chunks track*,

**Table 2:** Gold Chunks Images

| RunName    | Align         | Type   | Score         | T+S    | Rank |
|------------|---------------|--------|---------------|--------|------|
| IIScNLP R2 | 0.8929        | 0.5247 | 0.8231        | 0.5088 | 15   |

| DTSim R3   | 0.6095 | 0.5446   | 0.5029         | 0.552 | 1    |

all three runs used the same algorithm, with different training data for the supervised prediction of type and score. While, in system chunks track, we submitted different algorithm and data combination for various runs. Detailed run information follows:

– *Gold Chunks - Run 1* uses training data from

2015+2016 for the headlines and images dataset and 2016 data for answer-students dataset.

– *Gold Chunks - Run 2* uses training data of all datasets combined from 2015 and 2016 for headlines and images and 2016 data for answer-students.

– *Gold Chunks - Run 3* uses 2016 training data alone for each dataset.

– *System Chunks - Run 1* uses OpenNLP chunker with supervised training of type and score with data of all datasets combined for years 2015,2016.

– *System Chunks - Run 2* we use chunker based on stanford nlp parser and chunklink with training data of all datasets combined for years 2015,2016.

– *System Chunks - Run 3*, we use the OpenNLP chunker, with training data of 2016 alone.

Results of our system compared to the best performing systems in each track are listed in Tables 2-9. In both gold and system chunks track, run2 performs best owing to more data during training. Our system performed well for the answer-students dataset owing to our edit-distance feature that enables handling noisy data without any pre-processing for spelling correction. Our alignment score is best or close to the best in the gold chunks track, thus validating that our novel and simple approach based on ILP can be used for high quality monolingual multiple alignment at the chunk level. Our system took only 5.2 minutes for a single threaded execution on a Xeon 2420, 6 core system for the headlines dataset. Therefore, our technique is fast to execute. We observe that the quality of chunking has a huge impact on alignment and thereby the final score. We are actively exploring other chunking strategies that could improve results. Code for our alignment module is available at <https://github.com/lavanyats/iMATCH.git>

## 4 Conclusion and Future

We have proposed a system for Interpretable Semantic Textual Similarity (task 2- Semeval 2016) (Agirre et al., 2016). We introduce a novel monolingual alignment algorithm iMATCH for multiple-alignment at the chunk level based on Integer Linear Programming(ILP) that leads to the best alignment score in several cases. Our system uses novel features to capture dataset properties. For example,

we designed edit distance based feature for answer-students dataset which had considerable number of spelling mistakes. This feature helped our system perform well on the noisy data of test set without any preprocessing in the form of spelling-correction.

As future work, we are actively exploring features to improve our classification accuracy for type classification, which could help us improve our mean score. Some exploration in the techniques for simultaneous alignment and chunking could significantly boost the performance in sys-chunk track.

**Acknowledgment** We thank Prof. Partha Pratim Talukdar, IISc for guidance during this research.

# ***VENSEEVAL at Semeval-2016 Task 2: iSTS - with a full-fledged rule-based approach***

**Rodolfo Delmonte**

Department of Language Studies and Comparative Cultures &  
Department of Computer Science - Ca' Foscari University of Venice  
Ca' Bembo – Dorsoduro 1075 - 30123 VENEZIA  
Email:delmont@unive.it - Website: <http://project.cgm.unive.it>

## **Abstract**

In our paper we present our rule-based system for semantic processing. In particular we show examples and solutions that may be challenge our approach. We then discuss problems and shortcomings of Task 2 – iSTS. We comment on the existence of a tension between the inherent need to on the one side, to make the task as much as possible “semantically feasible”. Whereas the detailed presentation and some notes in the guidelines refer to inferential processes, paraphrases and the use of commonsense knowledge of the world for the interpretation to work. We then present results and some conclusions.

## **1 Introduction**

In this presentation we will focus on Task 2, Interpretable Semantic Textual Similarity. We will comment on the way in which the task has been defined and what is eventually made available to participants to the task. In the section below we will present our system created for RTE – Recognizing Textual Entailment - challenges, and how it has been reorganized to suit the new current task. We discuss examples that suit or challenge our approach. We then comment in detail problems and shortcoming related to issues related to the annotations and the choice of semantic relations. In a final section we will present our results and a discussion.

## **2 The system *VENSEEVAL***

The system is an adaptation of *VENSES* Venice team system used for RTE (Recognizing Text Entailment) challenges (see Delmonte et al. 2009).

In fact *Venses* was only partially adaptable to the new task, and so we had to partly recast it. In particular, the semantic evaluation module which was used to issue a binary (or ternary) decision in RTE challenges, in iSTS scenario works in a totally different manner. RTE required a Text - which could be constituted by a single simple or complex sentence - to be compared to an Hypothesis, this usually a simple sentence. From a purely theoretic and abstract point of view, measuring semantic similarity between two sentences (snippets) resembles very closely RTE as indicated in the paper accompanying 2015 challenge, (see Agirre et al. 2015). As the authors comment, iSTS can be defined as a graded similarity notion. In iSTS the comparison is between chunks which must be aligned first.

We find this approach certainly very useful and adequate for the task of semantic similarity checking. However, we had to reorganize and partly rewrite the modules for semantic matching. This has taken a lot of time and in fact the module hasn't been fully completed. So we assume that next year challenge will see a better – or at least complete - version of *VENSEEVAL*.

In the current challenge, we used only part of the original RTE system for various reasons. *Venses* was created to allow for semantic matching at different levels of complexity and representations. In particular, the task allowed semantic composition over different sentences, not necessarily adjacent to one another. It required anaphoric processes to be part of the semantic interpretation, again over a span of text made up of a number of different but referentially related sentences. For that reason, we used a complete system for semantic interpretation that not only had a level of anaphora and coreference resolution, it also ended up by creating a logical form representation which was then used for deep

semantic matching<sup>1</sup>.

*Venseeval* has a different structure and less components. iSTS task seems much more a word or chunk level interpretation process. It does not require anaphora/coreference resolution because it is bound at sentence level. It does not require a logical form to be computed, or at least we haven't found a real motivation to do that. In fact, we then found good reasons for computing predicate-argument structures, but only after the deadline expired – more on this below. Eventually we decided to limit ourselves to produce syntactic constituency structure which could then be used to produce non-embedded chunks. The pipeline we used is then fairly simple:

- a tokenizer + a sentence splitter
- a tagger + an augmented recursive transition network
- a chunker extracting simple chunks - in the same fashion in which they have been characterized in the task - from sentence level constituency.

The system had to be reorganized around the gold chunk option which is what we wanted to experiment with. In order to allow chunk alignment to work correctly, sentences have been tokenized without introducing any further computation which could modify the order of the tokens. We just wanted to use tagged tokens with the gold chunks options, and chunked structures with the system option of the task.

In particular, in our original system, NP chunks were organized internally as a list to show the Head of the chunk in first position: all modifiers were moved to the right of the head. This was no longer possible, given the fact that we had to preserve the word order of the input sentence. No multiwords have been created, and this is something that may have contributed to decrease our tagger accuracy and as a consequence also chunks have a lower level of accuracy. The final system used the Named Entity Recognition module which however was only activated at chunk level, all other cases have been neglected. The reason for not producing multiwords was also related to the fact that we wanted to keep matching procedures as simple as possible. But we intend to reintroduce it in a future reimplementation of the system.

The first pass into the sentence pair is done with

the aim to produce a general similarity evaluation based on tagged words only. To do this, we use part of the matching procedures explained below which erase function or stop words, and evaluate identity and similarity between content words without however issuing any score. Then we pass to the chunk-based analysis which is similar to the algorithm proposed in the Annotation Guidelines that can be taken as a starting point also for our module. For instance, as specified in the Procedure at pag.11, 3.d where it says “proceed from strongest to weakest 1:1 alignments”. This is exactly what our system does, as specified in the algorithm below:

- given one sentence pair,
  - select first chunk in sentence one
    - recursively try to match chunk one to each of the chunks in sentence two
      - start matching procedures from EQUIvalence/OPPOsite
      - succeed, move to second chunk in sentence one
    - repeat
    - fail
  - move to matching procedures for SPE1/SPE2
    - succeed, move to second chunk in sentence one
  - fail
  - move to matching procedures for SIMI, REL
    - succeed, move to second chunk in sentence one
  - fail
  - assign NOALI label to chunk
  - move to second chunk in sentence one
  - repeat until end of chunks in sentence one
- end

The main algorithm is a depth first attempt at finding the best match: we always select the first candidate available at each similarity level. We don't try all possible matches, in a breadth-first approach where we should score them and then choose the best candidate. At the end of the main recursion, the algorithm looks for possible recovery actions, by collecting all NOALI marked chunks and searching for possible matches with the already matched chunks except for the ones computed as EQUI. This is done trying to match

---

<sup>1</sup> A version of the RTE system is still working on our website, <http://project.cgm.unive.it/cgi-bin/venses/venses.pl>

the head of the NOALI chunk with the head of the companion chunk. In case of match, it substitutes the other chunk with the current one and turns it into a NOALI.

In the Annotation Guidelines we find two secondary features - Polarity and Factuality, appearing as extensions to main features, which are scarcely commented. We didn't implement these extensions because there were no clear instructions to do so in the guidelines. In the case of POLarity we only found four cases so labeled in the training gold standard for headlines – none in the images gold standard. As to FACTuality extensions we only implemented NOALI\_FACT for all those cases in which a communication verb was labeled. Also in this case, however, there was no clear definition of the task in the guidelines, but we found 29 labeled cases in the headlines gold standard, none in the images. 13 examples were cases of NOALI\_FACT which gave us sufficient confidence in assigning the label. The remaining cases were split between EQUI and SIMI with two SPE1 cases, and it was fairly hard to establish a rule that could fit with them all. SPE cases are individuated by matching the head of the two chunks which must be equal in the sense provided by EQUIvalence algorithm.

SIMI on the contrary requires some inferential step – but see section below. In particular we used a specialized label SIMI-2 to classify all chunk-pairs which involved differences in numbers, simple integers but also dates. Integers were then measured to check the distance in value and decide a score to associate to SIMI, which could vary from, 2 to 4. We used it also to indicate difference in country names, i.e. Locations recognized by the NER algorithm.

Problems arise for all those cases of paraphrases included in the corpus. There's a few examples in the training corpus of Headlines, in sentence 214,

```
//Iran says it captures drone ; U.S. denies losing one.  
//Iran says it has seized U.S. drone ; U.S. says it 's not true  
8 <==> 10 12 13 14 // EQUI // 5 // denies <==> says 's not true
```

Another such case is present in sentence 402,

```
//Egypt 's main opposition rejects president 's call for dialogue.  
//Egypt opposition mulls response to Morsi dialogue
```

call.

5 <==> 3 4 // SPE1 // 3 // rejects <==> mulls response  
Finally, consider the example in sentence n.670 again from Headlines,

```
//No plan to shut petrol pumps at night Moily.  
//India govt rejects proposal to shut petrol pumps at night  
1 2 <==> 3 4 // SIMI // 4 // No plan <==> rejects proposal
```

We set up a specialized algorithm for cases like the one in 214. But the other two cases we found are not computable: “no plan” can be paraphrased in an infinite number of different ways. The same applies to “mulls response”.

Coming now to the need to compute predicate-argument structures, we have been convinced of its usefulness only after discovering poor performance of the system in total NOALI classification. In all those cases in which the sentence pair did not share any chunk, the system was still trying to relate far-fetched similarities, despite the fact that the overall meaning was not compatible with that interpretation. Take for instance the pair from the test-set, sentence no.9:

```
// Many dead as asylum boat sinks off Australia  
// Mandela spends third day in hospital  
3 4 5 <==> 5 6 // SIMI // 2 // as asylum boat <==> in hospital
```

Our system wrongly found some similarity between two chunks, where “asylum” and “hospital” share meaning components. However, the two sentences are clearly talking about totally different topics so the apparent meaning similarity should not apply. Preventing this from happening could only take place in case predicate argument structures were made available. Main predicates SINK and SPEND would then be judged not to share any meaning nor would the SUBJECT “asylum” and “Mandela”. Argumenthood could then be used to prevent a SUBJECT “asylum boat” from being made to share semantic similarity components with a locative adjunct “in hospital”, where the sinking event doesn't find any correspondence.

## 2.1 Matching procedures

Matching is applied at different levels using different resources. We use WordNet<sup>2</sup> for EQUI relations by searching non identical predicates in the same synset. Again WordNet is used for SIMI by searching up and down the path one level only, for all non identical predicates; we also use an extended version of VerbOcean<sup>3</sup> for entailment relations between verbs, where we added some 250 new relations. For more general REL relations we use Roget's Thesaurus<sup>4</sup>. And of course there's a great number of gazeteers and lexica for NER that is made available, in particular, the ones by JRC made available by Ralph Steinberg<sup>5</sup>.

For more complex semantic similarity relations, we have reconstructed our Finite State Automaton that we introduced in our last participation in RTE n.5. We report it here below. It requires tagged words and a number of linguistic rules to be implemented. The current version of the algorithm is made up of 86 different rules.

The procedure takes as input the tagged list of words making up the current chunk pairs and tries to match it, by the predicate `match_template(Chunk1, Chunk2)`. If the match succeeds the semantic evaluation outputs a value that is indicative of the type of decision taken. This matching procedure is reached by the analysis only after EQUI have failed. Consider the example below where we highlight the portion of the chunk pair relevant for the semantic evaluation:

T: Trains, trams, cars and buses ground to a halt on Monday after a shoot-out between 18:00 CET and 19:00 CET in the historical *city of Basel in Switzerland*.

H: *Basel is a European city.*

In more detail, Augmented Finite State Automata mean that in addition to equality matching that is at the basis of the whole algorithm, the system looks for inferences and other lexical information to authorize the match. In fact, these procedures as a whole allow the matching to become more general though introducing some constraints. The instructions reported below are expressed in Prolog

which treats capitalized words as variables. Constants on the contrary are written with lower case letter, as for instance the words "of" and "in" below.

```
match_template([A, Is-_, T-_, F-, G|Hyp], [G, of-_, A, in-_, L-_|Text])
:- lightverbs(Is),
high_rank(T, Lex),
locwn(L),
is_in(L, F1),
(nat1(F1, F, _); natl(F1, _, F)), !.
```

where the procedure "lightverbs" looks for copulative verbs, i.e. the verb of the Chunk1 must be a copulative verb; "high\_rank" looks for high frequency words like articles; "locwn" verifies that the word present in the variable "L" is a location. Then there are two inferences: the first one is fired by the call "is\_in" that recovers the name of the continent to which "L" belongs, thus implicitly requiring "L" to be the name of a nation. Then the second inference looks for the corresponding nationality adjective. Values for all above variables (L,A,F,F1,T,G,Is), are then as follows:

L --> Switzerland, F1 --> Europe, F --> European  
A = Basel-np, Is = is, T = a, G = city-n

### 3 Analysing iSTS Annotation Criteria

As said above, measuring semantic similarity between two sentences (snippets) resembles very closely TE. However, differences are clearer seen that iSTS imposes an additional first step - chunk alignment - which is finding the chunk pair that is semantically closer and then assigning a type and a score. In this sense, it is intuitively limited to what pertains to semantics, while TE had no such limitation and the word Entailment was understood as possessing a much wider import than just semantics. In fact, if we read the annotation guidelines carefully, we discover at pag. 2 that the subdivision into chunks is defined as follows: "Chunks are aligned in context, taking into account the interpretation of the whole sentence, including common sense." Common sense has no reference whatsoever to SEMANTICS being rather based on knowledge of the world. The same we find at pag. 3, "Note that the interpretation of the whole sentence, including common sense inference, has

<sup>2</sup> <https://wordnet.princeton.edu/wordnet/download/current-version/>

<sup>3</sup> <http://demo.patrickpantel.com/demos/verbcean/>

<sup>4</sup> <http://www.gutenberg.org/ebooks/10681>

<sup>5</sup> <http://langtech.jrc.it/RS.html>

to be taken into account." Then in the annotation guidelines, we find other elements that indicate a need to go beyond semantics: "B. When aligning, take into account the deep meaning of the chunk in context, beyond the surface."

In fact, we expected task data to pertain to so-called "literal" and direct meaning decomposition subset of sentences and not to contain any "non-literal" or "indirect" interpretable data. We also didn't expect to find unexpressed or implicit meaning components that had to be reconstructed while interpreting chunks. As we will see, this is only partially confirmed. The task itself has been organized so as to favour semantic decomposition operations to be applicable to chunks which should be at first paired by the system and then interpreted and "semantically explained". Semantic explanation is to be carried out by choosing among a small number of semantic relational label, including:

- EQUI(valent) SIMI(lar) OPPO(site) SPE(cific)1  
SPE(cific)2 REL(ation) NOALI(gnment)

but also additional labels with further semantic content:

- EQUI\_FACT EQUI\_POL SIMI\_FACT  
SPE1\_FACT SPE2\_FACT NOALI\_FACT SIMI-2

In particular label SIMI-2 is not explained in the guidelines. As to the other additional labels, FACT stands for factuality and POL for polarity, i.e. these two extensions should be used in case the sentence contains elements of one or the other phenomenon. The 2016 version of the task introduces then some further difficulty, when it allows chunks to match not just in a 1:1 but also 2:1. As to this procedure, in our system we check for a possible match already in the first recursive search and at the end of the recursive matching procedure.

We will now look into semantic relation labels first and see whether they are adequate and consistent. The first label, EQUIvalent covers all cases of full identity between wordforms in the two chunks. Equivalence without full orthographic identity is very frequent and includes all cases where the system matching algorithm has to put up with capitalized, or fully upper case words, and sometimes dashed version of the same unique word. But certainly the most frequent cases of equivalence-not-identity are where the two wordforms have different morphology and lemmata have to be matched. During EQUI matching procedures, we transform head words

into their corresponding lemmata and try a match.

More difficult cases include named entity recognition processes, whenever an institution or a person is present with the abbreviated wordform in one chunk and the fully expressed name in the other; or when the name is used in one chunk and the other contains name and surname. Eventually, in some cases, the nationality has to match the word for the nation in the other chunk. Differentiating between SIMI and SPE is certainly hard<sup>6</sup>.

In all these definitions, we find the same words "similar meanings" except for REL where the word "relation" is used instead. Now differences between SPE and SIMI can only be found in the presence of "attributes" in the definition of SIMI, whereas in SPE we find reference to specificity, which we may assume can be related to the presence of "attributes" but in different measure. It would seem then that SPE relations are more "similar" than SIMI relations, where semantic relations are less close. Let's now look at the examples presented in the guidelines. The second one poses already a problem:

```
[Red double decker bus][driving][through the streets]
[Double decker passenger bus][driving][with traffic]
Alignment: 1<==>1(SPE1 4), 2<==>2(EQUI 5),
3<==>3(REL 3)
```

The first two chunks have been interpreted as entertaining a SPE1 relation, which means that the first chunk "Red double decker bus" is more SPEcific than the second one. But the second one also contains a specification which is not present in the first chunk, "double decker passenger bus", constituted by the noun modifier "passenger". The choice of regarding chunk 1 more specific is driven by the fact that the colour specification adds a more relevant information to the common "double decker bus" than the noun "passenger", which is regarded of no import to the identification of the semantic reference realized by the multiword head double\_decker\_bus. So it would seem that in order to decide whether to use SPE1 or SPE2 a system for semantic evaluation should be equipped with "commonsense" knowledge that would weigh the two attributes accordingly. However, it may be

---

<sup>6</sup> The guidelines defines it as follows (pag.3/4) very vaguely.

disputable to define reference to "colour" as a less relevant attribute than reference to "passenger", for the simple reason that this decision eventually depends on the spatial location of the event. If it is England the location, then it is a commonplace notion that double decker buses are just red. But suppose the location was Lisbon, where double decker are sometimes red sometimes multicoloured, these latter being used by tourists to tour the city. In that case colour would have been more relevant than passenger. Even though "passenger" constitutes a more general attribute than "tourist" bus. So eventually, in order to use commonsense knowledge, at least time/place location must be made available.

Similar problems may be raised in another example (pag.6), where the semantic relation is expressed by predicates:

[Hundreds]1[of Bangladesh clothes factory workers]2  
 [ill]3  
 [Hundreds]1[fall]2[sick]3[in Bangladesh factory]4  
 Alignment: 1<==>1 (EQUI 5), 2<==>4 (SPE1 3), 3<==>2,3 (EQUI 5)

Here the adjective "ill" is make to relate to "fall sick" by EQUI. However, (TO BE) "ill" where the verb to be is simply left implicit in the nominalized title, is interpretable as a STATE; whereas TO "fall sick" is clearly an EVENT. So maybe the two predicates are not EQUI but SIMI and in order to align FALL to the missing BE some inference is required. This goes against what is being affirmed under 2b, as to the fact that two events are (weakly) relatable but cannot be aligned because they "refer to different events". However the reference to different events is not clearly inferrable.

[Saudis]1 [to permit]2 [women]3 [to compete]4 [in Olympics]5  
 [Women]1 [are confronting]2 [a glass ceiling]3  
 Alignment: 1<==> $\emptyset$ (NOALI), 2<==> $\emptyset$ (NOALI), 3<==>1(SPE1 4), 4<==> $\emptyset$ (NOALI), 5<==> $\emptyset$ (NOALI),  $\emptyset$ <==>2(NOALI),  $\emptyset$ <==>3 (NOALI)

In one sentence we are told that women are in Saudi Arabia, but nothing is said in the second sentence, and since spatio-temporal locations can be left implicit we are unable to separate the two events and the two references to women. So we find it hard to consider the semantic relation

intervening between the two chunks as SIMI.

## 4 Results

We report here below results for two of the three corpora only. As to the corpus for student-answer, it was filled with typos and spelling errors, and this was regarded part of the task. We were unable to compute any reasonable semantic similarity match for an extended number of sentences. So we decided to abandon it. As to the other two texts, results for test texts are very similar to those we already obtained for training ones, so we only show test results.

|          | Ali    | Type   | Score  | TypSco |
|----------|--------|--------|--------|--------|
| Venseval | 0.7428 | 0.4667 | 0.6949 | 0.4624 |
| Baseline | 0.7100 | 0.4043 | 0.6251 | 0.4043 |

Table 1: Results compared to Baseline for IMAGES SYS – Rank 12 over 13

|          | Ali    | Type   | Score  | TypSco |
|----------|--------|--------|--------|--------|
| Venseval | 0.8443 | 0.5789 | 0.8046 | 0.5735 |
| Baseline | 0.8556 | 0.4799 | 0.7456 | 0.4799 |

Table 2: Results compared to Baseline for IMAGES GS – Rank 10 over 20

As can be noticed by comparing results in SYS and GS tables, in the analysis of Images corpus the decrease of performance of the system is higher than the difference between baselines. Here below results for Headlines.

|          | Ali    | Type   | Score  | TypSco |
|----------|--------|--------|--------|--------|
| Venseval | 0.7081 | 0.4679 | 0.6493 | 0.4531 |
| Baseline | 0.6486 | 0.4379 | 0.5912 | 0.4379 |

Table 3: Results compared to Baseline for HEADLINES SYS – Rank 12 over 13

|          | Ali    | Type   | Score  | TypSco |
|----------|--------|--------|--------|--------|
| Venseval | 0.8731 | 0.5927 | 0.8099 | 0.5729 |
| Baseline | 0.8462 | 0.5462 | 0.7610 | 0.5461 |

Table 4: Results compared to Baseline for HEADLINES GS – Rank 13 over 20

In the Headlines corpus analysis differences in performance between SYS and GS are comparable. If we look closer at results in terms of number of

teams we see that they are only 8, and our rank is now fifth, both in Images and Headlines results. In conclusion, we favoured a rule-based approach because we assume it can account for differences in text structures. However, rules require fine-tuning which cannot be completed in a short time. This is clearly born out by differences in performance between the two corpora analysed, Images and Headlines, where the first one should have been much easier to process than the second.

## Abstract

We introduce a system focused on solving SemEval 2016 Task 2 – Interpretable Semantic Textual Similarity. The system explores machine learning and rule-based approaches to the task. We focus on machine learning and experiment with a wide variety of machine learning algorithms as well as with several types of features. The core of our system consists in exploiting distributional semantics to compare similarity of sentence chunks. The system won the competition in 2016 in the “Gold standard chunk scenario”. We have not participated in the “System chunk scenario”.

## 1 Introduction

The goal of the *Interpretable Semantic Textual Similarity* task is to go deeper with the assessment of semantic textual similarity of sentence pairs. It is requested to add an explanatory layer that offers a deeper insight into the sentence similarities. The sentences are split into chunks and the first goal is to find corresponding chunks (with respect to their meanings) among the compared sentences. When the corresponding chunks are known, the chunks are annotated with their similarity scores and their relation types (e.g. equivalent, more specific, etc).

The task follows a pilot task from the preceding SemEval 2015 competition (Agirre et al., 2015). The best performing systems adopted various approaches, (Banjade et al., 2015) relied on hand-crafter rules, (Karumuri et al., 2015) employed a classifier for relation types and they associated each relation with a precomputed similarity score and

(Hänig et al., 2015) extended their word alignment algorithm for the task.

### 1.1 Math notation

The data consist of sentence pairs  $\mathbf{S}_i^a$  and  $\mathbf{S}_i^b$ , where  $a$  denotes the first item of the pair,  $b$  denotes the second item of the pair and  $i$  indexes the sentences (for simplicity we further omit  $i$  for sentences). We perceive a sentence  $\mathbf{S}^a$  to be an ordered set of chunks  $\mathbf{CH}_j^a \in \mathbf{S}^a$  and the chunks to be ordered sets of words  $w_k \in \mathbf{CH}_j^a$  (and analogically for sentence  $\mathbf{S}^b$ ).

Next we define two functions:  $\text{sim}(\mathbf{CH}_i^a, \mathbf{CH}_j^b) \in \{0, 1, 2, 3, 4, 5\}$  for chunk similarity and  $\text{rel}(\mathbf{CH}_i^a, \mathbf{CH}_j^b) \in \text{TYPE}$  for chunk relation type.

The possible types are:  $\text{TYPE} = \{\text{EQUI}, \text{OPPO}, \text{SPE1}, \text{SPE2}, \text{SIMI}, \text{REL}\}$ . These are the main types. All these types can have two modifiers (*FACT*, *POL*). The modifiers are optionally attached to the main types. For example, you can generate *SPE1 FACT*. For more information, please see the annotation guidelines<sup>1</sup>.

## 2 System Overview

### 2.1 Preprocessing

As a first step of our approach we perform the following text preprocessing:

- *Stopwords removal* – we mark the words found in a predefined list of 32 stopwords.

<sup>1</sup><http://alt.qcri.org/semeval2016/task2/data/uploads/annotationguidelinesinterpretablests2016v2.2.pdf>

- *Special character removal* we remove special characters that violate the tokenization. E.g. in one of the datasets, dots, commas, quotation marks and other punctuation characters were present in tokens.
- *Lowercasing* – we remove casing from the words.
- *Lemmatization* – we find lemmas with the Stanford CoreNLP tool (Manning et al., 2014).

Our preprocessing rather adds new information and does not modify the original information. Thus, the original word and all the generated variants are always available. In this way, we can generate the output file with identical words (including the special characters) from the input. The dataset are already tokenized.

## 2.2 Chunk Semantic Similarity

The core of our system is based upon computing semantic similarity of sentence chunks. More precisely, we are looking for the best estimation of  $\text{sim}(\mathbf{CH}_i^a, \mathbf{CH}_j^b)$ . The  $\text{sim}$  score should describe semantic similarity of a given chunk pair – the higher score the more easily both chunks can be replaced with each other without chaining the meaning of both sentences. The similarity score ranges from 0 to 5, where 0 is the lowest similarity and 5 is the highest similarity. Eg. the  $\text{sim}(\text{"a new laptop"}, \text{"a new notebook"}) = 5$  and  $\text{sim}(\text{"a new laptop"}, \text{"an old rock"}) = 0$ . We use the chunk similarity as a feature in our machine learning approach (Section 3) and as a metric in our unsupervised approach (Section 4).

Our attempts to estimate the  $\text{sim}$  function are based upon estimating semantic similarity of individual words and compiling them into one number for a given chunk pair. We experiment with Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) for estimating similarity of words. We compile all the word similarities in one number that reflects semantic similarity of whole chunks via the following methods: 1) the *vector composition* method and 2) an adapted method for constructing vectors called *lexical semantic vectors*.

**Vector composition** requires that the semantics of words is described by vectors. E.g. we have vectors for all words  $\vec{m}_i : \forall w_i \in \mathbf{CH}_j^a$  and  $\vec{n}_i : \forall w_i \in \mathbf{CH}_k^b$  in two given chunks  $\mathbf{CH}_j^a$  and  $\mathbf{CH}_k^b$ . The vectors for words in each chunk are summed (or averaged) to obtain one vector for each chunk:  $\vec{m} = \sum_i (\vec{m}_i)$  and  $\vec{n} = \sum_j (\vec{n}_j)$ . The vectors are then compared with cosine distance:  $\text{sim}(\mathbf{CH}_j^a, \mathbf{CH}_k^b) = \cos(\theta) = \frac{\vec{m} \cdot \vec{n}}{\|\vec{m}\| \|\vec{n}\|}$ .

**Lexical semantic vectors** were originally introduced in (Li et al., 2006). We have made two modifications. We do not weight words with their information content and we use methods for distributional semantics (Word2Vec and GloVe) rather than semantic networks. The modified method is explained here. First of all, we create a combined vocabulary of all unique words from chunks  $\mathbf{CH}_k^a$  and  $\mathbf{CH}_l^b$ :  $\mathbf{L} = \text{unique}(\mathbf{CH}_k^a \cup \mathbf{CH}_l^b)$ . Then we take all words from vocabulary  $\mathbf{L}$ :  $w_i \in \mathbf{L}$  and look for maximal similarities with words from chunks  $a$  and  $b$ , respectively. This way we get vectors  $\vec{m}$  and  $\vec{n}$  containing maximal similarities of chunk words and words from the combined vocabulary:

$$\begin{aligned} m_i &= \max_{j:1 \leq j \leq |\mathbf{CH}_k^a|} \text{sim}(w_i, w_j) : \forall w_i \in \mathbf{L} \\ n_i &= \max_{j:1 \leq j \leq |\mathbf{CH}_l^b|} \text{sim}(w_i, w_j) : \forall w_i \in \mathbf{L} \end{aligned} \quad (1)$$

where  $m_i$  and  $n_i$  are elements of vectors  $\vec{m}$  and  $\vec{n}$ .

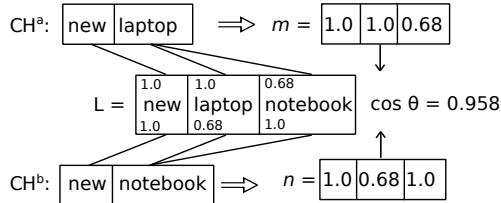

In order to obtain similarity of a chunk pair we compare their respective vectors with the cosine similarity similarly to the previous approach. The principle of the method is illustrated by the example in figure 1.

**iDF weighting.** We assume that some words are more important than others. In order to reflect this assumption, we try to weight the vectors with iDF weighting. We compute the iDF weights on the articles from English wikipedia text data (Wikipedia dump from March 7, 2015).

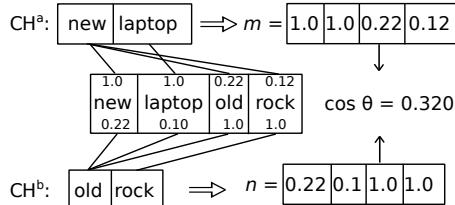

## 3 Machine Learning Approach

The main effort of our team was focused on the machine learning approach to the task. We divided the task into three classification / regression tasks:

`sim("a new laptop", "a new notebook"):`

`sim("a new laptop", "an old rock"):`

**Figure 1:** An example of the modified lexical semantic vectors method.

- *Alignment binary classification* – we decide whether two given chunks should be aligned with each other.
- *Score classification / regression* – we experiment with both classification and regression of the chunks similarity score.
- *Type classification* – we classify all aligned pairs of chunks into a predefined set of types – see Section 1.1.

### 3.1 Classifiers

We experiment with the following classifiers: *Maximum Entropy Classifier* (Berger et al., 1996), *Support Vector Machines Classifier* (Cortes and Vapnik, 1995), *Multilayer perceptron* and *Voted perceptron neural networks* (Freund and Schapire, 1999) and with *Decision / regression tree learning* (Breiman et al., 1984).

We employ the following two frameworks: *Brainy* (Konkol, 2014) and *Weka* (Hall et al., 2009).

### 3.2 Features

We divide the employed features into four categories: lexical, syntactic, semantic, external.

**Lexical features** consist of the following features: word base form overlap, word lemma overlap, chunk length difference, word sentence positions difference.

**Syntactic features** contains closest common parent comparison (we compute the closest common parent of all words for each chunk in the parse tree and retrieve the name of the parent node), parse tree path comparison (we compute the path from the root of the sentence to the chunk). POS (Part Of Speech) count difference (e.g. differences in counts of nouns, adjectives, verbs, etc). POS tagging and syntactic parsing are performed with Stanford CoreNLP (Manning et al., 2014).

**Semantic features** are described in Section 2.2. Additionally, some members of our team participated in the STS task (task 1) of the SemEval 2016 (Brychcín and Svoboda, 2016) and they annotated the semantic similarity of the whole sentences with their system for us. This score is used as one feature.

**External features** consist of the WordNet – Lin similarity metric (Lin, 1998) and the paraphrase database (Ganitkevitch et al., 2013) feature.

### 3.3 Post-processing

The alignment of chunks is generated by the binary classification of all possible chunk pairs. If one chunk is aligned with multiple chunks in the other sentence, these chunks should be merged into one chunk. Also, impossible multiple chunks to multiple chunks alignments are generated in some cases (e.g. two chunks from the first sentence belong a chunk in the second sentence but one of the two chunks from the first sentence belong also to a different chunk in the second sentence). These cases are resolved with few hand crafted rules.

## 4 Rule-based Approach

We attempt to solve the task with a rule-based approach as well. First, we define the similarity of chunks as described in Section 2.2. The similarity is then used for the chunk alignment. We employ an algorithm inspired by the IBM word model II for machine translation (Brown et al., 1993). We iterate over all chunks from sentence  $S_a$  and find the chunk with maximal similarity from sentence  $S_b$ . More chunks from sentence  $S_a$  can be aligned to one chunk in the sentence  $S_b$ . In this way, we obtain N:1 mapping. Then, we do the same with the reversed order of sentences and get the 1:M mapping. Then,

we compare the mappings and take the one with the highest overall similarity. In this way, it is ensured that we generate only valid mappings (unlike in the previous case of machine learning – see Section 3.3).

The relation types are then determined by an extremely simple algorithm:

- If the similarity is 5, then the relation type is *EQUI*.
- If the similarity is 4 or 3 and chunks contain the same amount of words, then the relation is *SIMI*.
- If the similarity is 4 or 3, then chunk with more words is more specific.
- If the similarity is 2 or 1, then the relation is *SIMI*.
- If the similarity is 0, then the relation type is *NOALI*.

## 5 Results

### 5.1 Experimental setup

**Machine learning approach** We employ the following classifiers and classification frameworks:

- *Alignment binary classification* – Voted perceptron (Weka).
- *Score classification* – Maximum entropy (Brainy).
- *Type classification* – Support vector machines (Brainy).

These classifiers perform best on the evaluation datasets.

We achieved the best results for estimating chunk similarity with Word2Vec and the modified lexical semantic vectors – see Section 2.2.

We experimented with reduced feature set (word overlap, word positions difference, POS tags difference, semantic similarity, global semantic similarity, paraphrase database) – run 1 and with all features – run 3. The run 1 contains the optimal combination of features. Since this combination is established on evaluation datasets it does not need to be optimal for the test datasets. To increase our chances in the

completion, we also run the system with all features – run 3.

We use the provided annotated evaluation dataset (*Images*, *Headlines*, *Answer students*) for training the models. We train three models, each for one dataset. For development, we use the 10-fold cross-validation. For final test runs, we train the three models on evaluation datasets and run the system on the corresponding test datasets (e.g. *Images* evaluation dataset based model is used to annotate *Images* test data). We do not neither modify the original datasets nor annotate any additional data.

**Rule-based approach** There are little options in this approach. Again, we have achieved the best results for estimating chunk similarity with Word2Vec and the modified lexical semantic vectors – see Section 2.2. We set the threshold for the similarity score to 2.5. All lower values are set to 0. This is the run 2.

**Individual setting for different dataset** We restrained from setting individual configurations for different datasets. The setup is completely identical for all datasets.

### 5.2 Results

In this section, we summarize the official results for the SemEval 2016 competition – see table 1. The results are calculated for the following dataset: *Headlines*, *Images* and *Answer students*. The results show F1 scores for chunk alignment (*Ali*), determination of the relation type (*Type*), chunk similarity score (*Score*) and combination of relation type and score similarity (*T+S*). The bold numbers are the overall best scores. We participated only in the gold standard chunk scenario.

The results clearly show that the unsupervised run 2 perform much worse than the supervised runs 1 and 3. We expected that. However, it is worth of noticing that the unsupervised alignment algorithm inspired by machine translation alignment placed quite well. In fact, it is newer loses more than 3% from the best alignment score in all datasets. The overall rank of the run 2 places in the top half among all system with exception of the *answer student* dataset. The poor performance of the run 2 on this dataset is most likely caused by the fact that the hand-crafted rules were prepared for the *images* and

| Run  | Ali           | Type          | Score         | T+S           | Rank |
|--|---------------|---------------|---------------|---------------|------|
| Images dataset (756 sentence pairs)          |               |               |               |               |      |
| 3  | 0.8922        | <b>0.6867</b> | 0.8408        | <b>0.6708</b> | 1    |
| 1  | <b>0.8937</b> | 0.6829        | 0.8397        | 0.6672        | 2    |
| 2  | 0.8713        | 0.6346        | 0.8083        | 0.6206        | 6    |
| Headlines dataset (750 sentence pairs)       |               |               |               |               |      |
| 3  | 0.8987        | 0.6412        | <b>0.8382</b> | 0.6296        | 6    |
| 1  | 0.8979        | 0.6319        | 0.8346        | 0.6212        | 7    |
| 2  | 0.8897        | 0.6146        | 0.815         | 0.6013        | 8    |
| Answer students dataset (330 sentence pairs) |               |               |               |               |      |
| 1  | 0.8644        | 0.6299        | 0.8089        | 0.6248        | 3    |
| 3  | 0.8588        | 0.6167        | 0.8038        | 0.6114        | 5    |
| 2  | 0.8752        | 0.4806        | 0.7826        | 0.4748        | 17   |
| <b>Overall results</b> (mean)                |               |               |               |               |      |
| 1  | 0.6672        | 0.6212        | 0.6248        | 0.6377        | 1    |
| 3  | <b>0.6708</b> | 0.6296        | 0.6114        | 0.6373        | 2    |
| 2  | 0.6206        | 0.6013        | 0.4748        | 0.5656        | 12   |

**Table 1:** Official system evaluation.

*headlines* datasets and they are clearly not applicable on the *answer student* which is substantially different.

The runs 1 and 3 perform very similarly. The optimized feature set of the run 1 helps especially in the *answer student* dataset. However, the differences between these runs are too small and they can be caused by chance. It is worth of noticing that the run 1 is not the best one in any of the datasets and it still wins in the overall results table. The reason is that it provides the most consistent results among all other runs of all systems in the competition.

In order to provide additional information about the features effectiveness, we have evaluated them on the final test datasets. In many cases, the obtained results are not conclusive. On some datasets, the features help slightly on others they even decrease the performance. However, the following three features have significant influence on the final results: modified lexical semantic vectors (+3% of the mean of T+S F1 scores), shared words (+2%), POS tags difference (+2%). The modified lexical semantic vectors method performed better than vector composition by 1% for the machine learning approach and by 2% for the rule-based approach in average. By optimizing the feature set, we were able to increase the mean score to 0.6484 of T+S F1 measure.

## 6 Conclusion

The machine learning approach with combination of methods for the distributional semantics (Word2Vec and GloVe) proved to be very capable of solving the advanced task of Interpretable Semantic Textual Similarity. We have chosen not to tune the system for individual datasets but to tune it for the task as a whole. The modified lexical semantic vectors approach seems to be an attractive alternative to the more traditional vector composition.

## Abstract

In this paper we describe our system (DTSim) submitted at SemEval-2016 Task 2: Interpretable Semantic Textual Similarity (iSTS). We participated in both gold chunks category (texts chunked by human experts and provided by the task organizers) and system chunks category (participants had to automatically chunk the input texts). We developed a Conditional Random Fields based chunker and applied rules blended with semantic similarity methods in order to predict chunk alignments, alignment types and similarity scores. Our system obtained F1 score up to 0.648 in predicting the chunk alignment types and scores together and was one of the top performing systems overall.

## 1 Introduction

Measuring the semantic similarity of texts is to quantify the degree of semantic similarity between a given pair of texts, such as two words or two sentences (Rus et al., 2008; Agirre et al., 2015). For example, a similarity score of 0 means that the texts are not similar at all and 5 means that they have same meaning. While useful, such quantitative or even qualitative assessments are hard to interpret because they do not provide details, i.e. they do not explain or justify why the similarity score was assigned high or low. One way to provide an explanatory layer to text similarity assessment methods is to align chunks between texts and assigning semantic relation to each alignment. To this end, Brockett (2007) and Rus et al. (2012) produced datasets

where corresponding words (or multiword expressions) were aligned and in the latter case their semantic relations were explicitly labeled

In interpretable Semantic Textual Similarity (iSTS) tasks (Agirre et al., 2016), participants had first to identify the chunks in each sentence (sys chunks) or use the chunks given by the task organizers (gold chunks), and then, align chunks across the two sentences indicating the semantic relation and similarity score of each alignment. The chunk alignment types were EQUI (semantically equivalent), OPPO (opposite in meaning), SPE (one chunk is more specific than other), SIMI (similar meanings, but not EQUI, OPPO, SPE), REL (related meanings, but not SIMI, EQUI, OPPO, SPE), and NOALI (has no corresponding chunk in the other sentence). The relatedness/similarity scores were assigned in the range of 0 to 5.

A pilot on iSTS task was organized in 2015 (Agirre et al., 2015). In 2016, the iSTS allowed many-to-many chunk alignment while in the pilot task of 2015 they only allowed one-to-one or no alignment. Also, a new dataset consisting of student answers given to a tutoring system was added in 2016. For further details about the task, please see Agirre et al. (2016).

We participated in both categories: system chunks and gold chunks. Our system first preprocesses texts, creates chunks (in sys chunks category) using our own chunking tool, and performs alignments and labels them with semantic relations and similarity scores. In this paper, we describe our system DTSim<sup>1</sup> and the submitted three different runs in the

\* These authors contributed equally to this work

<sup>1</sup> Available for download from <http://semanticsimilarity.org>

shared task. Our system was one of the top performing systems.

## 2 Preprocessing

Hyphens were replaced with whitespaces if they were not composite words (e.g. video-gamed). Also, the words starting with co-, pre-, meta-, multi-, re-, pro-, al-, anti-, ex-, and non- were left intact. Then, the texts were tokenized, lemmatized, POS-tagged and annotated with Named Entity (NE) tags using Stanford CoreNLP Toolkit (Manning et al., 2014). We also marked each word as whether it was a stop word. In the system chunks category, we had plain texts and we created chunks using our own Conditional Random Fields (CRF) based chunking tool (see Section 3). We normalized texts using mapping data. For example, *pct* and % were changed to *percent*. These preprocessing steps were performed for both gold chunks and system chunks category.

In student-answers dataset which consists of student answers given to a computer based logic tutor (Agirre et al., 2016), we replaced symbol *A/B/C* with *bulb A/B/C*. Similarly, *X/Y/Z* was replaced by *switch X/Y/Z*. We used this domain knowledge based on the notes found in student-answers training data description file.

## 3 Chunking

We developed a CRF based chunker<sup>2</sup> using both CoNLL-2000 shared task training and test data<sup>3</sup>. This data consists of a Wall Street Journal corpus: sections 15-18 as training data (211727 tokens) and section 20 as test data (47377 tokens). We generated shallow parsing features such as previous and next words from current word, current word itself, current word POS tag, previous and next word POS tags and their different combinations as described in Tjong Kim Sang and Buchholz (2000). We used CRF++ tool<sup>4</sup> to build the CRF models.

Furthermore, we analyzed its output (i.e. chunks) and added the following rules in the system to merge some of the chunks, resulting in chunks that make more sense and are consistent with iSTS gold chunks.

<sup>2</sup>Our chunker is available at <http://semanticsimilarity.org>

<sup>3</sup><http://www.cnts.ua.ac.be/conll2000/chunking/>

<sup>4</sup><https://taku910.github.io/crfpp/>

| DataSet       | Chunker | CL           | SL           |
|---------------|---------|--------------|--------------|
| Training data |         |              |              |
| Headlines     | O-NLP   | 53.74        | 13.49        |

|               | EO-NLP  | 89.30        | 72.13        |
|               | CRF     | <b>90.29</b> | <b>74.93</b> |

**Table 1:** Comparison of chunking accuracies of the various chunkers at chunk level (CL) and at sentence level (SL) with iSTS 2015 gold data.

- (a) PP + NP => PP
- (b) VP + PRT => VP
- (c) NP + CC + NP => NP

For example, it merges chunks [on] and [Friday] to form single PP chunk [on Friday] using rule (a).

We evaluated the chunking accuracy of the CRF chunker by comparing its output against the gold chunks of iSTS 2015 data: the training and test data sets each consist of 375 pairs of Images annotation data and 378 pairs of Headlines texts. This chunker yielded the highest average accuracies on both the training and test datasets compared to other chunkers which are described next. The accuracies on the training dataset were 86.20% and 68.34% at chunk level and sentence level respectively. For the test dataset, the accuracies were 86.81% and 69% at chunk and sentence level, respectively. The results are presented in Table 1.

We also chunked the input texts using the Open-NLP chunking tool (O-NLP). The average (of Images and Headlines data) accuracies were 53.04% at chunk level and a modest 9.27% at sentence level for the training dataset. It yielded similar results on test data. We extended Open-NLP chunker (EO-NLP) using the rules described before. The results were improved and resulted in 84.% chunk level

and 66.02% sentence level average accuracies on the training dataset, respectively. The accuracy on the test data was comparable at 85.13% chunk level and 66.15% at sentence level. However, the results of our CRF based chunker were superior in all cases.

## 4 Chunk Alignment System

For a given sentence pair, the chunks of the first sentence were mapped to those from the second by assigning different semantic relations and scores based on a set of rules, similarity functions, and lookup resources. Before performing alignments, we preprocessed texts as described in Section 2.

We built upon a previous system called NeRoSim (Banjade et al., 2015). The limitation of their system was that the alignments were restricted to 1:1. We modified it to support many to many alignments as well. Also, the NeRoSim system was able to process only gold chunks (i.e., chunks provided by the organizers). Now, the system can take input in the form of plain texts as well and create chunks on the fly. In addition to the chunking feature described in Section 3, the updates made to the systems are described below.

### Many-to-Many Alignments:

**MULTII:** If there is any ALIC chunk (i.e., chunk which does not have any corresponding chunk in the other sentence because of the 1:1 alignment restriction) in sentence A whose content words are subsumed by the content words of any already aligned chunk (C) in another sentence B, merge ALIC chunk with the chunk in A paired with C. If the content words of merged chunk and those of C are same/equal, realign chunk C with merged chunk as EQUI and update the score to 5.0.

For example:

```
// [Iran] [hopes] [nuclear talks] [...].  
// [Iran Nuclear Talks] [spur] [...].
```

Step 1:

*nuclear talks <=> Iran Nuclear Talks // SPE2*

*Iran <=> //ALIC*

Step2:

*Iran nuclear talks <=> Iran Nuclear Talks // EQUI*

**MULTI2:** In *MULTII*, if all the content words of merged chunk and those of C are not matching

completely, then realign chunk C with merged chunk but keep the previous alignment type and score.

Furthermore, we have expanded the rules for SIMI and EQUI.

**EQx:** If unmatched words are morphological inflections of each other and all other words in the chunks are already matched, assign the EQUI relation.

E.g. *Korean Air <=> Air Korea*

**SIMIx:** If nouns are matching but not the adjective or vice-versa, assign SIMI label.

E.g. *red carpet <=> brown carpet*

### Runs

**R1:** We included many-to-many alignment in NeRoSim (i.e., MULTI1 and MULTI2 were added).

**R2:** Same as R1 in alignment but the alignment scores were assigned based on the average scores for each alignment type in the full training data.

**R3:** Same as R2 but SIMIx and EQx rules added.

## 5 Results

The test data consisted of 1,094 sentence pairs which included texts from headlines (375), image annotations (375), and student-answers (344). The results (F1 scores)<sup>5</sup> on test datasets are presented in Table 2 and Table 3. Further details about the test data and the evaluation metrics can be found in Agirre et al. (2016).

Table 2 presents the results in terms of F1 scores on test set with gold chunks. We can see that the alignment scores are higher compared to the baseline system and are very close to the best results from all submissions in those categories. However, the alignment type score in each case is relatively lower than the alignment-only score and it ultimately impacted the F1 score calculated for type and score together (i.e. T+S).

Similar to Table 2, the Table 3 presents the results on the test set but this time with system chunks. In image and headlines data, our system obtained the best results. However, following the same pattern as in gold chunk results, the F1 scores for alignments

---

**Table 2:** F1 scores on test data with gold chunks. A, T and S refer to Alignment, Type, and Score, respectively. Max score is the best score for each metric given by any of the participating systems in the shared task including the system submitted by the team involved in organizing the task.

are high but the scores for predicting the alignment types are relatively lower. It indicates that the systems overall performance will be improved greatly if improvements can be made in predicting the alignment types. Also, the scores for student-answers are lower than headlines and image texts and it requires further analysis to fully understand why this is the case. One of the reasons might be that we did not use this dataset while developing the system and no prior information about such dataset was modeled. Additionally, more errors might have been introduced in our NLP pipeline as the texts in this dataset were not standard written texts.

In addition to the difficulty of the task of aligning the chunks and assigning relation types, we found some discrepancies in the annotation which we think induced some errors. For example, *on a sofa <=> on a blue sofa* (#65 in image data), the human annotated label is SIMI but arguably the SPE2 label best describes the relation. Similarly, *in a field <=> in a green field* (#693 in image data), the SPE1 label has

| System          | A      | T      | S      | T+S           |
|-----------------|--------|--------|--------|---------------|

| R1              | 0.8165 | 0.5157 | 0.7248 | 0.5049        |
| R2              | 0.8165 | 0.5157 | 0.7367 | <b>0.5074</b> |
| R3              | 0.8181 | 0.5112 | 0.7360 | 0.5029        |
| Max             | 0.8166 | 0.5651 | 0.7589 | 0.5547        |

**Table 3:** Results on test data with system chunks.

been found in the training set but it should be SPE2. In another example (#193 in image data), *A young boy <=> A young blonde girl* has been assigned a label SPE2 in the training data. Though the second chunk gives some additional details, the question is whether we should really compare them (and decide which one is more specific) because these two chunks are referring to different objects and therefore it sounds more like comparing apples and oranges.

## 6 Conclusion

This paper presented the system DTSim and three different runs submitted in SemEval 2016 Shared Task on Interpretable Textual Semantic Similarity (iSTS). We described our chunking tool and results on gold chunks as well as on system chunks categories. Our system was one of the best systems submitted in the shared task. However, there is room for improvement particularly on assigning alignment labels which we intend to address in future work. Furthermore, the annotated dataset is now quite big and it will certainly be useful in applying alternative approaches to predict chunk alignments and alignment types.

## Abstract

In this work we describe the system built for the three English subtasks of the SemEval 2016 Task 3 by the Department of Computer Science of the University of Houston (UH) and the Pattern Recognition and Human Language Technology (PRHLT) research center - Universitat Politècnica de València: UH-PRHLT. Our system represents instances by using both lexical and semantic-based similarity measures between text pairs. Our semantic features include the use of distributed representations of words, knowledge graphs generated with the BabelNet multilingual semantic network, and the FrameNet lexical database. Experimental results outperform the random and Google search engine baselines in the three English subtasks. Our approach obtained the highest results of subtask B compared to the other task participants.

## 1 Introduction

The key role that the Internet plays today for our society benefited the dawn of thousands of new Web social activities. Among those, forums emerged with special relevance following the paradigm of the Community Question Answering (CQA). These type of social networks allow people to post a question to other users of that community. The usage is simple, without much restrictions, and infrequently moderated. The popularity of CQA is a strong indicator that users receive some good and valuable answers.

However, there are several issues related to that type of community. First is the large amount of answers received that makes it difficult and time-consuming for users to search and distinguish the good ones. This is exacerbated with the amount of noise that these questions contain. It is not uncommon to have wrong or misguiding answers that produce more unrelated answers, discussions and sub-threads. Finally, there is a lot of redundancy, questions may be repeated or closely related to previously asked questions.

Details of the SemEval 2016 Task 3 on CQA can be found in the overview paper (Nakov et al., 2016). In this work we evaluate the three English-related Task 3 subtasks on CQA. We first represent each instance to rank — question versus (vs.) comments, question vs. related questions, or question vs. comments of related questions — with a set of similarities computed at two different levels: lexical and semantic. This representation allows us to estimate the relatedness between text pairs in terms of what is explicitly stated and what it means. Our lexical similarities employ representations such as word and character  $n$ -grams, and bag-of-words (BOW). The semantic similarities include the use of distributed word bidirectional alignments, distributed representations of text, knowledge graphs, and frames from the FrameNet lexical database (Baker et al., 1998). This type of dual representations have been successfully employed for question answering by the highest performing system in the previous edition of this Se-

mEval task (Tran et al., 2015). Other Natural Language Processing (NLP) tasks such as cross-language document retrieval and categorization also benefited from similar representations (Franco-Salvador et al., 2014). In this task, if the question or comment includes multiple text fields, e.g. body and subject, similarities are estimated using all possible combinations (see Section 3.2). Finally, the ranking of instances is performed using a state-of-the-art machine-learned ranking algorithm:  $\text{SVM}_{\text{rank}}$ .

## 2 Related Work

Automatic question answering has been a popular interest of research in NLP from the beginning of the Internet to more recently where voice interfaces have been incorporated (Rosso et al., 2012). The use of BOW representations allowed to correctly answer 60% of the questions of the first large-scale question answering evaluation at the TREC-8 Question Answering track (Voorhees, 1999). More complex systems used inference rules to connect expressions between questions and answers (Lin and Pantel, 2001). Similarly, Ravichandran and Hovy (2002) employed bootstrapping to generate surface text patterns in order to successfully answer questions. Other works such as Buscaldi et al. (2010) are based on the redundancy of  $n$ -grams in order to find one or more text fragments that include tokens of the original question and the answer. Jeon et al. (2005) studied the semantic relatedness between texts for question answering. They used translation obfuscation to paraphrase the text and to detect which terms are closer in context. Probabilistic topic models have been also useful for detecting the semantics in this task. Celikyilmaz et al. (2010) used Latent Dirichlet Allocation (LDA) (Blei et al., 2003) for representing questions by means of latent topics.

The previous edition of the SemEval CQA task included two English subtasks (Nakov et al., 2015). The first one was focused on classifying answers as *good*, *bad*, or *potentially relevant* with respect to one question. The second subtask answered a question with *yes*, *no*, or *unsure* based on the list of all answers. In addition, the

first subtask was also available in Arabic. Several teams experimented with complex solutions that included meta-learning, external resources, and linguistic features such as syntactic relations and distributed word representations. Similarly to our work, the highest performing approach employed a combination of lexical and semantic-based similarity measures (Tran et al., 2015). Its semantic features included the use of probabilistic topic models, translation obfuscation-based alignments, and pre-computed distributed representations of words both generated with the word2vec<sup>1</sup> and GloVe<sup>2</sup> toolkits. Their lexical features included BOW, word alignments, and noun matching. They employed a regression model for classification. Another interesting approach, Hou et al. (2015), included textual features — word lengths and punctuation — in addition to syntactical-based features — Part-of-Speech (PoS) tags.

In this work we aim at differentiating from the other approaches by enhancing our ranking model with new similarity measures. These include the use of knowledge graphs obtained using the largest multilingual semantic network — BabelNet — frames from the FrameNet lexical database, and bidirectional distributed word alignments.

## 3 Lexical and Semantic-based Community Question Answering

In this section we detailed the system that we designed for this CQA task. First in Section 3.1 we described our set of lexical features and semantic-based ones. Next, in Section 3.2 we detail the specific adaptation that we employed for each subtask and the ranking algorithm that we used. We note that all our features are similarity scores obtained with different text similarity measures. More details and examples can be found in their respective papers.

### 3.1 Feature Description

Our system exploits both the verbatim and the contextual similarities between texts, i.e., questions and comments. In Section 3.1.1 we

---

<sup>1</sup><https://code.google.com/archive/p/word2vec/>

<sup>2</sup><http://nlp.stanford.edu/projects/glove/>

detailed our lexical and in Section 3.1.2 our semantic-based features.

### 3.1.1 Lexical Features

The lexical features that we employed are the following:

- **Cosine Similarity.** We used cosine similarity to measure lexical similarity between two text snippets. We calculated cosine similarity based on word  $n$ -grams( $n=1,2$ ), character 3-grams and tf-idf (Salton and McGill, 1986) scores of words.
- **Word Overlap.** We used the count of common words between two texts. This count was normalized by the length.
- **Noun Overlap.** We used NLTK<sup>3</sup> to part-of-speech tag the text and computed the normalized count of overlapping nouns in two texts as a similarity measure.
- **N-gram Overlap.** We computed the normalized count of common  $n$ -grams( $n=1,2,3$ ) between two texts.

### 3.1.2 Semantic Features

The semantic features that we employed are the following:

- **Distributed representations of texts.** We used the continuous Skip-gram model (Mikolov et al., 2013) of the word2vec toolkit to generate distributed representations of the words of the complete English Wikipedia.<sup>4</sup> Next, for each text, e.g. question or comment, we averaged its word vectors in order to have a single representation of its content as this setting has shown good results in other NLP tasks (e.g. for language variety identification (Franco-Salvador et al., 2015a) and discriminating similar languages (Franco-Salvador et al., 2015b)). Finally, the similarity between texts, e.g. question vs. comment, is estimated using the cosine similarity.

<sup>3</sup><http://www.nltk.org/>

<sup>4</sup>We used 200-dimensional vectors, context windows of size 10, and 20 negative words for each sample.

• **Distributed word alignments.** The use of word alignment strategies has been employed in the past for textual semantic relatedness (Hassan and Mihalcea, 2011). Tran et al. (2015) employed distributed representations to align the words of the question with the words of the comment. A more recent work introduced the Continuous Word Alignment-based Similarity Analysis (CWASA) (Franco-Salvador et al., 2016a). CWASA uses distributed representations to measure the similarity by double-direction aligning words of texts. In this work we selected as feature the similarity provided by CWASA between questions and comments.

• **Knowledge graphs.** A knowledge graph is a labeled, weighted, and directed graph that expands and relates the concepts belonging to a text. Knowledge Graph Analysis (KGA) (Franco-Salvador et al., 2016b) measures semantic relatedness between texts by means of their knowledge graphs. In this work we used the BabelNet (Navigli and Ponzetto, 2012) multilingual semantic network to generate knowledge graphs from questions and comments, and measured their similarity using KGA.

• **Common frames.** We used FrameNet (Baker et al., 1998) to extract the frames associated with the lexical items in the text. For each frame present in the text, we calculated the common lexical items between sentences associated with this frame. The goal is to allow inference of similarity at the level of semantic roles.

As additional feature, for Subtasks A and C we also used the ranking provided by the Google search engine for the questions related to the original questions.

## 3.2 Data Representation and Ranking

Due to the representation of questions — composed by *subject* and *body* fields — and answers — a *comment* field — we adapted our system for the different English subtasks:

- **Subtask A (question-comment similarity ranking):** we used the aforementioned similarity-based features at three levels: question subject vs. comment, question body vs. comment, and full question vs. comment.
- **Subtask B (question-related question similarity ranking):** for this subtask we measured the similarities at body, subject, and full question level.
- **Subtask C (question-external comment similarity ranking):** we employed all the features of Subtasks A and B, plus the similarities of the original question — subject, body, and full levels — with the related question comments.

In order to rank the questions and comments, we selected a variant of Support Vector Machines (SVM) (Hearst et al., 1998) optimized for ranking problems: SVM<sub>rank</sub> (Joachims, 2002). In our evaluation of Section 4, we call our system as the combination of the acronyms of our member institutions: UH-PRHLT.

Preprocessing steps included stopword removal, lemmatization, and stemming. However, for the distributed representation and knowledge graph-based features we did not employ stemming. These decisions were motivated for performance reasons during our prototyping.

Note that each subtask allows to submit three runs per team: primary, contrastive 1 (contr. 1), and contrastive 2 (contr. 2). We used a linear kernel and optimized the cost factor parameter using Bayesian optimization<sup>5</sup> (Snoek, 2013). Our three runs differ only in the value for that parameter and correspond with the three best — and considerably distant — values. In addition to the ranking, the task requires also to provide with a label for each instance that reflects if the question or comment is relevant to the compared question. For each subtask we optimized a threshold to determine the relevance of each instance that is based on our predicted relevance ranking. In other words, we binarize our ranking.

---

<sup>5</sup>We used the Spearmint toolkit: <https://github.com/HIPS/Spearmint>

## 4 Evaluation

This section presents the evaluation of the SemEval 2016 Task 3 on CQA. Details about this task, the datasets, and the three subtasks can be found in the task overview (Nakov et al., 2016). Note that for our system we did not use data from SemEval 2015 CQA as we did not observe gains in performance.

We compared the results of our approach with those provided by the random baseline and the Google search engine when ranking the questions and comments.<sup>6</sup> The official measure of the task is the Mean Average Precision (MAP), but we included also two alternative ranking measures: Average Recall (AvgRec) and Mean Reciprocal Rank (MRR). In addition, we included four classification measures: Accuracy (acc.), Precision (P), Recall (R), and F1-measure (F1).

### 4.1 Results and Discussion

The best results per partition and subtask are highlighted in bold. In addition, we always refer to the run with the highest performance. Finally, our percentage comparisons use always absolute values. We can see the results of Subtask A (question-comment similarity ranking) in Table 1. In terms of ranking measures, our system outperformed both the random and the search engine baseline. Using the development set, we observed a MAP improvement of 9.4% compared with the results obtained by the search engine. We can see similar differences with respect to the other two ranking measures. Classification results are also superior. We obtain improvements in accuracy and F1 of 24.9% and 5.2% respectively. These results manifest the potential of the selected lexical and semantic-based features for this subtask.

Similar to Subtask A, the performance of our approach has been also superior in Subtask B

---

<sup>6</sup>Some considerations about the evaluation: these subtasks employed binary classification. At testing time, *Bad* and *PotentiallyUseful* are both considered *false*. The same occurs with *PerfectMatch* and *Relevant*, which are both considered *true*. In addition, following the rules of the task, the employed measures used only the top 10 ranked instances.

| Model                          | Ranking measures |              |              | Classification measures |              |              |              |
|--------------------------------|------------------|--------------|--------------|-------------------------|--------------|--------------|--------------|
|                                | MAP              | AvgRec       | MRR          | Acc.                    | P            | R            | F1           |

**Table 3:** Results of **Subtask C: English Question-External Comment Similarity**. (a) Baselines; (b) proposed approach.

(question-related question similarity ranking). As we can see in Table 2, using the development set, the improvement of MAP, AvgRec, and MRR has been of 4.6%, 5%, and 6.4% respectively compared to the search engine baseline. In this case, the similarity between questions was easier to estimate — also for the baselines — and the improvements in performance were slightly reduced. With respect to the classification measures, we outperformed the random baseline with 27.4% and 16.1 % of accuracy and F1-measure respectively.

In Table 3 we can see the results of the Subtask C (question-external comment similarity ranking). In this case, we are ranking 100 comments (10 times more compared to the other subtasks). Therefore, this has been the most difficult subtask. However, we obtained improvements in line with those reported for the other subtasks. Compared to the search engine baseline, the MAP, AvgRec, and MRR improved 8.7%, 8.5%, and 7.5% respectively when using the development partition. The accuracy and F1-measure improved 61.5% and 12.2% respectively. The largest number of comments to rank, and the use of top 10 results when measuring results, benefited our approach with this especially high difference in accuracy.

After the analysis of results in the three English subtasks, we highlight that the combination of lexical and semantic-based features that we employ in this work offers a competitive performance for the CQA task. This is true also when comparing results with other task participants. Our approach obtained the highest results — with considerable margin (1.04%) — for subtask B. It is worth mentioning that we designed our system for the subtask B and adapted it later for the other tasks. However, for the other two subtasks, we obtained a low ranking position. At this point we have not discovered any coding error that could explain this difference. In addition, we analysed the information gain ratio of the features for the three subtasks. That results showed an average decrease of ~66% for subtasks A and C. Therefore, we conclude that our approach is more adequate for tasks of similarity rather than

question answering. That analysis also manifests that the most relevant features are the word  $n$ -gram ones followed by the CWASA, distributed representation-based, and knowledge-graph-based ones. The comparison of results of all the submitted systems and task participants can be found in the task overview (Nakov et al., 2016).

## 5 Conclusions

In this work we evaluated the three English subtasks of the SemEval 2016 Task 3 on CQA. In order to measure similarities, our proposed approach combined lexical and semantic-based features. We included simple — and effective — representations based on BOW, character and word  $n$ -grams. We also employed semantic features which used distributed representations of words to represent documents or to directly measure similarity by means of distributed word bidirectional alignments. The use of knowledge graphs generated with the BabelNet multilingual semantic network has been exploited too. Experimental results showed that our system was able to outperform — with considerably differences — the random and Google search engine baselines in all the evaluated subtasks. In addition, our approach obtained the highest results in subtask B compared to the other task participants. This fact manifests the potential of our combination of lexical and semantic features for the CQA subtask.

As future work we will continue studying how to approach CQA with knowledge graphs and distributed representations. In addition, we will further explore how to employ this type of lexical and semantic-based representations for other NLP tasks such as plagiarism detection.

## Abstract

Ranking is an important task in the field of information retrieval. Ranking may be used in different modules in natural language processing such as search engines. In this paper, we introduce a competitive ranking system which combines three different modules. The system participated in SemEval 2016 question ranking task for the Arabic language. The task is a ranking task that targets reordering results retrieved from search engine. Results reordering is done based on relevancy between search result and the original query issued. The data provided in the competition is in the form of question (query) and 30 question answer pairs retrieved from search engine. For each question retrieved from the search engine the system generates a relevancy score that is to be used for ranking. The proposed system came in the third position in the Competition. Since the majority of modules are unsupervised the unsupervised naming was used.

## 1 Introduction

This paper describes RDI System, the system participated in SemEval 2016 Community question ranking shared task for the Arabic language (Nakov et al., 2016). The task is a ranking task for medical community questions, whenever a new user wants to submit a new question, the system should retrieve similar questions that are previously answered. Questions retrieved by the search engine are then to be ordered by its relevancy to query question in order to reduce redundancy.

The task proceeds as follows, for each query question 30 previously answered question answer pairs are retrieved through a search engine. The aim of the task is to reorder the retrieved 30 question answer pairs based on its relevancy to the query question.

As query expansion and results re-ranking are two major paradigms for search engine enhancements, (Mahgoub et al., 2014) used Google synonyms and Arabic Wikipedia to expand search queries, on the other hand (Abouenour et al., 2010) proposed a system that uses Arabic WordNet to expand queries. In this paper we are going to propose a

ranking system which consists of three modules merged with each other to produce a relevancy score. The proposed system managed to achieve the third position in the SemEval 2016 Community question ranking shared task for the Arabic. The 3 modules presented in this system are:

- 1- TF-IDF based module
- 2- Language model (LM) based module
- 3- Wikipedia-based module

The paper is organized as follows: Section 2 introduces some related work. Section 3 introduces data used. Section 4 contains proposed system. Section 5 contains Results obtained. In Section 6, some conclusions and perspective are discussed. Section 7 contains future work.

## 2 Related Work

The community question ranking problem is different than ordinary question answering system that aims to generate a satisfactory answer for a specific question. Community question ranking problem aims to find the most suitable answer for a question within a closed set of question answers pool.

(Zongcheng et al. 2012) argued that a question and answer can be considered the same topic distribution written in two different languages or written by two different writers. So they proposed extracting the latent topics from question and answer, they used the extracted topics to represent the question and answer, alongside measuring how much question and answer share topics.

(Jeon et al. 2006) used some non-textual features to cover the contextual information of questions and answers, and proposed using language modeling to process these features in order to predict the quality of answers collected from a specific CQA service. (Blooma et al. 2008) used regression to combine textual and non-textual features to generate predictive score to identify the best answer.

(Ko et al. 2007) proposed using probabilistic answer ranking model to calculate the answer relevance and answer similarity. They used logistic regression to calculate the correctness score for an answer using its relevancy to the question. The authors then improved their work by using probabilistic graphical model so that the correlation between all the answers can be taken into consideration.

## 3 Data

During the development of the proposed system 4 sets of data were used.

### A) Training data provided by SemEval

This data consists of 1030 search queries, each query is accompanied with 30 search engine retrieved results. Data is manually annotated with relevancy score and is marked as relevant or irrelevant. Where relevant annotated questions are questions that are actually relevant to the query question, and irrelevant annotated questions are irrelevant to the query question.

### B) Development data provided by SemEval

This data consists of 250 search queries, each query is accompanied with 30 search engine retrieved results. Data is manually annotated as relevant or irrelevant. Where relevant annotated questions are questions that are actually relevant to the query question, and irrelevant annotated questions are irrelevant to the query question.

### C) Test data provided by SemEval

This data consists of 250 search queries, each query is accompanied with 30 search engine retrieved results. In this case, data has no annotation provided.

### D) Crawled data

This data is in the form of question-answer pairs crawled from <http://www.altibbi.com>. 170,000 question answer pairs were crawled, all of these data samples were considered relevant samples as we considered relevancy between answer text and question text.

## 4 Proposed System

This section describes the proposed system in details. As shown in figure 1, three different modules are proposed. First, relevancy between search results retrieved from the search engine and the search query are calculated using three modules. The three relevancy values calculated are then converted into one relevancy score using weighted summation.

Retrieved documents are then re-ordered based on the new weighted sum scores. The best weights used for weighting the three modules ( $\alpha$ ,  $\beta$  and  $\gamma$ ) were inferred through tuning over development set.

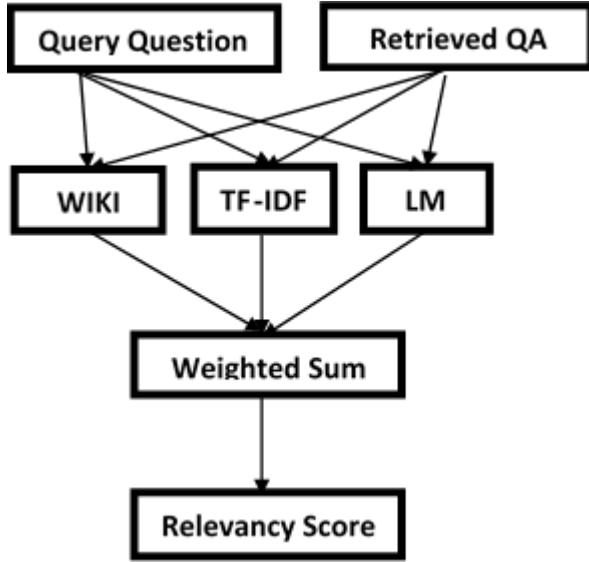

Figure 1. Proposed System

#### 4.1 TF-IDF Module

This module uses the crawled data as background corpora to calculate the relevancy between the query question and each of the 30 retrieved question answer pairs.

The main idea of the algorithm is that for each query question, cluster the background data into relevant and irrelevant classes. The two constructed classes are then used to calculate how much the retrieved 30 question answer pairs are relevant to the query question. The algorithm flows as follows:

- Crawled data and query question are normalized by removing (non-Arabic words, Numbers, Punctuations and Stop words).
- For the query question, cluster the crawled data into two classes; 1- Relevant and 2- Irrelevant. This can be done by counting the number of common words between the query question and each question answer pair of the crawled data. If the number of common words is more than or equal 3, then this pair is considered relevant, otherwise is considered irrelevant.
- For each pair of the retrieved question answer pairs, unigrams, bigrams and trigrams are extracted. For each unigram, bigram and trigram TF-IDF is calculated twice, once using IDF extracted from the relevant class question answer pairs and once using the IDF extracted from the irrelevant class question answer pairs.

- The TF-IDF for the question pair is calculated by weighting the unigram TF-IDF by  $\omega_1$ , bigrams by  $\omega_2$  and trigrams by  $\omega_3$ .
- The TF-IDF with relevant class and TF-IDF with irrelevant class are normalized into probability values.
- The relevant probability is then used as the final score for the current question answer pair.

#### 4.2 Language Model Module

This module utilizes the concept of language modeling into the ranking task. A language model was trained using the crawled data alongside the training data provided for the competition that was annotated as relevant question answer pair. In our experiments, we used the provided training data to reform new training samples as shown in figure.2.

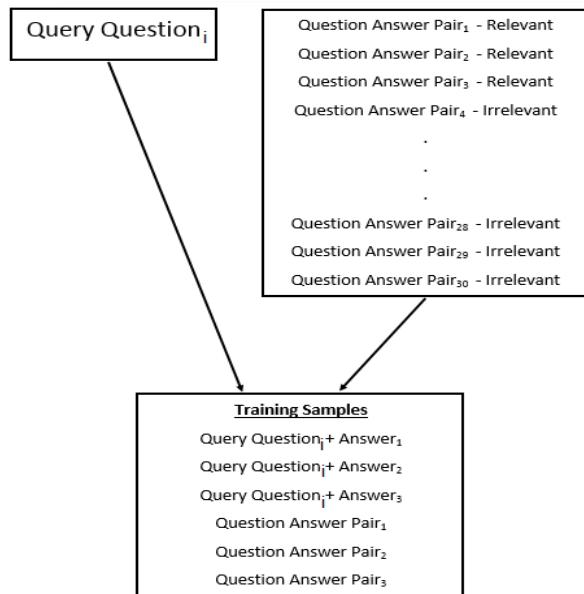

Figure 2. Generating LM training samples

As shown in figure.2, for each query question and its 30 retrieved question answer pairs, to form new text samples, query question text has been appended to answer text of pairs which are annotated as relevant. The main idea behind using language model is that, a sentence formed from question and its answer is coherent, so using the answer with the query question in case the answer is annotated as relevant; will lead to coherent sentence too.

By using the previous algorithm, we generated new training samples which represent the relevancy between questions and answers. Those training

samples are essential to feed the language model with more coherent training samples.

Using the previous generated samples a recurrent neural network for language modeling (Mikolov et al., 2011) with the following characteristics was trained;

- 1-hidden layer of size 200 neuron and sigmoid activation function.
- Hierarchical Softmax output layer over the whole vocabulary.

This module is the only supervised module used within the system, since human annotation was employed within this module.

### 4.3 Wikipedia-based module

This module uses medical information provided by Arabic-Wikipedia in order to provide better scoring methodology. The intuition behind using Wikipedia's medical terms is to provide higher matching score for those terms present in Wikipedia's medical tree over other matched terms.

Using the categorization system provided by Wikipedia, about 250,000 medical subcategories where extracted from the Medical category, the list is available for download from the author's website<sup>1</sup>. These extracted terms are then separated into three categories: unigrams, bigrams, or more, where each category weighted by a different matching factor.

To assign a total matching score between a query question and a question answer pair, the following steps are applied for each of the 30 retrieved question answer pairs:

- Top 1500 Most frequent words generated by (Zahran et al., 2015) were removed from both query question and the questions answer pairs.
- Find matching terms between the question and the question answer pair.
- For each matching term:
  - o If the matching term is a unigram which exists in Wikipedia extracted terms, then increment the total matching score by *Uni\_Wiki\_Factor*
  - o Else if the matching term is a unigram which doesn't exists in Wikipedia extracted terms, then increment the total matching score by *Uni\_Factor*.

- o Repeat the previous two steps for both: bi-grams and higher n-grams using (*Bi\_Wiki\_Factor*, *Bi\_Factor*) for bigrams and (*N\_Wiki\_Factor*, *N\_Factor*) for higher order n-grams.

Moreover, values of these matching factors are tuned over a subset of the provided training set and then validated on the development set. The optimum values of the matching factors are

- *Uni\_Wiki\_Factor* = 1.5
- *Uni\_Factor* = 1
- *Bi\_Wiki\_Factor* = 2
- *Bi\_Factor* = 1
- *N\_Wiki\_Factor* = 2
- *N\_Factor* = 1

## 5 Results

The proposed system achieved the 3<sup>rd</sup> position in the Arabic subtask of SemEval 2016 task3.

Follows a detailed analysis of the system performance on development data set, alongside the performance of each module on the same data:

### - TF-IDF Module:

| Data | System               | MAP         | AvgRec      | MRR       |
|------|----------------------|-------------|-------------|-----------|
| Dev  | <b>TF-IDF Module</b> | <b>40.6</b> | <b>0.42</b> | <b>47</b> |

Table 1. Performance of TFIDF module

### - Language Model Module:

| Data | System                | MAP         | AvgRec       | MRR       |
|------|-----------------------|-------------|--------------|-----------|
| Dev  | <b>Language Model</b> | <b>35.8</b> | <b>0.374</b> | <b>40</b> |

Table 2. Performance of Language Model module

### - Wikipedia Module:

| Data | System                  | MAP         | AvgRec      | MRR         |
|------|-------------------------|-------------|-------------|-------------|
| Dev  | <b>Wikipedia Module</b> | <b>42.6</b> | <b>0.46</b> | <b>48.3</b> |

Table 3. Performance of Wikipedia module

The best parameters used to combine the three modules were inferred from tuning the system over the development data set, the best weights are

$$\alpha \text{ (TF-IDF)} = 0.3$$

$$\beta \text{ (Language Model)} = 0.05$$

<sup>1</sup> <https://drive.google.com/file/d/0B0FhtCSJsoyoeT-Jkd1FUQksxRmM/view>

$$\gamma(\text{Wikipedia}) = 0.75$$

Table 4 shows the performance of the combined system on the development data set:

| Data | System                 | MAP         | AvgRec      | MRR         |
|------|------------------------|-------------|-------------|-------------|
| Dev  | <b>Combined System</b> | <b>44.8</b> | <b>0.48</b> | <b>51.1</b> |

Table 4. Performance of combined system on development data

Simple as it may seem, the Wikipedia module achieved the best results on development data set compared to the other two modules. This behavior is due to the ability of the Wikipedia module to highlight medical terms and assign it higher weights compared to other matched terms, on the other hand the other two modules neglect this property, as both modules focus on detecting similarity between sentences regardless of the domain.

The proposed system also achieved 43.80 Mean Average Precision (MAP) on test set. Follows the final scores achieved on the test set alongside the scores achieved by the other four participants.

| Data  | System          | MAP          | AvgRec       | MRR          |
|-------|-----------------|--------------|--------------|--------------|
| Train | <b>RDI</b>      | <b>78.3</b>  | <b>81.2</b>  | <b>83.3</b>  |
| Dev   | <b>RDI</b>      | <b>44.8</b>  | <b>47.9</b>  | <b>51.1</b>  |
| Test  | SLS             | 45.83        | 51.01        | 53.66        |
|       | ConvKN          | 45.50        | 50.13        | 52.55        |
|       | <b>RDI</b>      | <b>43.80</b> | <b>47.45</b> | <b>49.21</b> |
|       | QU-IR           | 38.63        | 44.10        | 46.27        |
|       | UPC US-MBA      | 29.09        | 30.04        | 34.04        |
|       | <b>Baseline</b> | <b>28.88</b> | <b>28.71</b> | <b>30.93</b> |

Table 5. Results achieved in SemEval 2016 task 3

We can see that the proposed system achieved very good results compared to the baseline system. The system also achieved comparable results to the systems that achieved first and second positions

## 6 Conclusion

In this paper, we have introduced a combination of different algorithms which can be used in ranking problems. The performance of different systems has been studied. The paper also presented a comparison with other systems, and the results show that the proposed system is efficient. The results achieved by the proposed system are very promising compared with other systems in the competition.

## 7 Future work

Future work includes the enhancement of the system using sentence representation in vector space, as well as the combination of this system with other types of features.

We are planning to try sentence representation models like recursive auto encoder (RAE) (Socher et al., 2011) to represent the whole sentence in a vector. Using a model like RAE can facilitate measuring similarity between 2 sentence using vector representations for sentences.

The use of weighted sum for merging the proposed three modules is a very naive method that also suffers from over fitting. So We are planning to merge the proposed modules by means of machine learning (SVR, Neural Network, etc..) instead of using the naïve weighted sum. We are also planning to invest some effort to perform more experiments on the language model module since it has contributed the less within the three modules.

## Abstract

This paper describes the KeLP system participating in the SemEval-2016 Community Question Answering (cQA) task. The challenge tasks are modeled as binary classification problems: kernel-based classifiers are trained on the SemEval datasets and their scores are used to sort the instances and produce the final ranking. All classifiers and kernels have been implemented within the Kernel-based Learning Platform called KeLP. Our primary submission ranked first in Subtask A, third in Subtask B and second in Subtask C. These ranks are based on MAP, which is the referring challenge system score. Our approach outperforms all the other systems with respect to all the other challenge metrics.

## 1 Introduction

This paper describes the KeLP system participating in the SemEval-2016 cQA challenge. In this task, participants are asked to automatically provide good answers in a cQA setting (Nakov et al., 2016). In particular, the main task is: given a *new question* and a large collection of *question-comment threads* created by a user community, rank the most useful comments on the top.

We participated in all English subtasks: the datasets were extracted from *Qatar Living*<sup>1</sup>, a web forum where people pose questions about multiple aspects of their daily life in Qatar. Three subtasks are associated with the English challenge:

**Subtask A:** Given a question  $q$  and its first 10 comments  $c_1, \dots, c_{10}$  in its question thread, re-rank

these 10 comments according to their relevance with respect to the question, i.e., the *good* comments have to be ranked above *potential* or *bad* comments.

**Subtask B:** Given a new question  $o$  and the set of the first 10 related questions  $q_1, \dots, q_{10}$  (retrieved by a search engine), re-rank the related questions according to their similarity with respect to  $o$ , i.e., the *perfect match* and *relevant* questions should be ranked above the *irrelevant* ones.

**Subtask C:** Given a new question  $o$ , and the set of the first 10 related questions,  $q_1, \dots, q_{10}$ , (retrieved by a search engine), each one associated with its first 10 comments,  $c_1^q, \dots, c_{10}^q$ , appearing in its thread, re-rank the 100 comments according to their relevance with respect to  $o$ , i.e., the *good* comments are to be ranked above *potential* or *bad* comments.

All the above subtasks have been modeled as binary classification problems: kernel-based classifiers are trained and the classification score is used to sort the instances and produce the final ranking. All classifiers and kernels have been implemented within the Kernel-based Learning Platform<sup>2</sup> (KeLP) (Filice et al., 2015b), thus determining the team's name. The proposed solution provides three main contributions: (i) we employ the approach proposed in (Severyn and Moschitti, 2012), which applies tree kernels directly to question and answer texts modeled as pairs of linked syntactic trees. We further improve the methods using the kernels proposed in (Filice et al., 2015c). (ii) we extended the features developed in (Barrón-Cedeño et al., 2015), by adopting several features (also derived from Word Embeddings (Mikolov et al., 2013)). (iii) we propose

<sup>1</sup><http://www.qatarliving.com/forum>

<sup>2</sup><https://github.com/SAG-KeLP>

a stacking schema so that classifiers for Subtask B and C exploit the inferences obtained in the previous subtasks.

Our primary submission ranked first in Subtask A, third in Subtask B and second in Subtask C, demonstrating that the proposed method is very accurate and adaptable to different learning problems. These ranks are based on the MAP metric. However, if we consider the other metrics also adopted in the challenge (e.g.,  $F_1$  or Accuracy) our approach outperforms all the remaining systems.

In the remaining, Section 2 introduces the system, Sections 3 and 4 describe the feature and kernel modeling, while Section 5 reports official results.

## 2 The KeLP system: an overview

In the three subtasks, the underlying problem is to understand if two texts are related. Thus, in subtasks A and C, each pair, (question, comment), generates a training instance for a binary Support Vector Machine (SVM) (Chang and Lin, 2011), where the positive label is associated with a *good* comment and the negative label includes the *potential* and *bad* comments. In Subtask B, we evaluated the similarity between two questions. Each pair generates a training instance for SVM, where the positive label is associated with the *perfect match* or *relevant* classes and the negative label is associated with the *irrelevant*; the resulting classification score is used to rank the question pairs.

In KeLP, the SVM learning algorithm operates on a linear combination of kernel functions, each one applied over a specific representation of the targeted examples: (i) feature vectors containing linguistic similarities between the texts in a pair; (ii) shallow syntactic trees that encode the lexical and morphosyntactic information shared between text pairs; (iii) feature vectors capturing task-specific information; (iv) in subtasks B and C, feature vectors encoding stacked information derived by applying the classifiers obtained in the previous subtasks.

While (i) and (ii) use linguistic information that can be applied in any semantic processing task defined over text pairs (see Sec. 3), the information derived via (iii) and (iv) is task specific (see Sec. 4).

## 3 Learning from Text Pairs with Kernels

The problem of deciding whether two questions are related or whether a comment answers a question,

can be somehow connected to the problems of recognizing textual entailment, and paraphrase identification. From a machine learning perspective, in these tasks, an example is a pair of texts, instead of a single entity. Conventional approaches convert input text pairs into feature vectors where each feature represents a score corresponding to a certain type of shared information or similarity between the elements within a pair. These intra-pair similarity approaches cannot capture complex relational pattern between the elements in the pair, such as a rewriting rule characterizing a valid paraphrase, or a question-answer pattern. Such information might be manually encoded into specific features, but it would require a complex feature engineering and a deep knowledge of the linguistic involved phenomena.

To automatize relational learning between pairs of texts, e.g., in case of QA, one of the early works is (Moschitti et al., 2007; Moschitti, 2008). This approach was improved in several subsequent researches (Severyn and Moschitti, 2012; Severyn et al., 2013a; Severyn et al., 2013b; Severyn and Moschitti, 2013; Tymoshenko et al., 2014; Tymoshenko and Moschitti, 2015), exploiting relational tags and linked open data. In particular, in (Filice et al., 2015c), we propose new inter-pair methods to directly employ text pairs into a kernel-based learning framework. In the proposed approach, we integrate the information derived from simple intra-pair similarity functions (Section 3.1) and from the structural analogies (Section 3.2).

### 3.1 Intra-pair similarities

In subtasks A and C, a *good* comment is likely to share similar terms with the question. In subtask B a question that is relevant to another probably shows common words. Following this intuition, given a text pair (either question/comment or question/question), we define a feature vector whose dimensions reflect the following similarity metrics:

- *Cosine similarity*, *Jaccard coefficient* (Jaccard, 1901) and *containment measure* (Broder, 1997) of  $n$ -grams of word lemmas. It captures lexical information and word ordering information ( $n = 1, 2, 3, 4$  was used in all experiments).
- *Cosine similarity* of  $n$ -grams of part-of-speech tags. It considers a shallow syntactic similarity ( $n = 1, 2, 3, 4$  was used in all experiments).

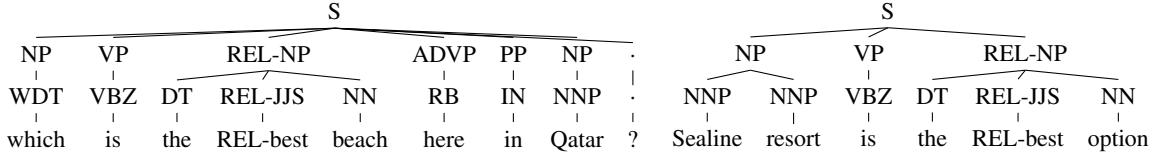

Figure 1: Structural Representation of a question-answer pair.

- *Partial tree kernel* (Moschitti, 2006) between the parse tree of the sentences. It performs a deep syntactic comparison.
- *Longest common substring measure* (Gusfield, 1997) determines the length of the longest contiguous sequence of characters shared by two text segments.
- *Longest common subsequence measure* (Allison and Dix, 1986) drops the contiguity requirement of the previous measure and allows to detect similarity in case of word insertions/deletions.
- *Greedy String Tiling* (Wise, 1996) provides a similarity between two sentences by counting the number of shuffles in their subparts.
- *Cosine similarity* between additive representations of word embeddings generated by applying word2vec (Mikolov et al., 2013) to the entire Qatar Living corpus from SemEval 2015<sup>3</sup>. We derived 250 dimensional vectors for 37,000 words by applying the settings min-count=50, window=5, iter=10 and negative=10. Five features are derived considering (i) only nouns, (ii) only adjectives, (iii) only verbs, (iv) only adverbs and (v) all the above words.

These metrics are computed in all the subtasks between the two elements within a pair, i.e.,  $q$  and  $c_i$  for subtask A,  $q$  and  $o$  for subtask B,  $o$  and  $c_i$  for subtask C. In addition, in subtasks B and C, the similarity metrics (except the Partial Tree Kernel similarity) are computed between  $o$  and the entire thread of  $q$ , concatenating  $q$  with its answers. Similarities between  $q$  and  $o$  are also employed in subtask C.

### 3.2 Inter-pair kernel methods

The kernels we proposed in (Filice et al., 2015c) can be directly applied to Subtask B and to subtasks A and C for learning question/question and question/answer similarities, respectively. As shown in

<sup>3</sup><http://alt.qcri.org/semeval2015/task3>

Figure 1, a pair of sentences is represented as pair of their corresponding shallow parse trees, where common or semantically similar lexical nodes are linked using a tagging strategy (which is propagated to their upper constituents). This method discriminates aligned sub-fragments from non-aligned ones, allowing the learning algorithm to capture relational patterns, e.g., *the REL-best beach* and *the REL-best option*. Thus, given two pairs of sentences  $p_a = \langle a_1, a_2 \rangle$  and  $p_b = \langle b_1, b_2 \rangle$ , some tree kernel combinations can be defined:

$$\begin{aligned} \text{TK}^+(p_a, p_b) &= \text{TK}(a_1, b_1) + \text{TK}(a_2, b_2) \\ \text{All}_{\text{TK}}^\times(p_a, p_b) &= \text{TK}(a_1, b_1) \times \text{TK}(a_2, b_2) \\ &\quad + \text{TK}(a_1, b_2) \times \text{TK}(a_2, b_1), \end{aligned}$$

where TK is a generic tree kernel, such as the Partial Tree Kernel (PTK) (Moschitti, 2006), or the Smoothed Partial Tree Kernel (SPTK) (Croce et al., 2011). Tree kernels, computing the shared substructures between parse trees, are effective in evaluating the syntactic similarity between two texts. The proposed tree kernel combinations extend such reasoning to text pairs, and can capture emerging pairwise patterns. Therefore this method can be effective in recognizing valid question/answer pairs, or similar questions, even in those cases in which the two texts have few words in common that would cause the failure of any intra-pair approach.

## 4 Task Specific Features

In this section, we describe features specifically developed for cQA. A single feature vector is generated for each of the following group of features.

### 4.1 Ranking Features

The ten questions related to an original question are retrieved using a search engine. We use their absolute and relative ranks<sup>4</sup> as features for subtasks B

<sup>4</sup>Some of the results retrieved by the search engine were filtered out, because they were threads with less than 10 comments, or documents out of Qatar Living. Therefore, the threads in the dataset may have an associated rank higher than 10. The relative rank maps such absolute values into [1;10].

and C (for the latter the question rank is given to all the comments within the related question thread).

## 4.2 Heuristics

We adopt the heuristic features described in (Barrón-Cedeño et al., 2015), which can be applied to sub-tasks A and C. In particular forty-four boolean features express whether a comment: (i) includes URLs or emails (2 feats.); (ii) contains the word “yes”, “sure”, “no”, “can”, “neither”, “okay”, and “sorry”, as well as symbols ‘?’ and ‘@’ (9 feats.); (iii) starts with “yes” (1 feat.); (iv) includes a sequence of three or more repeated characters or a word longer than fifteen characters (2 feats.); (v) belongs to one of the categories of the forum (*Socializing*, *Life in Qatar*, etc.) (26 feats.); (vi) has been posted by the same user who posted the question, such a comment can include a question (i.e., it contains a question mark), and acknowledgment (e.g., it contains *thank\**, *acknowl\**), or none of them (4 feats.);

An additional feature captures the length of the comment (as longer —*good*— comments usually contain detailed information to answer a question).

## 4.3 Thread-based features

In cQA, comments in a thread typically reflect an underlying concrete discussion, which contains more information than in a sequence of independent answers retrieved from different documents. For instance, users replicate to each other, ask for further details, or can tease other users. Therefore, as discussed in (Barrón-Cedeño et al., 2015), comments in a common thread are strongly interconnected. To exploit such thread-level dependencies, we used some specific features for subtasks A and C. The following notation will be adopted:  $q$  is the question posted by user  $u_q$ ,  $c$  is a comment from user  $u_c$ , in the comment thread.

The first four features indicate whether  $c$  appears in the proximity of a comment by  $u_q$ . The assumption is that an acknowledgment or further questions by  $u_q$  in the thread could signal a *good* answer. More specifically, they test if among the comments following  $c$  there is one by  $u_q$  (i) containing an acknowledgment, (ii) not containing an acknowledgment, (iii) containing a question, and, (iv) if among the comments preceding  $c$  there is one by  $u_q$  containing a question. These four features depend on the distance  $k$ , in terms of the number of comments,

between  $c$  and the closest comment by  $u_q$ :

$$f(c) = \begin{cases} 1.1 - 0.1k & \text{if } u_q \text{ exists,} \\ 0 & \text{if no comments by } u_q \text{ exist,} \end{cases}$$

that is, the closer the comment to  $u_q$ , the higher the value assigned to this feature. Other features try to model potential dialogues, which at the end represent *bad* comments, by identifying interlacing comments between two users. These dialogue features are identifying conversation chains:

$$u_i \rightarrow \dots \rightarrow u_j \rightarrow \dots \rightarrow u_i \rightarrow \dots \rightarrow [u_j]$$

Comments by other users can appear in between the nodes of this “pseudo-conversation” chain. Three features consider whether a comment is at the beginning, in the middle, or at the end of such a chain. Three more features are defined when  $u_j = u_q$ , i.e., the user who asked the question is one of the participants of these pseudo-conversations.

Another interesting aspect is whether a user  $u_i$  has been particularly active in a question thread. One boolean feature captures whether  $u_i$  wrote more than one comment in the current thread. Three more features identify the first, the middle and the last comments by  $u_i$ . One extra feature counts the total number of comments written by  $u_i$ . Moreover, it can be empirically observed that the likelihood of a comment being *good* decreases with its position in the thread. Therefore, another real-valued feature was included:  $i/10$ , where  $i$  represents the position of the comment in the thread.

## 4.4 Stacking classifiers across subtasks

The three subtasks are interconnected: the predictions from a subtask can provide useful information to carry out the other subtasks. This suggests the use of a stacking strategy.

**Stacking classifiers in Subtask B.** If the comments in the question thread of  $q$  are *good* answers for an original question  $o$ , we can suppose that  $o$  and  $q$  are strongly related. In Subtask B, we thus exploit the model trained on Subtask A. In particular, given the original question  $o$ , and the related question  $q$  with its comments,  $c_1 \dots c_n$ , we use the model from Subtask A to classify the question/comment pairs,  $\langle q, c_i \rangle$  and  $\langle o, c_i \rangle$ , obtaining respectively the scores  $p_{q,c_i}$  and  $p_{o,c_i}$ . We consider these scores as distributions and derive the following features: (i) *mean squared*

*error* (MSE) =  $\sum_i (p_{q,c_i} - p_{o,c_i})^2$ ; (ii) *Pearson correlation coefficient* between the  $p_{q,c_1}, \dots, p_{q,c_n}$  and the  $p_{o,c_1}, \dots, p_{o,c_n}$ ; (iii) ten features corresponding to the sorted differences between  $p_{q,c_i}$  and  $p_{o,c_i}$ ; (iv) *agreement percentage*, i.e., percentage of times  $\text{sign}(p_{q,c_i}) = \text{sign}(p_{o,c_i})$ ; (v) *max score* =  $\max_i(p_{o,c_i})$ ; (vi) *mean score* =  $\frac{1}{n} \sum_i p_{o,c_i}$ ; (vii) *positive percentage*, i.e., percentage of times  $p_{o,c_i} > 0$ ; (viii) *normalized positive percentage*, i.e., percentage of times  $p_{o,c_i} > 0$  when  $p_{q,c_i} > 0$ .

**Stacking classifiers in Subtask C.** A *good* comment for a question  $q$  should be also *good* for an original question  $o$  if  $q$  and  $o$  are strongly related, i.e.,  $q$  is *relevant* or a *perfect match* to  $o$ . We thus developed a stacking strategy for Subtask C that uses the following scores in the classification step, w.r.t. an original question  $o$  and the comment  $c_i$  from the thread of  $q$ :

- $p_{q,c_i}$ , which is the score of the pair  $\langle q, c_i \rangle$  provided by the model trained on Subtask A;
- $p_{o,c_i}$ , which is the score of the pair  $\langle o, c_i \rangle$  provided by the model trained on Subtask A;
- $p_{o,q}$ , which is the score of the pair  $\langle o, q \rangle$  provided by the model trained on Subtask B.

Starting from these scores, we built the following features: (i) values and signs of  $p_{q,c_i}$ ,  $p_{o,c_i}$  and  $p_{o,q}$  (6 feats); (ii) a boolean feature indicating whether both  $p_{q,c_i}$  and  $p_{o,q}$  are positive; (iii) *min value* =  $\min(p_{q,c_i}, p_{o,q})$ ; (iv) *max value* =  $\max(p_{q,c_i}, p_{o,q})$ ; (v) *average value* =  $\frac{1}{2}(p_{q,c_i} + p_{o,q})$ .

## 5 Submission and Results

We chose parameters using a 10 fold cross validation (cv) on the official train and development sets<sup>5</sup>. In Subtask B, some features depend on the scores provided on Subtask A, while in Subtask C the dependency is from both Subtasks A and B. Such scores are generated with the 10-fold cv. We used the OpenNLP pipeline for lemmatization, POS tagging and chunking to generate the tree representations described in Section 3.2. All the kernel-based learning models are implemented in KeLP (Filice et al., 2015b). For all the tasks, we used the C-SVM learning algorithm (Chang and Lin, 2011). The MAP@10 was the official metric. In addition, results are also reported in Average Recall (AvgR),

<sup>5</sup>We merged the official Train1, Train2 and Dev sets.

|      |      | MAP          | AvgR  | MRR   | P     | R     | F <sub>1</sub> | Acc   |

## 5.1 Subtask A

**Model:** The learning model operates on question-comment pairs  $p = \langle q, c \rangle$ . The kernel is  $\text{PTK}^+(p_a, p_b) + \text{LK}_A(p_a, p_b)$ . Such kernel linearly combines  $\text{PTK}^+(p_a, p_b) = \text{PTK}(q_1, q_2) + \text{PTK}(c_1, c_2)$  (see Section 3.2) with a linear kernel  $\text{LK}_A$  that operates on feature vectors including: (i) the similarity metrics between  $q$  and  $c$  described in Section 3.1; (ii) the heuristic features introduced in Section 4.2; (iii) the thread-based features discussed in Section 4.3. PTK uses the default parameters (Moschitti, 2006), while the best SVM regularization parameter we estimated during cv is  $C = 1$ .

**Results:** Table 1 reports the outcome on Subtask A. The good results on the 10 fold cross validations are confirmed on the official test set: the model is very accurate and achieved the first position among 12 systems, with the best MAP. In this task the data distribution among classes is quite balanced and the accuracy is also a good performance indicator. In this case we achieved the second position.

## 5.2 Subtask B

**Model:** The proposed system operates on question-question pairs  $p = \langle o, q \rangle$ . The kernel is  $\text{All}_{\text{SPTK}}^\times(p_a, p_b) + \text{LK}_B(p_a, p_b)$ , by adopting the kernels defined in Section 3.2. This task is close to Paraphrase Identification, which is inherently symmetric. Therefore, in our primary submission, we adopted a tree kernel combination that exploits such characteristic, performing cross comparisons between the questions within pairs:  $\text{All}_{\text{SPTK}}^\times(p_a, p_b) = \text{SPTK}(o_1, o_2) \times \text{SPTK}(q_1, q_2) + \text{SPTK}(o_1, q_2) \times \text{SPTK}(q_1, o_2)$ . Such combination is based on the SPTK with standard parameters and a word similarity derived from the word embeddings described in Section 3.1.  $\text{LK}_B$  is a linear kernel that oper-

|      |      | MAP          | AvgR  | MRR   | P     | R     | F <sub>1</sub> | Acc          |

|      | KeLP | 75.83        | 91.02 | 82.71 | 66.79 | 75.97 | <b>71.08</b>   | <b>79.43</b> |
|      | KC1  | <b>76.28</b> | 91.33 | 82.71 | 63.83 | 77.25 | 69.90          | 77.86        |
|      | KC2  | 76.27        | 91.44 | 84.10 | 64.06 | 77.25 | 70.04          | 78.00        |

**Table 2:** Results on Subtask B on a 10 fold Cross-Validation (CV) and on the official test set. KeLP is our primary submission, while KC1 and KC2 are the contrastive ones. IR is the baseline system based on the search engine results

ates on feature vectors including: (i) the similarity metrics between  $o$  and  $q$ , and between  $o$  and the entire answer thread of  $q$ , as described in Section 3.1; (ii) ranking features discussed in Section 4.1; (iii) the features derived from the Subtask A scores (see Section 4.4). The best SVM regularization parameter estimated during the tuning stage is  $C = 5$ .

We made two additional submissions in which the model has minor variations: in the Contrastive 1 (KC1), we substituted  $All_{SPTK}^X$  with  $SPTK^+$  whereas in the contrastive 2 (KC2) we do not include the features derived from the Subtask A scores.

**Results:** Table 2 shows the results on Subtask B. On the official test set, our primary submission achieved the third position w.r.t. MAP among 11 systems. Differently from what observed in the tuning stage, on the official test set the contrastive systems achieve a higher MAP and would have ranked second. The primary system achieves the highest F<sub>1</sub> and accuracy on both tuning and test stages. Considering these two metrics, our primary submission is overall the best model.

### 5.3 Subtask C

**Model:** The learning model operates on the triplet,  $\langle o, q, c \rangle$ , using the kernel,  $PTK^+(p_a, p_b) + LK_C(t_a, t_b)$ , where  $PTK^+(p_a, p_b) = PTK(o_1, o_2) + PTK(c_1, c_2)$  (see Section 3.2) and  $LK_C$  is a linear kernel operating on feature vectors, which include: (i) the similarity metrics between  $o$  and  $c$ , between  $o$  and  $q$ , and between  $o$  and the entire thread of  $q$ , as described in Section 3.1; (ii) the heuristic features introduced in Section 4.2; (iii) the thread-based features discussed in 4.3; (iv) the ranking features (see Section 4.1); (v) the features derived from the scores of subtasks A and B, described in Section 4.4.

|      |      | MAP          | AvgR  | MRR   | P     | R     | F <sub>1</sub> | Acc          |

|      | KeLP | <b>38.57</b> | 44.09 | 41.28 | 21.55 | 64.64 | 32.32          | 81.32        |
|      | KC1  | 38.00        | 43.74 | 41.18 | 21.97 | 64.64 | 32.79          | 81.72        |
|      | KC2  | 37.22        | 42.63 | 42.80 | 22.30 | 71.30 | 33.98          | 80.88        |
| test | IR   | 40.36        | 45.97 | 45.83 | -     | -     | -              | -            |
|      | KeLP | 52.95        | 59.27 | 59.23 | 33.63 | 64.53 | 44.21          | 84.79        |
|      | KC1  | 52.95        | 59.34 | 58.06 | 34.08 | 65.29 | <b>44.78</b>   | <b>84.96</b> |
|      | KC2  | <b>55.58</b> | 63.36 | 61.19 | 32.21 | 70.18 | 44.16          | 83.41        |

**Table 3:** Results on Subtask C on the official development set, and on the official test set. KeLP is our primary submission, while KC1 and KC2 are the contrastive ones. IR is the baseline system based on the search engine results

PTK uses the default parameters. The subtask data is rather imbalanced, as the number of negative examples is about 10 times the positive ones. We took this into account by setting the regularization parameter for the positive class,  $C_p = \frac{\#negatives}{\#positives} C$ , as in (Morik et al., 1999). The best SVM regularization parameter estimated during the tuning stage is  $C = 5$ . We also submitted a Contrastive 1 (KC1) with  $PTK^+$  using  $All_{PTK}^X$  and a Contrastive 2 (KC2) identical as KC1 but with  $C$  set to 2.

**Results:** Table 3 shows the results for Subtask C. The organizers reported that the training labels were affected by noise, while the development labels were double-checked. Therefore, we decided to perform parameter tuning applying cv to the development set only. Our primary submission achieved the second highest MAP, while our Contrastive 2 is the best result. It should be also noted that the F<sub>1</sub> our system is the best among 10 primary submissions. In this subtask, accuracy is not a reliable measure, as the data is significantly imbalanced.

In a future work we would like to change the learning paradigm from classification, e.g., demonstrated in (Filice et al., 2015a) for several NLP applications, to a learning to rank problem. This can be enabled by the preference kernel (Severyn and Moschitti, 2012) and should have a positive impact on the MAP metric since the SVM classification algorithm we used optimizes accuracy.

## Abstract

Community question answering platforms need to automatically rank answers and questions with respect to a given question. In this paper, we present the approaches for the *Answer Selection* and *Question Retrieval* tasks of SemEval-2016 (task 3). We develop a bag-of-vectors approach with various vector- and text-based features, and different neural network approaches including CNNs and LSTMs to capture the semantic similarity between questions and answers for ranking purpose. Our evaluation demonstrates that our approaches significantly outperform the baselines.

## 1 Introduction

Community Question Answering (cQA) forums are rapidly growing, resulting in an urgent need to automatically search for relevant answers among many responses provided for a given question (Answer Selection), and search for relevant questions to reuse their existing answers (Question Retrieval). In this paper, we aim to address the SemEval 2016 tasks (Nakov et al., 2016) that are designed for Answer Selection (AS) and Question Retrieval (QR). These tasks are briefly described as follows:

A **Question-Comment Similarity**: given a question and its first 10 comments in the question thread, rerank these 10 comments according to their relevance with respect to the question.

B **Question-Question Similarity**: given a new question (named *original* question) and the set of

the first 10 related questions retrieved by a search engine, rerank the related questions according to their similarity regarding the original question.

C **Question-External Comment Similarity**: given a new question (*original* question) and the set of the first 10 related questions retrieved by a search engine, each associated with its first 10 comments appearing in its thread, rerank the 100 comments (10 questions x 10 comments) according to the new question.

D **Question-External Question-Comment Pair Similarity**: Given a new question and a set of 30 related questions retrieved by a search engine, each associated with one correct answer, rerank the 30 question-comment pairs according to their relevance with respect to the original question.

Task B is considered as QR and the others as AS problems. The first three tasks are evaluated on an English dataset and the fourth on an Arabic dataset. Several factors make all these tasks more challenging. First, cQA forums contain *open-domain* and *non-factoid* questions and answers, resulting in high variance Q&A quality (Màrquez et al., 2015). A second factor is that the Q&A are *long* and their length may vary from several words to several hundred words. The third factor concerns the relatively close relation between some annotation labels; the comments in the tasks A and C are labeled as *Relevant*, *Potential* and *Irrelevant*, and the *Relevant* comments need to be ranked above the *Potential* and *Irrelevant* comments. From a natural language processing perspective, it is difficult to define a clear distinction between the relevant and potential labels.

To address these tasks, we first present a bag-of-vectors (BOV) approach in which various vector- and text-based features are designed and passed through a linear SVM classifier to compute the degree of relatedness between the Q&As. Then, we present different NN-based approaches including CNNs and LSTMs to compute the representations of the Q&As. We evaluate our models on the cQA corpus provided by SemEval. The results demonstrate that our approaches outperform the baselines.

## 2 Method

Given a question  $q$ , a list of answers  $A$  for AS, and a list of questions  $Q$  for QR, we aim to rank the lists  $A$  and  $Q$  with respect to  $q$ . To address these problems, we present a bag-of-vectors (BOV) approach to compute various vector- and text-based features for a classifier. Furthermore, we present NN-based approaches (LSTM with attention, CNN and RCNN) for learning the vector representations of the questions and answers to be used for capturing their semantic similarity. The degree of similarity between the Q&A is used for their ranking.

### 2.1 Bag-of-Vectors (BOV)

Previous work presented a BOV approach to address the classification tasks in cQA (Belinkov et al., 2015). In this paper, we aim to extend the previous approach for the ranking tasks by updating the feature sets and developing new models. The features are categorized into text, vector and meta-data based features that are briefly explained below (in the experiments section below we detail the features chosen for each task). Then, we explain our approach to shorten the length of Q&As in the Arabic data.

**Text-based features** These features are mainly computed using text similarity metrics, word clustering and topic modeling. As the first set of text-based features, we use various text similarity metrics that measure string overlap between Q&As: *Longest Common Substring* (Gusfield, 1997), *Longest Common Subsequence* (Allison and Dix, 1986), *Longest Common Subsequence Norm*, *Greedy String Tiling* (Wise, 1996), *Monge Elkan Second String* (Monge and Elkan, 1997), *Jaro Second String* (Jaro, 1989), *Jaccard coefficient* (Lyon et al., 2004) and *Containment measures* (Broder,

1997). These metrics are explained in (Belinkov et al., 2015).

Another set of text-based features are computed using word clustering that has been useful in many supervised NLP approaches. We use Brown clustering (Brown et al., 1992; Liang, 2005) that creates word clusters such that they are hierarchical in a binary tree. In the tree, each word is assigned to a bitstring depending on its tree path, and the prefixes of the bitstring are the ancestor clusters used as additional features. We use an implementation of Brown clustering,<sup>1</sup> that is designed as an HMM-based algorithm which partitions words into a base set of  $N$  ( $=500$ ) clusters. Given a question or an answer as a document, its clusters are determined based on its word clusters. This captures the global clusters.

Topic modeling approaches can also be used to automatically identify topics of documents. We use Non-negative Matrix Factorization (NMF) for topic modeling. A document-term matrix is constructed with TF-IDF weights. This matrix is factored into a term-topic and a topic-document matrix. The  $N$  ( $=100$ ) topics are derived from the contents of the documents, and the topic-document matrix describes topics of related documents. We use each column of the topic-document matrix as features for each individual document. The entire train, development and test datasets provided by SemEval 2015 and 2016 are employed to compute the word clustering and topic modeling features.

**Vector-based features** The concatenation of the normalized Q&A representations is used as vector-based features for a  $(q, a)$  pair. The question or answer representation is obtained with the average of its word representations computed from Word2Vec vectors (Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c). For English word vectors we use the GoogleNews vectors dataset.<sup>2</sup> For Arabic word vectors we use Word2Vec to train 100-dimensional vectors on either the general domain Arabic Gigaword (Linguistic Data Consortium, 2011) or the domain-specific raw data provided with the task. We select the word vector set based on the performance of the development set.

---

<sup>1</sup><https://github.com/percyliang/brown-cluster>.

<sup>2</sup><https://code.google.com/p/word2vec>.

Furthermore, for the Arabic the pair of sentence vectors in the question and answer with the highest cosine similarity is used as features.

We use a zero vector if the question or answer contains only out-of-vocabulary words. To make it easier for the classifier to ignore the vectors in these cases, we design two boolean features to identify whether the question and answer are zero vectors.

**Metadata-based features** We use a metadata-based feature that identifies whether the user who posted the question is the same user who wrote the answer. This feature is useful to identify irrelevant dialogue answers, and used for the tasks A and C.

**Shrinking the sentence length** Some of the questions and answers in the community forum are very long. In fact, in the Arabic dataset questions and answers have an average length of 50 and 120 words, respectively. Therefore, we preprocess the texts using TextRank (Mihalcea and Tarau, 2004), a graph-based keyword extraction algorithm, for finding the most meaningful words within every thread. Once the meaningful words are found, we filter all other words from each thread instance, and build the subsequent feature representation based on the shortened texts.

Given a document, TextRank builds a graph representation, where nodes stand for word types, connected by undirected links representing co-occurrence within a window of size  $N$ . An importance weight is then calculated for each node, using an iterative formula introduced by PageRank (Brin and Page, 1998). We use our implementation of TextRank, in which we select a certain percentage of the words, defined as  $P$ , sorted top-down by importance weight, as the final keywords.

We treat each thread, including all its question-answer pairs, as an individual document for TextRank. We preprocess each document with MADA 3.1 (Habash et al., 2009), a context-sensitive lemmatizer, for finding word lemmas and part-of-speech tags. Finally, our TextRank graphs include only lemmas of content words, Latin-script words and words with no lemmas. Content words in this sense are defined as nouns, verbs, adjectives and adverbs. All other TextRank parameters are assigned with values according to (Mihalcea and Tarau, 2004).

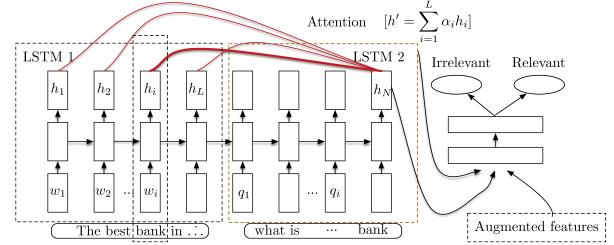

Figure 1: The Architecture of the LSTM with attention for cQA

## 2.2 Long Short-Term Memory (LSTM) Networks with Attention

LSTMs have shown great success in many different fields, such as textual entailment (Rocktäschel et al., 2015), language modeling (Sundermeyer et al., 2012), and acoustic modeling (Graves et al., 2013). The recurrent structure as well as the ability to store long-term information make LSTMs suitable for encoding sequences of variable length into fixed-length representations.

However, for very long sequences, such as the comments in cQA tasks (~hundreds of words), an LSTM may still fail to compress all information into this representation. Recently, a neural attention model (Bahdanau et al., 2014) has been proposed to alleviate this issue by enabling the network to attend to all past outputs. The attention mechanism along with an LSTM is ideal for cQA tasks.

Following (Mohtarami et al., 2016), as illustrated in Figure 1, we apply two LSTMs to encode  $(q, q')$  or  $(q, a)$  respectively. The first LSTM reads one object, and passes information through hidden units to the second LSTM. The second LSTM then reads the other object and generates its representation biased by the first object after finishing reading.

By augmenting an attention mechanism to the encoder, we allow the second LSTM to attend to the sequence of output vectors from the first LSTM, and hence generate a weighted representation of the first object according to both objects. Let  $h_N$  be the last output of the second LSTM and  $M = [h_1, h_2, \dots, h_L]$  be the sequence of output vectors of the first object. The weighted representation of the first object is

$$h' = \sum_{i=1}^L \alpha_i h_i \quad (1)$$

|                 |   |
|-----------------|---|
| Embedding       | <b>init</b> or random, fix or <b>update</b> |
| Two LSTM        | shared or <b>not</b>                        |
| #cells for LSTM | 64, <b>128</b> , 256                        |
| # nodes for MLP | 128, <b>256</b>                             |
| Optimizer       | <b>AdaGrad</b> , AdaDelta, SGD              |
| learning rate   | 0.001, <b>0.01</b> , 0.1                    |
| Regularizer     | <b>Dropout</b> , L2 regularization          |
| Dropout rate    | 0.0, 0.2, 0.3, <b>0.4</b> , 0.5             |
| L2              | 0, 0.001, <b>0.0001</b> , 0.00001           |

**Table 1:** Hyper-parameters of the LSTM model. The bold value is the selected parameter.

The weight is computed by

$$\alpha_i = \frac{\exp(a(h_i, h_N))}{\sum_{j=1}^L \exp(a(h_j, h_N))} \quad (2)$$

where  $a()$  is the importance model that produces a higher score for  $(h_i, h_N)$  if  $h_i$  is useful for determining the object pair’s relationship. We parametrize this model using a feed-forward neural network.

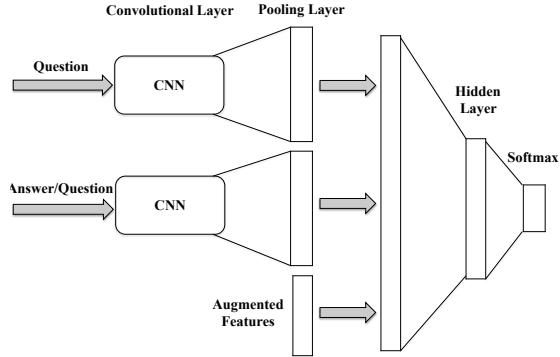

To classify the relationship of this pair, another feed-forward neural network is built on top of the LSTMs that takes the representations of both objects,  $h_N$  and  $h'$ , as input. Note that in our framework, we can use the augmented features  $f$  to enhance the classifier. In this case, the final input to the classifier will become  $h_N$ ,  $h'$ , and  $f$ . The details of this model are explained in (Mohtarami et al., 2016).

Our system is based on Theano (Bastien et al., 2012; Bergstra et al., 2010). Table 1 gives a list of hyperparameters we tried. As suggested by (Greff et al., 2015), the hyperparameters for an LSTM can be tuned independently. We tune each parameter separately on a dev set and pick the best one.

### 2.3 Convolutional Neural Network (CNN)

Convolutional Neural Networks (CNNs) are useful in many NLP tasks, such as language modeling (Kalchbrenner et al., 2014), semantic role labeling (Collobert and Weston, 2008) and semantic parsing (Yih et al., 2014). Our reason for using a CNN for cQA is that it can capture both features of n-grams and long-range dependencies (Yu et al., 2014), and can extract discriminative word sequences that are common in the training instances (Severyn and Moschitti, 2015). These traits make CNNs useful for dealing with long questions.

Following (Mohtarami et al., 2016), as illustrated in Figure 2, we employ a CNN-based model to first

**Figure 2:** The Architecture of the CNN for cQA

compute a relatedness score for each pair,  $(q, a)$  or  $(q, q)$ , and then rank the lists based on the resulting scores. In the model, for a given pair, the embedding vectors of  $q$  and  $a$  are considered as input. The CNN convolution and pooling layers then generate the convolutional vector representations. These vectors are concatenated with other additional feature vectors and used as input to a fully connected Multi-Layer Perceptron (MLP) whose softmax layer generates a probability score  $P(y|q, a)$  over the labels  $y \in \{0, 1\}$ , where 1 means *relevant*, and 0 means *irrelevant*. The hyperparameter configuration of the CNN model is shown in Table 3, and the details of this model are explained in (Mohtarami et al., 2016).

### 2.4 Recurrent Convolutional Neural Network (RCNN)

For task B, we also apply the recurrent convolutional neural network model, which has been recently proposed and successfully applied to a similar question retrieval problem (Lei et al., 2015). Unlike traditional CNNs which only extract local n-gram features, RCNNs extract and aggregate all possible n-grams within the input sequence, including ones that are not consecutive. Similar to LSTMs and Gated Recurrent Units (GRUs), which have internal “memory” states, RCNNs maintain aggregated vectors to store the weighted average of n-gram features. These vectors are updated in a recurrent fashion when the input tokens are successively read into the network.

Following the set-up in (Lei et al., 2015), we take the last state vector as the final representation of the question. The parameters of RCNN encoder are trained in a max-margin fashion, maximizing the

**Table 3:** The hyper-parameters of CNN model.

(cosine) similarity difference between positive question pairs and negative pairs. The hyperparameter configuration of the model is shown in Table 2.

### 3 Experimental Results

We evaluate our approaches on all the cQA tasks. We use the cQA datasets provided by SemEval 2016. The English data were collected from the Qatar Living forum.<sup>3</sup> and the Arabic data were collected from medical forums. Table 4 provides statistics for the datasets. As evaluation metrics, we use F1-score for a global assessment of the approaches in addition to the following ranking metrics: Mean Average Precision (MAP), Average Recall (AveRec) and Mean Reciprocal Rank (MRR). For the MAP, we use the average of MAP@1 to MAP@10.

**Baselines** For a baseline, we use the Information Retrieval (IR) ranking score that is computed as follows: given a  $q$ , the top 100 threads retrieved by Google from the Qatar Living forum are considered and the order of each thread is used as its IR ranking score. As another baseline, we use a system that randomly ranks a given list of Q or A.

**Question-comment similarity** The results for this task are shown in Table 5(a). The first two rows are the IR and random baseline results, and the next two rows are the best two performances among all SemEval submissions for this task. The other three rows are the results of our approaches and respectively submitted to SemEval as *primary*, *con-*

|                    | A      | B     | C      | D      |
|--------------------|--------|-------|--------|--------|
| Original questions | -      | 317   | 317    | 1,281  |
| Related questions  | 6,398  | 3,169 | 3,169  | 37,795 |
| Comments           | 40,288 | -     | 31,690 | 37,795 |

**Table 4:** Statistics of the dataset through the tasks.

*trastive1* and *contrastive2* results. As shown in the table, our results are significantly higher than the baselines and comparable with the best results over all performance metrics, and there is no significant difference between the results of our approaches for this task. We use various combinations of our BOV, LSTM and CNN approaches, then select the best ones with respect to the development set. The combination of the approaches is computed by  $1/(R_1 + R_2 + \dots + R_i)$  where  $R_i$  is the ranking of the  $i^{th}$  approach.

In this task, the BOV includes all the features except for the NMF features, and we employ the order of the answers in their threads as augmented features for our NN-based approaches. The structure of the threads (e.g., answer order) can help to extract relevant answers (Barrón-Cedeño et al., 2015).

**Question-question similarity** Table 5(b) shows the results for this task. The first two rows are the results for IR and random baselines, and the next two are the best two performances of SemEval. The other three results are related to our approaches and respectively submitted to SemEval as *primary*, *contrastive1* and *contrastive2* results. The table shows that our results are significantly better than the baselines. While there is no significant difference between our *contrastive1* and *contrastive2* results with the best result, these results are higher than the second best SemEval result on MAP, and the highest result is obtained with our primary result on accuracy. With respect to our results, the combination of BOV, LSTM and RCNN achieves the highest result on MAP and the combination of BOV and RCNN is the best on F1.

In this task, the combination of the approaches is computed using a linear SVM with the feature vector  $R_1, R_2, \dots, R_i$  where  $R$  is the ranking of the  $i^{th}$  approach. Furthermore, in this experiment, the BOV includes all the features except the word clustering features, and we employ the ranking order of the IR as augmented features for our NN-based approaches.

**Table 5:** Results on test data for answer selection and question retrieval tasks

**Question-external comment similarity** The results for this task are shown in Table 5(c). The first two rows are the IR and random baseline results and the next two rows are the best two SemEval results. The other three rows are our results that respectively are *primary*, *contrastive1* and *contrastive2* results. As shown in the table, our results are significantly higher than the baselines but lower than the best SemEval results. We use a similar combination approach to task A for our contrastive results and the *primary* is computed using the BOV and IR features as the augmented features for LSTM. In this task, the BOV includes all the features except for the word clustering and NMF features, and we employ both the ranking order of the IR and answer order as augmented features for our NN-based models.

**Question-external question-comment pair similarity** This task is only available for Arabic. Our feature set for this task is somewhat simplified compared to the English tasks: we only use our BOV approach with simple text- and vector-based features. Similarities are computed only on word- and sentence-level, and not on chunk-level as in (Belenkov et al., 2015). We do not use word clustering or topic modeling features and we note that the Arabic dataset has no associated metadata. Furthermore, in this dataset every original question has a number of related question-answer pairs. To fully exploit this information we compute two sets of features: one between the original and related questions, and one between the original question and the related answer. We then concatenate the two sets as

the final feature representation to the classifier.

Our *primary* submission is a uniform combination of scores from four different settings of shrinking the length: (i) no shrinking (all words are kept as is);<sup>4</sup> (ii) only keeping content lemmas (iii) only content lemmas and TextRank with  $N = 3$ ,  $P = 5$ ; (iv) only content lemmas and TextRank with  $N = 4$ ,  $P = 1$ . We also submit (i) as *contrastive1* and (iii) as *contrastive2*. These settings were chosen based on the performance on the development set.

As Table 5(d) shows, our *primary* submission ranks first on all ranking metrics and on F1. Our *contrastive* submissions are also very competitive.

Finally, we experimented with two sets of word vectors, either trained from the general domain Gigaword corpus ( $\sim 1B$  words) or the domain-specific unsupervised data provided with the task ( $\sim 26M$  words). Despite the very different sizes of the raw corpora, we found mixed results: the general domain vectors were useful with no shrinking (i) while the domain-specific ones were more beneficial with shrinking (ii-iv); we used these settings for the submission. Using word vectors trained on a combined corpus from both raw datasets did not result in additional improvement.

## 4 Conclusion

We developed bag-of-vectors and neural network approaches, and demonstrated their effectiveness on the cQA tasks for ranking a list of questions or answers for a given question. We evaluated our approaches on the SemEval-2016 corpus and our results significantly outperform the baselines. In addition, our results are comparable to the result of the best submission to SemEval-2016 for English and achieved the first place for Arabic.

## Acknowledgments

This research was supported by the Qatar Computing Research Institute (QCRI). We would like to thank Alessandro Moschitti, Preslav Nakov, Lluís Márquez, and other members of the QCRI Arabic Language Technologies group for their collaboration on this project.

---

<sup>4</sup>In this setting we found it useful to omit all “Relevant” question-answer pairs from training and only keep “Direct” and “Irrelevant” pairs. This helps probably due to annotation issues.

## Abstract

We present the system we built for participating in SemEval-2016 Task 3 on Community Question Answering. We achieved the best results on subtask C, and strong results on subtasks A and B, by combining a rich set of various types of features: semantic, lexical, metadata, and user-related. The most important group turned out to be the metadata for the question and for the comment, semantic vectors trained on QatarLiving data and similarities between the question and the comment for subtasks A and C, and between the original and the related question for Subtask B.

## 1 Introduction

SemEval-2016 Task 3 on Community Question Answering<sup>1</sup> (Nakov et al., 2016) aims to solve a real-life application problem. The main **subtask C (Question-External Comment Similarity)** asks to find an answer in the forum that will be appropriate as a response to a newly posted question. This is achieved by retrieving similar questions and ranking their answers with respect to the new question. Two additional supporting subtasks are defined:

**Subtask A (Question-Comment Similarity):** Given a question from a question-comment thread, rank the comments within the thread based on their relevance with respect to the question.

**Subtask B (Question-Question Similarity):** Given a new question, re-rank the similar questions retrieved by a search engine with respect to that question.

<sup>1</sup><http://alt.qcri.org/semeval2016/task3/>

## 2 Related Work

We build our preprocessing and feature extraction pipeline based on the system of Zamanov et al. (2015), which was developed by a subset of our 2016 team for SemEval-2015 Task 3 on Answer Selection in Community Question Answering (Nakov et al., 2015). The task in 2015 was to classify comments in a thread as *relevant*, *potentially useful*, or *bad* with respect to the thread question. This year’s Community Question Answering subtask A is similar to subtask A in 2015, but now it is a ranking task, asking to rank the answers in a thread based on their relevance with respect to the thread’s question. Given this similarity, most of the techniques used by participants in the 2015 subtask A are potentially valuable for this year’s subtask A as well. Below we mention just the few most relevant among them.

In their 2015 system, Belinkov et al. (2015) used vectors of the question and of the comment, metadata features, and text-based similarities. Nicosia et al. (2015) used similarity measures, URLs in the comment text and statistics about the user profile: number of good, bad, and potentially useful comments. Similarly, we use the number of posts by the same user in the thread, the ID of the question’s author, topic model-based feature, special words, etc.

Determining the overall sentiment of the question can also be useful, and it was used in 2015 (Nicosia et al., 2015). One way to do it is to build a sufficiently large question taxonomy as described in (Li and Roth, 2006). This may help determine the quality of the answer, but it requires significant efforts in order to build such a taxonomy.

### 3 Data

For training and testing, we used data provided by the SemEval-2016 Task 3 organizers. The datasets consist of 6,398 questions and 40,288 comments for Subtask A, 317 original + 3,169 related questions for Subtask B, and 317 original questions + 3,169 related questions + 31,690 comments for Subtask C.

For subtask A, the comments in a question-answer thread are annotated as *Good*, *PotentiallyUseful* and *Bad*. A good ranking is one that ranks all *Good* comments above *PotentiallyUseful* and *Bad* ones (without distinguishing between the latter two).

For subtask B, the potentially relevant questions are annotated as *PerfectMatch*, *Relevant* and *Irrelevant* with respect to the original question. A good ranking is one where the *PerfectMatch* and the *Relevant* questions (without distinguishing between them) are both ranked above the *Irrelevant* ones.

We also used semantic vectors (Mikolov et al., 2013a) pretrained on Google News data: 300-dimensional vectors, available for three million words and phrases.

For all subtasks, we further trained semantic vectors using Gensim (Řehůřek and Sojka, 2010) on 200,000 questions and two million comments from the Qatar Living Forum,<sup>2</sup>, which were provided by the task organizers.

Finally, using this same data, and following (Mihaylov et al., 2015a; Mihaylov et al., 2015b), we scraped information about the users from the forum and we extracted for each of them the time in the forum, the active period, the number of questions, the comments in the forum, etc.

### 4 Method

We build our system on top of the framework developed by our colleagues (Zamanov et al., 2015). In particular, we approach the task as a classification problem similarly to the approach we took for SemEval 2015 Task 3 (Nakov et al., 2015). However, unlike 2015, this year we have a ranking problem for all subtasks, e.g., for subtask A we have to rank the comments depending on how likely the classifier thinks they are to be *Good* vs. them being *Bad* or *PotentiallyUseful*.

<sup>2</sup>Qatar Living: <http://www.qatarliving.com/forum>

We use variety of features like question and comment metadata; question and comment lexical features; distance measures between the question and the comment; text readability measures applied to the question and to the comment; lexical semantics vectors for the question and for the comment; features modeling the likelihood of a user being a troll.

These features proved quite useful for ranking comments with respect to a given question (Subtask A and C), but they did not achieve as high results when ranking questions with respect to other questions (Subtask B).

#### 4.1 Features

##### Metadata Features

These features are based on surface observations of the thread’s structure and properties. From the comments’ attributes we extract whether the comment is written by the author of the question. We further extract the comment’s position in the thread, and the ID of the author of the comment. Next, we tokenize the text and we calculate the ratio of the comment length and of the question length (in terms of number of tokens). In terms of the threads we measure, the number of comments from the same user in a particular thread and the order in which they are written by the user, i.e., first, second, etc. comment by the same user. In terms of the whole QatarLiving forum, we calculate the number of questions in a category.

Another family of metadata features explores the presence and the number of links in the question and in the comment. We counted both inbound (i.e., to `qatarliving.com`) and outbound links. Our hypothesis was that the presence of a reference to another resource is indicative of a relevant comment. Investigations on the training set showed that a relevant comment was more likely to contain such a link. Unfortunately, less than 10% of the comments had links, and ultimately these features did not have a very high impact on the results.

##### Lexical Features

These features represent the lexical content of questions and comments. They are obtained with the help of the GATE (Cunningham et al., 2011; Cunningham et al., 2002) preprocessing pipeline with some hand-crafted rules and various statistics.

We use token-, NP-, and sentence-based features as well as features based on the following entities: Person, Location, Organisation and Address. The latter ones are used to mark whether the comment contains an answer to a **wh**-question (**where**, **who**, **what**, etc.), e.g., if the question contains the word “where”. We further add a boolean feature modeling whether the comment contains a Location or an Address. We tagged the named entities using the high-quality named entity recognition pipeline of Ontotext.<sup>3</sup> We further extracted statistics about the number of verbs, nouns, pronouns, and adjectives in the question and in the comment, as well as the number of question marks in the comments, and the number of question words in the question and in the comment.

Another group of lexical features are extracted from the comment text only and show whether it contains smileys, currency units, e-mails, phone numbers, only laughter, “thank you” phrases, personal opinions, or disagreement.

Other lexical features relate to spelling and include number of misspelled words that are within edit distance of 1 from a word in our vocabulary and number of offensive words from a predefined list.

We also borrow a dictionary from the PMI-cool system (Balchev et al., 2016), which is based on unigram and bigram occurrences across the classes. We use it to compute the *Pointwise Mutual Information* (PMI) between a dictionary entry and a class. Based on it, we add features that sum the PMI for all tokens in a given comment. This family of features are weighed most heavily by the classifier.

We further computed lexical similarity between a question and a comment using *SimHash* (Sadowski and Levin, 2007), which is a near-duplicate similarity measure but it did not help much.

We also apply a set of statistical scores to measure the **level of readability** and complexity of the text (Aluisio et al., 2010). The standard readability measures include Automated Readability Index, Coleman-Liau Index, Flesch Reading Ease, Gunning Fog Index, Flesch-Kincaid Grade Level, LIX, SMOG grade. We also employ statistics about the average number of words per sentence in the comment or question, and type-to-token ratios.

---

<sup>3</sup><http://ontotext.com/>

## Semantic Features

Our semantic features try to capture the proximity between the meanings encoded in the word sequences of the questions and of the answers.

One of the semantic features uses **Mallet topic modelling** (McCallum, 2002). We build a topic model with 100 topics. Then we measure the cosine distance between the topics in the first text and the topics in the second text, i.e., in the question and in the answer (Subtasks A and C), or in the original and in the related question (Subtask B).

We also used **semantic vectors** trained with word2vec (Mikolov et al., 2013b). We performed experiments to select the best vectors for the task. We tried pre-trained vectors from Google News. We further trained vectors from the unannotated data from the QatarLiving forum. We used the latter vectors in our system as they yielded better results.

We experimented with training vectors of different sizes and different minimal word counts. Because of the many common misspelled words, the smaller word count yields better results. We tried different tokenizations for the words. To capture the specifics of the forum language, we added identifiers for numbers, smileys, URLs and images. For each question-comment pair, we calculated the centroid vectors of the question and of the comment and we used the components of the resulting vectors as features for the classifier. We used Gensim (Řehůřek and Sojka, 2010) for building the vectors.

## User Features

We downloaded and used characteristics about the users from the QatarLiving forum, such as number of questions, comments, classifieds; time since registration, time since last activity in the forum, time of the day in which the user was active, etc. We also added as user characteristics the number of good and bad comments from the annotated training data. However, the user features did not improve the results. We noticed that over time, the number of both good and bad comments for a user in the forum grew, and the number of good and bad comments for most of the users was similar.

We also used troll user features, e.g., number of mentions of the user as troll and troll behavior characteristics as described in (Mihaylov et al., 2015a; Mihaylov et al., 2015b; Mihaylov and Nakov, 2016a).

**Table 1: Subtask A:** Experiments with all features and excluding some feature groups.

## Credibility Features

We further added some of the credibility features described in (Castillo et al., 2013). We trained a prediction model on tweets from the dataset described in that paper. We used **linear Support Vector Machines** (linear SVMs) with Stochastic Gradient Descent (SGD) and L2 regularization. We used an off-the-shelf implementation of SVM, provided in the **Apache Spark** library (Apache Software Foundation Team, 2015).

For each answer we extracted the following features: length of the answer (characters); does the answer contain special punctuation, like question marks, exclamation marks, etc.; is there an emoticon in the text; is there a first person singular (*I, me, my, mine, we*) or plural pronoun (*our, ours, we, us*); is there a third person singular (*he, she, it, his, hers, him, her*) or plural pronoun (*they, them, their*); does the answer contain a user mention (@user); does the text contain URLs in it.

Based on these features we trained an SVM model to classify items as credible or not. For our submission, we used all the features used to train the credibility module as well as the predicted label and the probability it is predicted with.

## 4.2 Classifier

Using the above features, we formed vectors associated with each question-answer pair. Those vectors are a concatenation of the extracted features, including the centroid of the semantic vectors for the question and for the comment.

We then used an SVM classifier as implemented in LibSVM (Chang and Lin, 2011) for classification. We experimented with different kernels (Hsu et al., 2003), and we achieved the best results with the RBF kernel, which we use to train the model for our submissions. The ranking score for a question-comment pair in Subtask A is the calculated probability of the pair to be classified as *Good*.

For Subtask C, we used the same approach as in Subtask A. We first ranked the comments with respect to the relevant question. For the final ranking, we multiplied the probability of the pair “relevant question – comment” being *Good* by the reciprocal rank of the related question as given by Google.

For subtask B, we passed to the classifier characteristics of the pair “original question – relevant question”. For ranking, we used the probability of the pair to be classified as *Good*.

| Features                      | Dev-2016 as test set |          | Test-2016 as test set |          |
|-------------------------------|----------------------|----------|-----------------------|----------|
|                               | MAP                  | Accuracy | MAP                   | Accuracy |
| All                           | 41.46                | 69.32    | 55.62                 | 70.21    |
| All – semantic vectors        | 35.57                | 71.52    | 52.51                 | 71.04    |
| All – metadata                | 39.90                | 69.08    | 54.58                 | 71.10    |

| Contrastive-1                 | 42.54                | 81.38    | 48.23                 | 82.49    |
| Contrastive-2                 | 42.56                | 68.64    | 53.48                 | 69.20    |

Table 2: Subtask C. Experiments with all features and excluding some feature groups.

| Features                           | Dev-2016 as test set |          | Test-2016 as test set |          |
|------------------------------------|----------------------|----------|-----------------------|----------|
|                                    | MAP                  | Accuracy | MAP                   | Accuracy |
| Only semantic vectors              | 71.17                | 67.20    | 74.91                 | 68.71    |
| Semantic vectors + cosine distance | 71.76                | 69.00    | 74.43                 | 72.43    |
| Above + topic distance             | 72.34                | 70.80    | 75.22                 | 74.43    |
| Above + metadata                   | 72.84                | 70.20    | 74.82                 | 74.86    |
| Above + text distance              | 72.39                | 72.00    | 75.17                 | 75.57    |
| All – semantic vectors             | 71.98                | 71.20    | 74.43                 | 77.14    |

Table 3: Subtask B. Experiments with the different feature sets for the related and the original question.

## 5 Experiments and Evaluation

We grouped our features in several groups and we ran experiments by excluding some of them in order to identify the most important types of features. In particular, we used the LibSVM fselect script for feature selection. We achieved the best results by combining the features with the semantic vectors of the question and of the comment trained on Qatar-Living data.

In Table 1, we present the results for Semeval-2016 Task 3, Subtask A using all features, as well as when excluding individual feature groups. Our primary submission includes the top-rated features and semantic vectors. We selected our primary submission as it achieved higher score on Dev than Contrastive1 and Contrastive2.

Compared to Contrastive-1, our Primary has some additional features: number of user comments in the thread, cosine between the comment text with question subject and category, more locations and organizations. Our Contrastive-1 submission included the top-rated features and semantic vectors, and our Contrastive-2 submission included the same features as our Primary submission, but used Dev-2016 as additional training set.

In Table 2, we show the results for Semeval-2016 Task 3, Subtask C using all features, as well as when excluding individual feature groups. Our Primary submission includes all features excluding user statistics and troll features. Our Contrastive-1 submission includes all features, including PMI, while Contrastive-2 includes all features, excluding PMI.

| Features                   | Dev-2016 as test |          |
|----------------------------|------------------|----------|
|                            | MAP              | Accuracy |
| Vectors from Google News   |                  |          |
| Nouns                      | 54.95            | 68.52    |
| Nouns + verbs              | 55.21            | 69.06    |
| Nouns + verbs + adjectives | 54.97            | 68.48    |
| Vectors from QatarLiving   |                  |          |
| Nouns + verbs              | 61.48            | 70.82    |
| Nouns + verbs + adjectives | 60.43            | 70.37    |
| MWC=40; words only         | 58.95            | 71.27    |
| MWC=40; + special symbols  | 59.65            | 71.27    |
| All words; MWC=5           | 62.68            | 71.80    |
| Included cosine distance   | 63.88            | 72.99    |

**Table 4: Selection of semantic vectors.** Experiments with different sources, vector size, and minimum word count.

Tables 1 and 2 have shown that the most important feature groups are the metadata characteristics, the distance measures between the question and the comment, and the semantic vectors. Other features that fselect scored highly are the credibility score, text readability measures and the number of tokens of some parts of speech in the comment text (namely, number of adjectives and nouns). The least useful features are statistics about the forum users and characteristics of the question: question length and number of tokens of different parts of speech in the question text. In all above reported results, we used vectors for which we achieved the best results on the development dataset.

In Table 4, we present the results from experiments with semantic vectors. We experimented with pre-trained vectors from Google News and we also trained vectors with word2vec on the unannotated Qatar Living forum data. When training vectors on Qatar Living data, we experimented with different vector sizes and minimum word frequencies. We also added the following entities as words: numbers, images, URLs, smileys (referred to in the table as “special symbols”). We achieved best results with vectors from QatarLiving, vector size 100, and minimum word frequency of 5. Including special symbols as words also improved the results. We experimented with calculating the centroids of the question and of the comment using specific parts of speech only; however, ultimately we found that using all words from all parts of speech worked best.

For **Subtask B**, we used a similar approach as for Subtask A: we passed to the classifier the semantic vectors of the original and of the related question, some metadata and distance features. However, we could not experiment much with this subtask, and thus our results are not as strong, as Table 3 shows.

## 6 Conclusion

We have presented the system developed by our team for participating in SemEval-2016 Task 3 on Community Question Answering. We achieved the best results on subtask C, and strong results on subtasks A and B, by combining a rich set of various types of features: semantic, lexical, metadata, and user-related. The most important group turned out to be the metadata for the question and for the comment, semantic vectors trained on QatarLiving data and similarities between the question and the comment for subtasks A and C, and between the original and the related question for Subtask B.

In future work, we would like to experiment with new, interesting features, e.g., based on various word embeddings as in the SemanticZ system (Mihaylov and Nakov, 2016b). We also want to use our features in a deep learning architecture, e.g., as in the MTE-NN system (Guzmán et al., 2016a; Guzmán et al., 2016b), which borrowed an entire neural network framework and architecture from previous work on machine translation evaluation (Guzmán et al., 2015).

We further plan to use information from entire threads to make better predictions, as using thread-level information for answer classification has already been shown useful for SemEval-2015 Task 3, subtask A, e.g., by using features modeling the thread structure and dialogue (Nicosia et al., 2015; Barrón-Cedeño et al., 2015), or by applying thread-level inference using the predictions of local classifiers (Joty et al., 2015; Joty et al., 2016). How to use such models efficiently in the ranking setup of 2016 is an interesting research question.

Finally, we would like to address subtask C in a more solid way, making good use of the data, the gold annotations, the features, the models, and the predictions for subtasks A and B.

## Acknowledgments

This research was performed by a team of students from MSc programs in Computer Science in the Sofia University “St Kliment Ohridski”.

It is also part of the Interactive sYstems for Answer Search (Iyas) project, which is developed by the Arabic Language Technologies group at the Qatar Computing Research Institute, HBKU, part of Qatar Foundation in collaboration with MIT-CSAIL.

We would also like to thank Ontotext for providing us with their high-quality NER pipeline.

## Abstract

We describe our submission to SemEval-2016 Task 3 on Community Question Answering. We participated in subtask A, which asks to rerank the comments from the thread for a given forum question from good to bad. Our approach focuses on the generation and use of goodness polarity lexicons, similarly to the sentiment polarity lexicons, which are very popular in sentiment analysis. In particular, we use a combination of bootstrapping and pointwise mutual information to estimate the strength of association between a word (from a large unannotated set of question-answer threads) and the class of good/bad comments. We then use various features based on these lexicons to train a regression model, whose predictions we use to induce the final comment ranking. While our system was not very strong as it lacked important features, our lexicons contributed to the strong performance of another top-performing system.

## 1 Introduction

Online forums have been gaining a lot of popularity in recent years. In these forums, one can ask a question, and based on the wisdom of the crowd, expect to get some good answers. In practice, unless there is strong moderation, most such forums get populated with bad answers, which can be annoying for users as it takes time to read through all answers in a long thread. As the importance of the problem was recognized in the research community, this gave rise to two shared tasks on Community Question Answering at SemEval-2015 (Nakov et al., 2015) and SemEval-2016 (Nakov et al., 2016).

Here we describe the PMI-cool system, which we developed to participate in SemEval-2016 Task 3, subtask A, which asks to rerank the answers in a question-answer thread, ordering them from good to bad (Nakov et al., 2016). As the name of our system suggests, our approach is heavily based on pointwise mutual information (PMI), which we use to estimate the association strength between a word and a class, e.g., the class of good or the class of bad comments. Based on this association strength, we perform bootstrapping in a large unannotated set of question-answer threads to generate specialized *goodness polarity* lexicons. We then use various features based on these lexicons to train a regression model, whose predictions we use to induce the final comment ranking.

While our PMI-cool system did not perform very well at the competition as it lacked important features and as we found a bug in our submission, our goodness polarity lexicons proved useful and contributed to the strong performance of another top-performing system at SemEval-2016 Task 3: Super\_team (Mihaylova et al., 2016).

## 2 Method

Our solution can be separated into two phases: (*i*) feature extraction, and (*ii*) machine learning. The feature extraction phase consists of extracting various PMI-based and other features, which we describe in the following sections. In the second phase, we apply a support vector machine (SVM) regression model (Drucker et al., 1997), taking the features as an input and returning the similarity score for each question-answer pair as an output.

At test time, we generate regression scores for each answer in a question-answer thread and we rerank the answers accordingly. Before exploring our features, we will first introduce PMI and how we use it to generate goodness polarity lexicons.

### 3 Pointwise Mutual Information and Strength of Association

The pointwise mutual information (PMI) is a notion from the theory of information: given two random variables  $A$  and  $B$ , the mutual information of  $A$  and  $B$  is the “amount of information” (in units such as bits) obtained about the random variable  $A$ , through the random variable  $B$  (Church and Hanks, 1990).

Let  $a$  and  $b$  be two values from the sample space of  $A$  and  $B$ , respectively. The *pointwise* mutual information between  $a$  and  $b$  is defined as follows:

$$pmi(a; b) = \log \frac{P(A = a, B = b)}{P(A = a) \cdot P(B = b)} \quad (1)$$

$$= \log \frac{P(A = a|B = b)}{P(A = a)} \quad (2)$$

$pmi(a; b)$  takes values between  $-\infty$ , which is when  $P(A = a, B = b) = 0$ , and  $\min\{-\log P(A = a), -\log P(B = b)\}$ , when  $P(A = a|B = b) = P(B = b|A = a) = 1$ .

The mutual information between  $A$  and  $B$  is the expected value of  $pmi(a; b)$ :

$$MI(A, B) = \sum_{a \in A} \sum_{b \in B} pmi(a; b) \quad (3)$$

PMI is central to a popular approach for bootstrapping sentiment lexicons proposed by Turney (2002). The idea is to start with a small set of seed positive (e.g., *excellent*) and negative words (*bad*), and then to use these words to induce sentiment polarity orientation for new words in a large unannotated set of texts (in his case, product reviews). The idea is that words that co-occur in the same text with positive seed words are likely to be positive, while those that tend to co-occur with negative words are likely to be negative. To quantify this intuition, Turney defines the notion of semantic orientation (SO) for a term  $w$  as follows:

$$SO(w) = pmi(w, pos) - pmi(w, neg)$$

where *pos* and *neg* stand for any positive and negative seed word, respectively.

The idea was later used by other researchers, e.g., Mohammad et al. (2013) built several lexicons based on PMI between words and tweet categories. Here the categories (positive and negative) were defined by a seed set of emotional hashtags, e.g., `#happy`, `#sad`, `#angry`, etc. or by simple positive and negative smileys, e.g., ;), :), ;(, :(,. In this case, the resulting lexicons included not only words, but also bigrams and discontinuous pairs of words.

Another related work is that of Severyn and Moschitti (2015), who proposed an approach to lexicon induction, which, instead of using PMI for SO, assigns positive/negative labels to the unlabeled tweets (based on the seeds), and then trains an SVM classifier on them, using word  $n$ -grams as features. These  $n$ -grams are then used as lexicon entries with the learned classifier weights as polarity scores. While this is an interesting approach, in our experiments below, we will stick to PMI as a more established method to estimate SO.

Finally, there is a related task at SemEval-2016 on predicting the out-of-context sentiment intensity of phrases (Kiritchenko et al., 2016), but there the focus is on multiword phrases.

### 4 Building Goodness Polarity Lexicons

We use SO to build goodness polarity lexicons for good/bad comments in the forum. Instead of using positive and negative sentiment words as seeds, we start with seed words that are associated with good or bad comments. Unlike the work above, we do not do pure bootstrapping, but rather we use a semi-supervised approach, which works in two steps.

**Step 1:** In order to come up with a list of words that signal a good/bad comment (which is not as easy as it is to come up with such words manually), we look for words that are strongly associated with good vs. bad comments in the annotated training dataset, using SO. We then select the top 5% of the words with the most extreme positive/negative values of SO, which corresponds to the most extreme good/bad comment words.

**Step 2:** We then apply the SO again, but this time using the seed words that we selected in Step 1, in order to build the final large-scale goodness polarity lexicon, as in the above-described work.

## 5 Features

We used a variety of features based on the textual content of the question and of the answer and on metadata about the question and about the question-answer pair.

### 5.1 Metadata features

All the metadata features we used are included with their SO with the good/bad class. We used the following features:

- *SameAuthor*: This feature checks whether the target answer is given by the same user who asked the question. The assumption here is that the author of the question is unlikely to provide a good answer to his/her own question. We do not use this boolean feature directly, but we use the SO between it and the good/bad classes.
- *AnswerNumber*: This is the rank of the answer (e.g., first, second, third, . . . , tenth). The assumption is that most discussions tend to degenerate and to lose focus over time. This is also visible in the baseline that ranks the answers based on their chronologicak rank, which performs better than random (Nakov et al., 2016). The feature value is the SO of the answer rank and of the good/bad classes.
- *AnswerAuthor*: This is the ID of the person who gave the answer. The idea is that some users might tend to give mostly good/bad answers. Thus, the SO between the author ID and the good/bad classes is useful for user modeling.

### 5.2 Word PMI

The main feature of our PMI-cool system is based on the lexicon constructed by computing the SO of each word, used in all the answers in the training corpus. Using this technique, we identify words commonly used in good versus bad answers in general, regardless of the question; we used words without stemming as stemming lowered the performance. For instance, bad answers often contain variants of thanks statements, insults, words generally used in off-topic comments and interjections, etc. Table 1 shows some of the top words that are most strongly associated with bad answers in terms of SO.

### 5.3 Sentiment Lexicon

Another resource we used is the Sentiment140 lexicon, which was constructed by Mohammad et al. (2013) using SO for word weighting, as we mentioned above. Our assumption here is that good/bad sentiment expressed in the answer suggests good/bad answers, as previously suggested in (Nicosia et al., 2015). The feature we calculate is the sum of the sentiment scores of the sentiment-bearing words in the answer.

### 5.4 Bootstrapped PMI

As explained above, we used bootstrapping to induce larger goodness polarity lexicons from the large unannotated corpus provided for the task. For this purpose, we first used PMI to build a lexicon from the labeled training data, removing rarely mentioned words and taking the top and the bottom 5% of the rest, based on the SO score. Then, we used PMI again, using these words as good/bad seeds to generate the large lexicon. Unfortunately, due to implementation issues before the submission deadline, this feature was not included in the submitted system’s feature set.

## 6 Ineffective Features

We further used some features that turned out to be ineffective. Still, we describe them here as we believe this might be useful for other researchers.

### 6.1 Personality Trait Features

We used the lexicons of Schwartz et al. (2013), which were designed to measure a user’s big-five personality traits: openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism. These lexicons were also computed using PMI and SO metrics between words in a large set of user-generated content on social media: 75,000 Facebook user profiles with personality values and 700 million words, phrases, and topic instances. There are two lexicons for each trait, with the 100 most and the 100 least characteristic words for the target trait.

We calculated a personality score for each of the five traits by summing the scores of all matching words in all answers written by the author of the answer, thus modeling his/her personality profile. However, this feature, did not yield improvements.

**Table 1:** Words with the smallest SO.

## 6.2 Topic Features

The text features used in PMI-cool are based on words only. We also tried to build a Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) on the question and on the answers and to add the resulting topic distributions as features. However, this did not help on the development dataset, and thus we did not use it in our final submission.

## 7 Experiments and Evaluation

For training the prediction model for good versus bad answers, we used an SVM with a linear kernel as implemented in LibLinear (Fan et al., 2008). We treated each answer as a separate instance with all the above features, merging the PotentiallyUseful and the Bad labels under the *bad* class, and we ranked the answers based on the SVM score.

| Features                 | MAP   |
|--------------------------|-------|
| MAX possible score       | 0.865 |
| All features             | 0.638 |
| All – metadata           | 0.620 |
| All – personality        | 0.638 |
| All – sentiment          | 0.636 |
| All – word PMI           | 0.572 |
| Baseline (chronological) | 0.595 |
| Baseline (random)        | 0.535 |

**Table 2:** Ablation results on the development dataset.

Here is a list of the useful features we experimented with:

- *SO SameAuthor*;
- *SO AnswerNumber*;
- *SO AnswerAuthor*;
- sum of  $SO(w)$  for the answer words;
- sum of the sentiment for the answer words;
- one feature for each personality trait: sum of the scores of the lexicon words for that trait in all posts by the answer author;
- number of words with positive *BootstrapedSO* in the answer;
- number of words with negative *BootstrapedSO* in the answer;
- fraction of words with positive *BootstrapedSO* in the answer;
- fraction of words with negative *BootstrapedSO* in the answer;
- sum of the positive *BootstrapedSO* scores for the answer words;
- sum of the negative *BootstrapedSO* scores for the answer words;
- maximum value of *BootstrapedSO* for a word in the answer;
- minimum value of *BootstrapedSO* for a word in the answer;
- sum of *BootstrapedSO* scores for all answer words.

The MAP scores resulting from our experiments on the development dataset are shown in Table 2. The first row shows the maximum possible score: it is lower than 1, as 33 of the 244 dev threads had no good answers. Next, we show the MAP score when all features are enabled; we can see that it outperforms both the chronological and the random baseline, by 4 and 10 MAP points absolute, respectively. The following four rows show results with some class of features disabled. We can see that the personality features had virtually no impact on the results, sentiment had a minimal impact (0.2 MAP points), metadata had a real impact (1.8 MAP points), while the word PMI features had the largest impact (6.6 MAP points).

## 8 Post-Submission Analysis

After the competition ended, we fixed a bug in the bootstrapped lexicon construction, which resulted in sizable improvements. We further replaced the uniting SVR with SVC, and we excluded the PotentiallyUseful comments from training. These changes collectively yielded a boost in MAP to 74.67 on the test dataset. As Table 3 shows, this is 6 MAP points absolute higher than the score for the system we submitted to the competition. It is also only 4.5 MAP points behind the best, and only 3 points behind the second-best team.

## 9 Conclusion and Future Work

We have described our PMI-cool system for SemEval-2016, Task 3 on Community Question Answering, subtask A, which asks to rerank the comments from the thread for a given forum question from good to bad. Our approach relied on using SO scores based on PMI to construct various features, the most important of which were our goodness polarity lexicons, which are based on an idea we borrowed from sentiment analysis. In particular, we used a combination of bootstrapping and point-wise mutual information to estimate the strength of association between a word (from a large unannotated set of question-answer threads) and the class of good/bad comments. We then used various features based on these lexicons to train a regression model, whose predictions we used to induce the final comment ranking.

While our PMI-cool system did not perform very well at the competition as it lacked important features and as we had a bug at submission time, our goodness polarity lexicons proved useful and contributed to the strong performance of another top-performing system at SemEval-2016 Task 3: Super\_team (Mihaylova et al., 2016).

In future work, we plan to strengthen our system with more features. In particular, we would like to incorporate rich knowledge sources, e.g., semantic similarity features based on fine-tuned word embeddings and topics similarities as in the SemanticZ system (Mihaylov and Nakov, 2016b). There are also plenty of interesting features to borrow from the Super\_Team system (Mihaylova et al., 2016), including veracity, text complexity, and troll user features as inspired by (Mihaylov et al., 2015a; Mihaylov et al., 2015b; Mihaylov and Nakov, 2016a). It would be interesting to combine these in a deep learning architecture, e.g., as in the MTE-NN system (Guzmán et al., 2016a; Guzmán et al., 2016b), which borrowed an entire neural network framework and architecture from previous work on machine translation evaluation (Guzmán et al., 2015).

We further plan to use information from entire threads to make better predictions, as using thread-level information for answer classification has already been shown useful for SemEval-2015 Task 3, subtask A, e.g., by using features modeling the thread structure and dialogue (Nicosia et al., 2015; Barrón-Cedeño et al., 2015), or by applying thread-level inference using the predictions of local classifiers (Joty et al., 2015; Joty et al., 2016). How to use such models efficiently in the ranking setup of 2016 is an interesting research question.

## Acknowledgments.

This research was performed by Daniel Balchev, a student in Computer Science in the Sofia University “St Kliment Ohridski”, as part of his MSc thesis.

This research is also part of the Interactive sYstems for Answer Search (Iyas) project, which is developed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation in collaboration with MIT-CSAIL.

## Abstract

This paper describes the results of the participation of The University of Melbourne in the community question-answering (CQA) task of SemEval 2016 (Task 3-B). We obtained a MAP score of 70.2% on the test set, by combining three classifiers: a NaiveBayes classifier and a support vector machine (SVM) each trained over lexical similarity features, and a convolutional neural network (CNN). The CNN uses word embeddings and machine translation evaluation scores as features.

## 1 Introduction

In this paper we present the system we submitted for the community question-answering (CQA) task of the SemEval 2016 workshop (Task 3-B: Nakov et al. (2016)). By finding an automatic way to answer new questions based on existing ones, we unlock an enormous wealth of information stored in online CQA archives. In the task as specified for the SemEval workshop, we were given 70 query questions. Each question had at most ten candidate questions, which we were to re-rank according to their similarity to the query question. Each question consisted of a title and a description. The data was taken from the Qatar Living forum.<sup>1</sup> The training data set was small: 267 queries, with ten candidate duplicate questions each. The candidate questions were originally labelled according to the three classes: RELEVANT, PERFECT-MATCH and IRRELEVANT. Subsequently, however, RELEVANT and PERFECTMATCH were merged into a single class. In an ideal ranking, documents with

relevant labels were to be ranked higher than the IRRELEVANT documents.

The system we submitted combines the predictions of three different classifiers through simple voting. The first two classifiers (naive Bayes and SVM) made use of semantic similarity measures as features, and the third one was a convolutional neural network (CNN) that used word embeddings and machine translation evaluation scores as input. The combined system achieved a MAP score of 70.2% on the test set.

## 2 Approach

Our system combined the scores of three different classifiers based on simple voting. If at least two of the three classifiers considered a candidate question relevant to a query question, it was considered to be relevant. The candidate questions were then ranked according to this judgement, with the relevant ones on top (in any order, since this was not taken into account in the official evaluation). In this section we will describe the details of the three classifiers.

### 2.1 String Similarity Features (SS1)

Our first set of features consisted of string similarity measures, which we selected based on our recent success in applying these features to measure the compositionality of multiword expressions (Salehi and Cook, 2013), to estimate semantic textual similarity (Gella et al., 2013), and to detect cross-lingual textual entailment (Graham et al., 2013).

To measure the string similarity between two questions, the titles and the descriptions of the questions were lemmatized using NLTK (Bird, 2006).

<sup>1</sup><http://www.qatarliving.com/forum>

We used two string similarity measures in this study: longest common substring and the Smith-Waterman algorithm.<sup>2</sup> The output of each measure was normalized to the range of [0, 1], where 0 indicated that the questions were completely different, while 1 showed that they were identical. More details on the string similarity measures and how we normalise the scores are described in Salehi and Cook (2013).

Our primary experiments showed that measuring string similarity between the titles of questions led to a higher accuracy than using the question descriptions. Therefore, we only considered the titles in our final run. Ultimately, in order to combine all string similarity measures into one score, we used the linear kernel SVM as implemented in the scikit-learn package<sup>3</sup>, using the default parameters.

## 2.2 String Similarity Features 2 (SS2)

For our second model, we used five more lexical similarity measures as features: the Jaccard similarity, cosine similarity calculated over binary term vectors, the overlap coefficient, de Sørensen-Dice coefficient, and Kullback-Leibler (KL) divergence. With these features we obtained the best results by using both the title and the description of the question. In contrast to our first classifier, no stemming or lemmatization was applied because it was found not to make any difference. The classifier we used was naive Bayes.<sup>4</sup>

## 2.3 Convolutional Neural Network (CNN)

The third classifier we used was a convolutional neural network (“CNN”). CNN structures have been shown to be very successful in speech recognition and computer vision tasks (Graves et al., 2013; Krizhevsky et al., 2012). Recently, they have also been applied to natural language tasks, and again, have achieved good results (Collobert and Weston, 2008; Yin and Schütze, 2015).

Kalchbrenner et al. (2014) developed a CNN-based model that can be used for sentence modelling

<sup>2</sup>We also experimented with Levenshtein and modified Levenshtein, but we did not observe any improvement when using these features.

<sup>3</sup><http://scikit-learn.org>

<sup>4</sup>We used the version implemented in the Weka toolkit: <http://www.cs.waikato.ac.nz/ml/weka/>, using the default settings.

problems. With several combinations of convolutional filters and dynamic  $k$ -max pooling filters, the model is very good at capturing features on both the local word level and the global sentence level. The word-level features are combined in several stages to model sentences. This characteristic of capturing meaning at different levels is particularly attractive for the target domain, as two questions with similar meaning may have a very different surface form. A neural network that can model meaning at the sentence level may recognise two questions as being similar even though they have very little lexical overlap. This is the reason we decided to use Kalchbrenner’s CNN for our task, enhanced with some aspects of Yin and Schütze (2015)’s model, who used a CNN for Paraphrase Identification (PI).

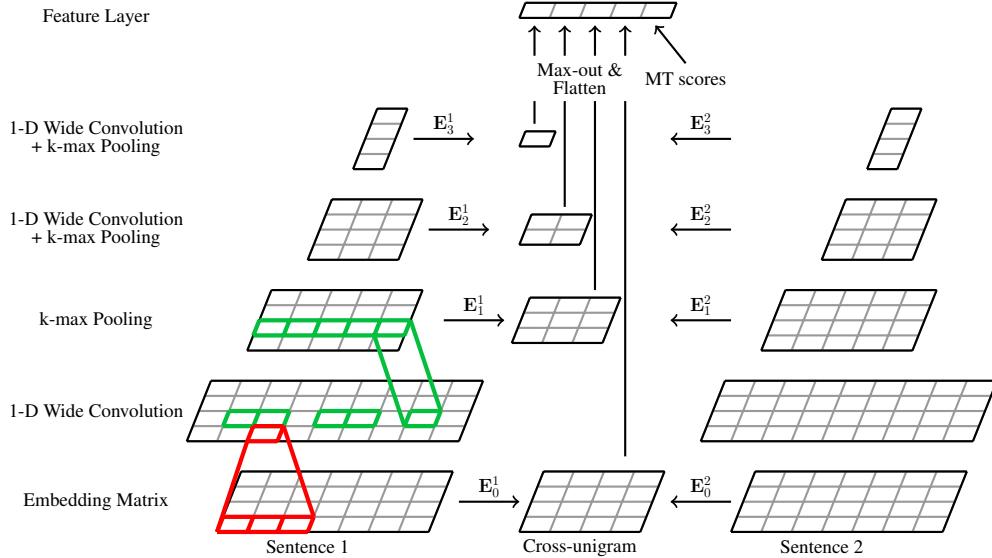

In our approach, we used the CNN to compare two sentences at different levels in the model. The similarity scores obtained in this way were combined with several machine translation evaluation scores and fed into a multi-Layer perceptron (MLP) classifier to get a final similarity score. We decided to make this final classifier a neural network too so that we could get a non-linear output for the newly added features. The expectation is that this will improve the classification.

In the following subsections we explain the details of the CNN: how to model sentences on different levels and how to generate the features using sentence embeddings. We also explain some other features that we added, and how we trained the model.

### 2.3.1 Model Overview

Figure 1 show the CNN model. Each tokenised input sentence  $S$  consists of  $n$  words  $\{w_1, w_2, \dots, w_n\}$ , where  $n$  denotes the length of the sentence. Each word has a word vector  $e_n \in \mathbb{R}^d$ , where  $d$  is the dimension of the word vector. All the word vectors combined form a sentence matrix embedding  $E \in \mathbb{R}^{d \times n}$ , which is used as the input to our CNN model. Different input sentences will have different lengths, but this is not a problem at this stage. We deal with this issue when comparing the sentences to obtain features, as explained in Section 2.3.2.

For each convolutional level  $l$ , we convolved the input matrix with a wide one-dimensional convolution filter, and generated a convolutional matrix

**Figure 1:** The Convolutional Neural Network.

$\mathbf{C} \in \mathbb{R}^{d \times (n+m-1)}$ , where  $m$  is the filter width, which is set to 3 (see the red highlighting in Figure 1). We then applied a non-linear function (rectified linear units (ReLU)) to get the convolutional layer  $\mathbf{C}' = \text{ReLU}(\mathbf{C})$ .  $\mathbf{C}$  and  $\mathbf{C}'$  are combined in Figure 1 and shown as "1-D Wide Convolution". Next, we applied Kalchbrenner et al. (2014)'s dynamic  $k$ -max pooling approach on  $\mathbf{C}'$ . For each dimension of  $\mathbf{C}'$ , we extracted a maximum of  $k$  features and calculated the pooling layer. The output of the pooling layer is  $\mathbf{E}_l \in \mathbb{R}^{d \times k_l}$ .  $\mathbf{E}_l$  is the sentence embedding of level  $l$  and is used as the input for the next level ( $l+1$ ) of the CNN.

After a series of such convolution operations, we get a deep CNN structure as a representation of each question.

### 2.3.2 Features

As explained in the previous section, the input features to the CNN consisted of word embeddings. We used constant word embeddings directly from Mikolov et al. (2013)'s pre-trained word embeddings model, with dimension  $d = 300$ .

After applying the convolution operations on a question pair  $(\mathbf{S}_1, \mathbf{S}_2)$ , we obtained an embedding set for each question:  $\{\mathbf{E}_0^1, \mathbf{E}_1^1, \dots, \mathbf{E}_l^1\}$  and  $\{\mathbf{E}_0^2, \mathbf{E}_1^2, \dots, \mathbf{E}_l^2\}$ , where  $l$  is the number of levels in our CNN structure. Different embeddings represent the semantics of the question with a different granularity.  $\mathbf{E}_0$  corresponds to the input word em-

beddings, which represent the semantics of the question at the word level. Each increase in subscript represents a convolutional level in the model. The higher up we get, the more convolved the features will be, until we end up with  $\mathbf{E}_l$ , which represents the document-level meaning of the question.

To obtain the features for the final classifier, we determined the similarity of the embedding matrices  $\mathbf{E}_l^1$  and  $\mathbf{E}_l^2$  for each level, by comparing each vector in  $\mathbf{E}_l^1$  to each vector in  $\mathbf{E}_l^2$ ; a process known on the word level as cross-unigram comparison. The similarity of the vectors was calculated using both cosine similarity and Euclidean distance. This resulted in two matrices per question pair per level, which we concatenated. To reduce the size of these low-level matrices we applied a two-dimensional maxout filter on them. The height and width of the filter were adjusted for different sentence lengths of the questions  $\mathbf{S}_1$  and  $\mathbf{S}_2$ , to ensure that the output always had the same length. Next we flattened the matrix into a vector and used this as our sentence embedding similarity features that formed part of the input to our final classifier.

Apart from the sentence embedding similarity features, we also used several machine translation evaluation measures as extra features before applying the final classifier. Machine translation evaluation measures are designed to detect whether two sentences have a similar meaning or not. They have

|                    | Training Set | Development Set | Test Set |
|--------------------|--------------|-----------------|----------|
| query questions    | 267          | 50              | 70       |
| archived questions | 2,669        | 500             | 700      |

**Table 1:** The number of query and archived question pairs in the SemEval-2016 dataset

been shown to be useful features for paraphrase identification (Madnani et al., 2012), a task very similar to ours. The measures we used were BLEU (Papineni et al., 2002), NIST (Doddington, 2002), METEOR (Banerjee and Lavie, 2005), Ter (Snover et al., 2006), Ter-Plus (Snover et al., 2009), and MaxSim (Chan and Ng, 2008). After adding these additional features to the sentence embedding similarity features, we fed our feature vectors into a Multiple Layer Perceptron (MLP) classifier to get a final similarity score.

### 2.3.3 Training the model

In this section we will explain how we trained our model. Our CNN consisted of three convolutional layers, with a MLP classifier at the top. The MLP combined three fully-connected hidden layers, which contained 512 nodes each and ReLU as its activation function, with a softmax layer on the top.

For the network training, we used AdaDelta (Zeiler, 2012) to update the weights of the model, and set the initial learning rate to  $\alpha = 10^{-4}$ . Dropout (Srivastava et al., 2014) was added to the input layer of the MLP, with  $L_2$ -regularization. The dropout rate was set to 0.5.

## 3 Experiments

In this section, we will describe the experimental setup and the results of our experiments.

### 3.1 Dataset

Table 1 presents basic statistics for the SemEval-2016 Task 3-B dataset. Each query question was paired up with at most ten archived questions, which we had to re-rank according to relevance. The dataset was partitioned into three components: (1) a training set, (2) a development set, and (3) a test set.

### 3.2 Results

To evaluate the effectiveness of the different feature sets, we report on the results of both the combined model and the separate classifiers in Tables 2 and 3. Baselines 1 and 2 are the official baselines as given by the SemEval organisers. The information retrieval (IR) baseline was produced using Google to rank the candidate questions.

We use the Mean Average Precision (MAP) as our primary evaluation metric,<sup>5</sup> but also report the Average Recall (AvgRec), Mean Reciprocal Rank (MRR), Precision (P), Recall (R), F1-measure (F1), and Accuracy (Acc) scores.

On the development set, we obtained the best MAP score with the majority voting model, but on the test set we did not see the same result. On the test set, the CNN model by itself obtained the best results. It is interesting to see that all three models separately performed better on the test set than on the development set, but the combined model did not.

Although models SS1 and SS2 both make use of string similarity measures, they produced different classification outputs for 60.2% of the development set queries. SS1’s predictions differed from the CNN’s in 54.8% of the development queries, and SS2’s predictions differed from the CNN’s in 72.6% of the development queries. The fact that the three models produced such different results, while each performed reasonably well, was the motivation for combining them.

One reason for the different results on the test and development sets might be the difference in the class balance. In the development set, 43% of the candidate questions were labeled as relevant, and 57% as irrelevant. In the test set this was 33% and 67% respectively. The training data resembled the development set more than the test set, with 45% relevant and 55% irrelevant candidate questions. We suspect that more training data is needed to obtain consistent results.

It would be interesting to see whether the scores improve when we add the string similarity features to the CNN directly (thereby losing the majority voting component), in the same way as we added the

---

<sup>5</sup>This is also what the official ranking of the participating systems is based on.

| Test Set            |              |           |       |        |       |       |       |

machine translation evaluation features. We leave this for future work.

## 4 Summary

In this paper, we proposed a method based on the combination of three different classifiers for the task of duplicate question ranking, in the context of SemEval 2016 Task 3-B. The classifiers we combined were a CNN using word embeddings and machine translation evaluation metrics, and two classifiers that used lexical similarity features: a naive Bayes classifier and a support vector machine (SVM). The results we obtained on the test set were quite different from the results on the development set, which may be explained by the small size of the training data set.

# ICL00 at SemEval-2016 Task 3: Translation-Based Method for CQA System

Minghua Zhang Yunfang Wu  
Institute of Computational Linguistics, Peking University

## Abstract

We participate in the English subtask B and C at SemEval-2016 Task 3 “Community Question Answering”. This paper is concerned with the description of our participating system. We propose a ranking model that combines a translation model with the cosine similarity-based method. Compared to the traditional bag of words method, the proposed model is more effective because the relationships between words can be explicitly modeled through word-to-word translation probabilities. Experiments conducted on the official test data demonstrate that our proposed ranking method obtains promising results.

## 1 Introduction

The SemEval-2016 Task 3 (Nakov et al., 2016) Community Question Answering (CQA) covers a full task on CQA and which is, therefore, closer to a real application. To facilitate the participation of non IR/QA scholar to the task, the search engine step is already carried out which means that the task organizers explicitly provides the set of potential answers to be reranked. That is to say, given a new question (aka original question) and the set of the first 10 related questions (retrieved by a search engine) in subtask B, our system will focus on reranking the related questions according to their similarity with the original question. Similar to subtask B, in subtask C that is the main English subtask, Given a new question and the set of the first 10 related questions, each associated with its first 10 comments appearing in its thread, we will rerank the 100 comments (10 questions \* 10 comments) according to their relevance with respect to the original question.

Note that the subtask B will give us enough tools to solve the main subtask. And therefore, our paper will give an overall description of the system based on subtask B. In section 2, we will briefly discuss an important difference between the subtask C and subtask B in the course of reranking.

However, the major challenge for subtask B, as for most of CQA systems, is the word mismatch between the original question and the related question. For example, “Where I can buy good oil for massage?” and “Is there any place I can find scented massage oils in Qatar?” are two very similar questions, but they only have a few words in common. To solve the word mismatch problem, we focus on translation-based approaches in this paper.

The remainder of this paper is organized as follows. Section 2 introduces the methods used in the ranking model clearly. Section 3 presents the translation probabilities Estimation. We will talk about an overview of the system in section 4. Section 5 presents the experimental results. In Section 6, we conclude with ideas for future research.

## 2 Ranking Approach

In SemEval-2016 Task 3, the dataset file is a sequence of question pair instances. Each instance contain an original question and a thread which consists of a potentially related question, together with 10 comments for it. Next, let  $Q-Q$  denotes the set of all original-related question pairs in the archive,  $Q-Q = \{ \dots, [(\text{org}_i, \text{rel}_1), (\text{org}_i, \text{rel}_2), \dots, (\text{org}_i, \text{rel}_j), \dots, (\text{org}_i, \text{rel}_{10})], \dots \}$ . So, the goal of subtask B is to re-rank the related questions according to the  $\text{Score}(\text{org}_i, \text{rel}_j)$ . Typically, this score can be modeled by the probability that  $\text{org}_i$  is generated by  $\text{rel}_j$ . Thus, the following part of this section focus on how to calculate  $P(\text{org}_i|\text{rel}_j)$ .

However, the job of subtask C is to rerank the 100 comments according to their relevance with respect to each original question. For clarity, let Q-C denotes the set of all question-comment pairs, Q-C = {..., [(org<sub>i</sub>, rel<sub>j</sub>, C<sub>ij1</sub>), (org<sub>i</sub>, rel<sub>j</sub>, C<sub>ij2</sub>), ..., (org<sub>i</sub>, rel<sub>j</sub>, C<sub>ijk</sub>), ..., (org<sub>i</sub>, rel<sub>j</sub>, C<sub>ij100</sub>)], ...}. To begin the process, we apply the tool which is designed for subtask B to calculate the relevance between original question and related question, then regard it as a weight. In the next step, we make use of translation model to obtain the relevance between original question and comment. Finally, we will rerank the comments according to the Score(org<sub>i</sub>, C<sub>ijk</sub>) which can be written as:

$$Weight_j = \frac{P(org_i|rel_j)}{\sum_{j'=1}^n P(org_i|rel_{j'})} \quad (1)$$

$$Score(org_i, C_{ijk}) = Weight_j * P_{trans}(org_i|C_{ijk}) \quad (2)$$

where org<sub>i</sub> is the original question, rel<sub>j</sub> is the related question, and C<sub>ijk</sub> is the comment for rel<sub>j</sub>.

## 2.1 Word-Based Translation Model

Previous work (Jeon et al., 2005) were the first to apply the translation based method to CQA, subsequent work (Xue et al., 2008) proposed to linearly combine language model and word-based translation model into a unified framework. The experiments show that this model gains better performance than both the language model and the word-based translation model. Following Xue et al. (2008), this model can be written as:

$$Score(org_i, rel_j) = \prod_{w \in org_i} P(w|rel_j) \quad (3)$$

$$P(w|rel_j) = \alpha \frac{\#(w, rel_j)}{|rel_j|} + \beta \sum_{t \in rel_j} P(w|t) \frac{\#(t, rel_j)}{|rel_j|} + \gamma \frac{\#(w, B)}{|B|} \quad (4)$$

where #(w, rel<sub>j</sub>) and #(t, rel<sub>j</sub>) is the frequency of term w and t in rel<sub>j</sub> respectively, B denotes the whole archive, |rel<sub>j</sub>| and |B| denote the length of rel<sub>j</sub> and B respectively, P(w|t) denotes the translation probability from word t to word w.

## 2.2 Combination of Cosine similarity and Translation Method

We compared the performances of a unigram language model and a cosine similarity-based method on the development dataset, which demonstrated

that the cosine similarity method outperforms the language model. Therefore, we propose to linearly combine the cosine similarity and translation model into a ranking model, which can be written as:

$$Score(org_i, rel_j) = \alpha P_{cos}(org_i, rel_j) + \beta P'_{trans}(org_i|rel_j) \quad (5)$$

$$P_{trans}(org_i|rel_j) = \prod_{w \in org_i} (\sum_{t \in rel_j} P(w|t) \frac{\#(t, rel_j)}{|rel_j|}) \quad (6)$$

$$P'_{trans}(org_i|rel_j) = 10 / -\log_2 P_{trans}(org_i|rel_j) \quad (7)$$

where P<sub>cos</sub>(org<sub>i</sub>, rel<sub>j</sub>) denotes the cosine similarity. P<sub>trans</sub>(org<sub>i</sub>|rel<sub>j</sub>) denotes the translation probabilities. The two parts are not in an order of magnitude. So when we obtained the two similarity scores, the translation probabilities have to be transformed according to the formula (7).

## 3 Translation Probabilities Estimation

### 3.1 Parallel Corpus Collection

The performance of the proposed ranking model heavily depends on the quality of the translation probabilities. Therefore, besides designing translation based ranking method, another important problem is how to learn good word-to-word translation probabilities.

In the given training dataset, the similarity relationship between the related question and original question can be accessed from the attribute "RELQ\_RELEVANCE2ORGQ" belonging to the tag "RelQuestion", which can be PerfectMatch, Relevant and Irrelevant. When the attribute value takes PerfectMatch or Relevant, there's a strong possibility that the original question and relevant question express similar meanings with different words. So, it is natural to use the matching original-relevant question pairs as the "parallel corpus" to estimate word-to-word translation probabilities. Furthermore, it is easy to realize that if one original question is similar with two different relevant questions simultaneously, then the two relevant questions would also express similar meanings. As an example, from the initial parallel corpus {[org<sub>1</sub>, rel<sub>1</sub>], [org<sub>1</sub>, rel<sub>2</sub>], [org<sub>1</sub>, rel<sub>3</sub>], [org<sub>2</sub>, rel<sub>4</sub>], [org<sub>2</sub>, rel<sub>5</sub>]}, we can obtain the new big parallel corpus {[org<sub>1</sub>, rel<sub>1</sub>], [org<sub>1</sub>, rel<sub>2</sub>], [org<sub>1</sub>, rel<sub>3</sub>], [rel<sub>1</sub>, rel<sub>2</sub>], [rel<sub>1</sub>, rel<sub>3</sub>], [rel<sub>2</sub>, rel<sub>3</sub>], [org<sub>2</sub>,

$[\text{rel}_4], [\text{org}_2, \text{rel}_5], [\text{rel}_4, \text{rel}_5]$ } through the simple extension method.

In the IBM translation model 1, sentences are normally translated from one language into another language. But in our task, the similar sentence pairs are written in the same language, the correspondence of words is not as strong as in the bilingual sentence pair. The word-to-word translation probabilities can be learned with either part as the source language and the other part as the target. Accordingly, the training data is doubled. When there is a parallel corpus consisting of the similar sentence pairs, the training module will utilize IBM translation model 1 incorporating an EM-based algorithm to learn the word-to-word translation probabilities.

### 3.2 Consolidation Method

The parallel sentence pairs are written in the same language. If source sentences contain word “ $w_i$ ” and target sentences contain word “ $w_j$ ”, we can obtain the word-to-word translation probabilities  $P(w_j|w_i)$ . Conversely, the word “ $w_i$ ” can also appear in target sentences and the word “ $w_j$ ” appear in source sentences. So, we can obtain the reverse translation probabilities  $P(w_i|w_j)$  through the same training process. Then we assume that the reverse translation probabilities are additional information to improve the word-to-word translation probabilities, and the combination of both will be consolidation beneficial. So we linearly combine the trained word-to-word translation probabilities:

$$P_{lin}(w_i|w_j) = \gamma P(w_i|w_j) + (1 - \gamma)P(w_j|w_i) \quad (8)$$

To see how much the consolidation strategy benefits the rerank task, we introduce two baseline methods for comparison. The first method denotes the initial word-to-word translation probabilities, and the second denote the reverse translation probabilities. Table 1 reports the experimental results of Subtask B on the development dataset. We can see that the consolidation strategy outperforms the two baseline methods in our task. From the experimental result, we can see that the reverse translation probabilities do have some positive effects.

| Model                                      | Trans Prob         | MAP    |
|--|--------------------|--------|
| $\text{Score}(\text{org}_i, \text{rel}_j)$ | $P(w_j w_i)$       | 0.7312 |
|  | $P(w_i w_j)$       | 0.7376 |
|  | $P_{lin}(w_i w_j)$ | 0.7415 |

Table 1: The impact of consolidation strategy.

## 4 System overview

In the following part, we will introduce the details of the implementation. The whole calculation process can be divided into two main modules: Pre-processing and Estimate.

**Pre-processing.** This module tries to extract the subject text and the main body of questions from the XML-formatted input file first of all, then combine the two parts together to form the original question and related question. Next, the system makes word segmentation for each pairs of original question and related question, and removes stop words at the same time. Furthermore, Porter stemmer is employed to extract stem, which will be beneficial to learn good word-to-word translation probabilities. For the sake of saving the evaluation times, we execute statistical calculations on the word list which represents the original question and related question after segmentation. For example, there is a words list [massage, oil, where, buy, good, oil, massage], we'll obtain a dictionary {massage:2, oil:2, where:1, buy:1, good:1} after statistics, and we also know that the length of list is seven.

**Estimate:** In this stage, the system loads the word-to-word translation probability table, which we select defaultdict<sup>1</sup> as its storage structure. Finally, we compute the similarity score of original question and related question according to our ranking model which linearly combines the cosine similarity and translation model. In subtask B, the labels Perfect-Match and Relevant should be regarded as equal, so our goal is to rank the PerfectMatch and Relevant candidates at the top, in any order, and the Irrelevant candidates at the bottom, also in any order.

## 5 Experiments

In this section, experiments are conducted on DEV

<sup>1</sup> Defaultdict is a subclass of the dict that calls a factory function to supply missing values in Python.

dataset to demonstrate the performance of our proposed ranking model.

### 5.1 Data Set and Evaluation Metrics

The official dataset contains TRAIN, DEV and TEST. The development dataset is intended to be used as a development-time evaluation dataset as we develop our systems. However, when submitting prediction results, we will add the development dataset to training data as well. The total available data of the TRAIN part is made up of 267 original questions and 2669 related questions for Subtask B, plus 26690 related comments for Subtask C. DEV dataset which were manually double-checked and are very reliable consist of 50 original questions, 500 related questions, and 5,000 comments. As far as the TEST is concerned, the task organizers provide participants with 70 original questions, so, there would be 700 predictions for subtask B and 7,000 predictions for subtask C. The official scorer will provide a number of evaluation measures to assess the quality of the output of a system, but the official evaluation measure towards which all systems will be evaluated and ranked is Mean Average Precision (MAP).

### 5.2 Results

Five types of baselines are used to compare with our proposed ranking model. Table 2 presents the MAP performance comparison of different methods on DEV dataset in subtask B. Row 1 to row 5 are the IR engine default ordering, Language Model, Cosine Similarity-based method, Translation Model and Translation-based Language model. Row 5 is our proposed translation-based reranking method. Compared with other baselines approaches, our proposed model received good results. Finally, the competition result for our primary submissions are 0.7511 against 0.7475 baseline in Subtask B, and 0.4919 against 0.4036 baseline in Subtask C.

## 6 Conclusions and Future Work

In this paper, we propose a ranking model that combines a translation model with the cosine-based similarity method to solve the rerank task in CQA. Experiments on test data demonstrate the effectiveness of our method.

There are some ways in which this research could be continued. First, we plan to apply neural machine

| # | Methods      | MAP    |
|---|--------------|--------|
| 1 | IR-engine    | 0.7135 |
| 2 | LM           | 0.7248 |
| 3 | Cosine       | 0.7287 |
| 4 | Trans        | 0.7342 |
| 5 | Trans-LM     | 0.7360 |
| 6 | Trans-Cosine | 0.7415 |

**Table 2:** Comparison of different methods in subtask B.

translation (Bahdanau et al., 2014) to learn good translation probabilities. In addition, phrase-based translation model for question retrieval (Zhou et al., 2011) have shown superior performance compared to word-based translation models. So it is necessary to try this method to further improve the performance.

## Abstract

This paper presents an approach for estimating the question-question similarity of an English dataset specified in Shared Task 3, subtask B of SemEval-2016. Given a new question and a set of the first 10 related questions retrieved by a search engine, participants are asked to produce a binary relevant/irrelevant judgement and rerank the related questions according to their similarity with respect to the original question. Our submitted system uses a 2-layer feed-forward neural network with the averages of word embedding vectors to predict the semantic similarity score of two questions. We also evaluate the results of Random Forests and Support Vector Machine in comparison to the Neural Network. Results on the test dataset show that the model achieves a Mean Average Precision 69.681.

## 1 Introduction

Finding semantically related questions is a difficult task due to two main factors: (1) paraphrasing, which can appear at different levels, e.g., lexical, phrasal, sentential (Madnani and Dorr, 2010); and (2) two questions could be asking different things but look for the same solution. Thus, traditional surface similarity measures such as Edit Distance, Jaccard, Dice and Overlap coefficient and their variations are not able to capture many cases of semantic relatedness. To preserve the semantic meaning of a question, we use weighted average word embedding vectors to model questions. We evaluate several algorithms that take the weighted average word

embedding vectors of two questions as inputs and predict whether two questions are related or not.

To provide a benchmark so as to compare and develop question-question similarity measuring models in Community Question Answering forums, the Question-Question Similarity task in SemEval-2016 Task 3, Subtask B (Nakov et al., 2016) requires the participants to determine whether two questions are semantically related and given a new question, rerank all similar questions retrieved by a search engine. **Table 1** presents an example of a pair of semantically related questions.

We perform an extensive number of experiments using data from Shared Task 3 and compare three types of classifiers: Neural Network (NN), Support Vector Machine (SVM) and Random Forests (RF), as well as the impact of different weighting schemes for averaging word embedding vectors and different word embedding dimensions. The results show that 2-layer Feedforward Neural Network with Idf weighting scheme and in-domain word embeddings outperforms the rest of models.

**Title:** Best Bank

**Body:** Which is a good bank as per your experience in Doha

**Title:** Good Bank

**Body:** Hi Guys; I need to open a new bank account. Which is the best bank in Qatar ? I assume all of them will roughly be the same; but still which has a slight edge (Money transfer; benefits etc) Thanks !!!

**Table 1:** An example of semantically related questions

## 2 Word Embedding Features

Recently (Mikolov et al., 2013) introduced word2vec, a novel word-embedding procedure. Their model is able to learn continuous vector representations of words from a very large dataset by using a feedforward Neural Net Language Model (NNLM). Specifically, The CBOW architecture predicts the current word based on the context, and the Skip-gram architecture predicts surrounding words given the current word. Learning the word embedding is entirely unsupervised and it can be computed on the text corpus of interest.

Each word is encoded by a column vector in an embedding matrix  $W_e \in \mathbb{R}^{d \times |V|}$  learnt by using word2vec, where  $V$  is a fixed-sized vocabulary. Each column of the matrix represents the word embedding vector of the  $i$ -th word in  $V$ . Each word  $w$  is transformed into its vector representations  $v_w$  by using a matrix-vector product:

$$v_w = W_e b_w \quad (1)$$

where  $b_w$  is a one-hot encoding vector of size  $|V|$  which has value 1 at the index of the word  $w$  and zero in all other positions. Let  $X_t$  and  $X_b$  be the set of word tokens of a question’s title and body, then the vector representations of the question’s title and body are the weighted vector average of the word embeddings associated with tokens in  $X_t$  and  $X_b$ :

$$Q_t = \frac{1}{|X_t|} \sum_{w \in X_t} v_w c_w \quad (2)$$

$$Q_b = \frac{1}{|X_b|} \sum_{w \in X_b} v_w c_w \quad (3)$$

where  $c_w$  denotes the weight of the word  $w$ . We also investigate the impact of different weighting schemes:

1.  $c_w = 1$
2.  $c_w = IDF(w)$  where  $IDF$  denotes inverse document frequency (Sparck Jones, 1972). Specifically,

$$IDF(w) = \log\left(1 + \frac{N}{n_w + 1}\right) \quad (4)$$

$N$  is the total number of documents in the corpus and  $n_w$  is the number of documents where the term  $w$  appears. In our case, we define each question’s body in the training dataset as a document.

Given a pair of questions  $(Q^{(1)}, Q^{(2)})$ , we compute  $Q_t^{(1)}, Q_b^{(1)}, Q_t^{(2)}$  and  $Q_b^{(2)}$  by using the above transformations. Given vectors  $u$  and  $v$ , we denote the similarity features  $sim_{(u,v)}$  as the concatenation of  $u \cdot v$  (component-wise product of  $u$  and  $v$ ) and  $|u - v|$ . These two features were also used by (Tai et al., 2015). The final vector representations or features for the input pair of questions  $(Q^{(1)}, Q^{(2)})$  is defined as the concatenation of  $sim_{(Q_t^{(1)}, Q_t^{(2)})}$  and  $sim_{(Q_b^{(1)}, Q_b^{(2)})}$ . Those features are then fed into a classifier to predict a binary True/False label.

## 3 Experiments and Results

### 3.1 Datasets

In our experiments we use data from the community-created Qatar Living Forums<sup>1</sup> collected for SemEval-2016 task 3, subtask B. There are 317 original questions and 3,169 related questions. The dataset is pre-split into 264 original questions and 2669 related question for training, as well as 50 original questions and 500 related question for validation. Each data point is a pair of questions (an original question and a related question) and a similarity label, which is either “PerfectMatch”, “Relevant” or “Irrelevant”. According to the task description, we need to predict a binary label where “True” covers “PerfectMatch” and “Relevant”, and “False” covers “Irrelevant”, and rerank a set of related questions according to their similarity with respect to the original question.

### 3.2 Preprocessing

Several text preprocessing operations are performed before we extract features. We first transform all words into lowercase, filter out stop words, remove all punctuations and replace numbers with the token “NUMBER”. Then the Phrase Detection Toolkit implemented in Gensim is used to group tokens together if they form a phrase. After that, all unique words and phrases are selected from the training set as our vocabulary which has a size of 11990. We deal with unseen words in the test set by marking them as “UNK”.

**Table 2:** Description of models

### 3.3 Word Embedding Features

We perform pre-training using the skip-gram NN architecture (Mikolov et al., 2013) available in the Gensim Word2vec tool<sup>2</sup>. We use in-domain word embeddings vectors trained on the Community Question Answering dataset provided by SemEval-2016 Task 3 with the following parameter settings: (1) 30, 80 and 100 dimensional embedding vectors; (2) the maximum distance between the current and predicted word within a sentence is set to 5; (3) ignoring all words with total frequency lower than 5; (4) for each positive sample, 5 negative samples are drawn for negative sampling; (5) the number of iterations is set to 30.

### 3.4 Models

Several classification algorithms are explored on development dataset including Feedforward Neural Network (NN), Support Vector Machine (SVM) and Random Forests (RF). Due to the lack of the time, we only submitted the predictions from one of our NN classifiers. Configuration details of each model are presented in **Table 2**.

#### 3.4.1 Feedforward Neural Network

We consider a two-layer Feedforward Neural Network with 64 sigmoid activation hidden units as our classifier. Weights are initialized with random orthogonal conditions (Saxe et al., 2013). We apply Dropout (Srivastava et al., 2014) with a fixed dropping probability of 0.9 for the input layer and 0.5 for the hidden layer. Our network is trained by minimizing the categorical cross entropy error over the training set using Adam (Kingma and Ba, 2014), a first-order gradient-based optimization method. We use the backpropagation algorithm (Rumelhart et al.,

1988) to compute gradients of the network. In our experiments, we implement the NN and the back-propagation algorithm using Keras<sup>3</sup>.

#### 3.4.2 Support Vector Machine

We use the (Gaussian) radial basis function kernel

$$K(x, x') = \exp(-\gamma|x - x'|^2) \quad (5)$$

with  $\gamma = \frac{1}{4d}$ , where  $d$  is the dimension of word embedding vectors. We set the regularization parameter  $C$  of soft margin cost function to 1.

#### 3.4.3 Random Forests

We explored a large set of parameter values by doing randomized search and selecting only the best set of parameters for our RF models. Specifically, we use the following fine-tuned parameters:

- The number of trees: 382
- Measurement of the quality of a split: entropy
- The maximum depth of the tree: 33
- The minimum number of samples required to split an internal node: 5
- The minimum number of samples in newly created leaves: 2
- The number of features to consider when looking for the best split: 116

### 3.5 Results and Discussion

**Table 3** summarizes the performance of our systems, along with the baseline systems provided by the organizers and the top three systems (UH-PRHLT-primary, ConvKN-primary and Kelp-primary). The results show that models with Idf weighting scheme outperform models using naive word embedding averages. The performance differences between different models using the same weighting scheme and the same word embedding

**Table 3:** Performance of our top 6 systems and baseline systems on test dataset, as well as top ranking systems. The second column shows the rank of the primary runs with respect to the official MAP score. NN-Avg-30 is the model we used for the official submission. MAP and MRR stand for Mean Average Precision and Mean Reciprocal Rank, respectively.

dimension are not significant, which shows that the type of the classifier is not the bottleneck of overall performance. Also, we find that RF and NN perform slightly better than SVM. We also observe that using a large word embedding dimension ( $\geq 80$ ) results in severe overfitting on the development dataset since we have a small dataset. Applying strong regularization such as Dropout with high dropping probability reduces overfitting and helps our NN models achieve high performance. Our best classifier (NN-Idf-100) achieves the highest Mean Average Precision among our classifiers.

## 4 Conclusion

In this paper, we address the Question-Question Similarity task by building three types of supervised classifiers. The results show that classifiers without heavy feature engineering are able to outperform the random baseline by a large margin. It also demonstrates that using the proposed features based on word embeddings is effective and able to capture semantic meanings of a question.

# QU-IR at SemEval 2016 Task 3: Learning to Rank on Arabic Community Question Answering Forums with Word Embedding

Rana Malhas and Marwan Torki and Tamer Elsayed

Qatar University

Department of Computer Science & Engineering

Doha, Qatar

{rana.malhas, mtorki, telsayed}@qu.edu.qa

## Abstract

Resorting to community question answering (CQA) websites for finding answers has gained momentum in the past decade with the explosive rate at which social media has been proliferating. With many questions left unanswered on those websites, automatic and smart question answering systems have seen light. One of the main objectives of such systems is to harness the plethora of existing answered questions; hence transforming the problem to finding good answers to newly posed questions from similar previously-answered ones. As SemEval 2016 Task 3 “Community Question Answering” has focused on this problem, we have participated in the Arabic Subtask. Our system has adopted a supervised learning approach in which a learning-to-rank model is trained over data (questions and answers) extracted from Arabic CQA forums using word2vec features generated from that data. Our primary submission achieved a 29.7% improvement over the MAP score of the baseline. Post submission experiments were further conducted to integrate variations of the word2vec features to our system. Integrating covariance word embedding features has raised the the improvement over the baseline to 37.9%.

## 1 Introduction

The ubiquitous presence of community question answering (CQA) websites has motivated research in the direction of building automatic question answering (QA) systems that can benefit from previously-answered questions to answer newly-posed ones (Shtok et al., 2012). A core functionality

of such systems is their ability to effectively rank previously-suggested answers with respect to their degree/probability of relevance to a posted question. The ranking functionality is vital to push away irrelevant and low quality answers, which is commonplace in CQA as they are generally open with no restrictions on who can post or answer questions.

Figure 1: A question and 4 of its given 30 candidate QApairs

To this effect, SemEval 2016 Task 3 “Community Question Answering” has emphasized the ranking component in the main task of the challenge. We have participated in Task 3-Subtask D (Arabic Subtask) which is confined to the main task of ranking answers; given a new question and a set of 30 question-answer pairs (QApairs) retrieved by a

search engine, re-rank those QApairs by their degree/probability of relevance to the new question. Figure 1 shows an example of a question and four of its 30 given candidate question-answer pairs.

The Arabic training, development and test datasets provided by the organizers were extracted from Arabic medical forums (webteb<sup>1</sup>, altibbi<sup>2</sup>), and “Consult Islamweb”<sup>3</sup>. Further details about SemEval 2016 Task 3 can be found in (Nakov et al., 2016).

In this paper, we describe the system we developed to participate in SemEval-2016 Task 3 (Arabic Subtask). The system has leveraged a supervised learning approach over word2vec features extracted from a collection of questions and their candidate question-answer pairs to build a ranking model. The functionality of the developed system is confined to the answers re-ranking task described by SemEval 2016 Task 3. With the MAP (Mean Average Precision) being the official measure for evaluation, our efforts were mainly focused on optimizing this measure. Our developed system has achieved a MAP score improvement of 29.7% over the baseline via our primary submission, and an improvement of 37.9% via our post-submission enhancements and experiments.

The rest of the paper is organized as follows; the approach and the generated features are introduced in section 2; the experimental evaluation and setup followed by our submissions to the Arabic Subtask and their results are presented in section 3. Enhancements and further experiments conducted are also presented in section 3 before concluding with final remarks.

## 2 Approach

We tackled the answer ranking task with a supervised learning approach that leveraged learning-to-rank models. The features used in training are mainly semantic, where vectorized word embedding representations were used as features in different alternatives, as explained below. An overview of our system is depicted in Figure 2. Details regarding the specific models and features used in our primary and

contrastive submissions are presented in section 3.

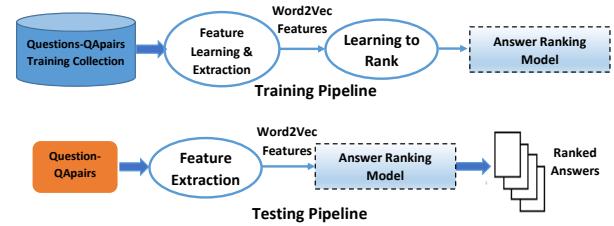

Figure 2: System overview

### 2.1 Data Setup

We are given a set of questions  $Q$ ; each is associated with  $P$  question-answer pairs. To compute our features, we define a document according to three setups:

- **QQA:** We consider the concatenation of an original question  $q$  and one **pair**  $p$  of its associated question-answer pairs as a document  $d$ .
- **QA:** We consider the concatenation of an original question  $q$  and one **answer** of its associated question-answer pairs as a document  $d$ .
- **QQ:** We consider the concatenation of an original question  $q$  and one **question** of its associated question-answer pairs as a document  $d$ .

We have extracted features for the above data setups seeking those with the most discriminating power against our ranking problem; this is further elaborated in section 3.

### 2.2 Features

Every document  $d_n \in D$ , where  $n \in \{1, \dots, N\}$ , has a set of words. Each word has a fixed-length word embedding representation,  $w \in \mathbb{R}^{Dim}$ , where  $Dim$  is the dimensionality of the word embedding. Thus for every document  $d_n$  in the set  $D$ , we define  $d_n = \{w_1, \dots, w_{k_n}\}$ , where  $k_n$  is the number of words in the document  $d_n$ . The word embedding representation is computed offline following Mikolov et al approach (Mikolov et al., 2013).

To enable learning, we represent each document by a feature vector; different alternatives for feature representations are adopted as described next.

<sup>1</sup><https://www.webteb.com/>

<sup>2</sup><http://www.altibbi.com/>

<sup>3</sup><http://consult.islamweb.net/mainpage/index.php>

### 2.2.1 Average Word Embedding

For a document that has  $k_n$  words, we compute the average vector as follows:

$$\mu_n = \frac{\sum_{i=1}^{k_n} (w_i)}{k_n} \quad (1)$$

Notice that  $\mu_n \in \mathbb{R}^{Dim}$ . For our primary and contrastive submissions, we only used the average vector  $\mu_n$  to represent its respective document.

### 2.2.2 Covariance Word Embedding

Instead of computing the average vector, we can compute a covariance matrix  $C \in \mathbb{R}^{Dim \times Dim}$ . The covariance matrix  $C$  is computed by treating each dimension as a random variable and every entry in  $C_{n_{u,v}}$  is the covariance between the pair of variables  $(u, v)$ . The covariance between two random variables  $u$  and  $v$  is computed as in eq. 2, where  $k_n$  is the number of observations (words).

$$C_{n_{u,v}} = \frac{\sum_{i=1}^{k_n} (u_i - \bar{u})(v_i - \bar{v})}{k_n - 1} \quad (2)$$

The matrix  $C_n \in \mathbb{R}^{Dim \times Dim}$  is a symmetric matrix. We compute a vectorized representation of the matrix  $C_n$  as the stacking of the lower triangular part of matrix  $C_n$  as in eq. 3. This process produces a vector  $v_n \in \mathbb{R}^{Dim \times (Dim+1)/2}$

$$\text{vect}(C_n) = \{C_{n_{u,v}} : u \in \{1, \dots, Dim\}, v \in \{u, \dots, Dim\}\} \quad (3)$$

In our post submission experiments we used the covariance descriptors  $v_n$  in comparison to the basic  $\mu_n$  average vectors.

### 2.2.3 Unigrams and tf-idf weighting

In our post submission experiments, we also used the standard unigram representation with tf-idf weighting. We have chosen the most frequent 5000 unigrams from the training data to represent every document as a sparse vector of 5000 dimensions.

## 2.3 Ranking Models

A learning-to-rank (L2Rank) setup was adopted that is similar to (Chen et al., 2015; Surdeanu et al., 2008). The L2Rank models were trained over the labeled Arabic data provided by the SemEval 2016 Task 3 organizers. The data constituted 1,031 original questions and their potentially related 30,411

question-answer pairs (QApairs); i.e. about 30 QApairs per original question. Each QApair is labeled by either being *Direct*, *Relevant* or *Irrelevant* with respect to the original question; the distribution of these labels are 3.0%, 57.0% and 40.0%, respectively (Nakov et al., 2015).

Two algorithms were used to train our learning-to-rank models, namely the MART (Multiple Additive Regression Trees, a.k.a. Gradient boosted regression tree) algorithm and the Random Forests algorithm.

## 3 Experimental Evaluation

In this section we present the experimental setup and results of our primary, contrastive-1 and contrastive-2 submissions, in addition to our post-submission experiments.

### 3.1 Experimental Setup

We have used the Arabic collection of questions and their potentially related question-answer pairs provided by Task3 organizers for training our models. We evaluated those models using the development dataset of 7,355 question-QApairs instead of the full provided dataset of 7,385 question-QApairs; one question (out of the 250) and its potentially related 30 QApairs were not properly formed and thus excluded. Another data preprocessing step was to parse and transform the XML files into flat files for easier data processing/tracking of question-answers.

The Gensim<sup>4</sup> tool was used to generate the word2vec model from training data<sup>5</sup>. We used the learned model to compute our features as described in section 2.2. Features were generated for the three data setups described in section 2.1.

RankLib<sup>6</sup> was used to create and evaluate our learning-to-rank models. Although we have experimented with a number of pairwise and listwise learning-to-rank algorithms, we adopted pointwise L2Rank algorithms in our submissions as they exhibited a relatively better performance than the other two categories.

<sup>4</sup><http://radimrehurek.com/gensim/>

<sup>5</sup>Testing data are held out during the computation of the word2vec model.

<sup>6</sup><http://sourceforge.net/p/lemur/wiki/RankLib/>

### 3.2 Evaluation Measures

Since MAP (Mean Average Precision) is the official evaluation measure to evaluate Task 3-Subtask D submissions, we focused our experiments and evaluations to optimize this measure. Time constraints have withheld us from optimizing the other evaluation measures that are also adopted by the task’s official scorer, such as F1 measure, accuracy, etc.

### 3.3 Submissions and Results

Table 1 below summarizes the official results of our submissions which are discussed in the context of the following sub-sections.

#### 3.3.1 Primary and Contrastive Submissions

The average word embedding features were used in all three submissions. We used  $Dim = 100$  for the word2vec model we learned from training data. The differences among submissions lie in the data setup (QQA, QA or QQ) used in generating the features; and the algorithm deployed in training the L2Rank model that ranks the answers.

| Submission    | MAP   |
|---------------|-------|
| Primary       | 38.63 |
| Contrastive-1 | 37.80 |
| Contrastive-2 | 39.07 |
| Baseline      | 29.79 |

**Table 1:** The official MAP scores attained by our primary and contrastive submissions to SemEval 2016 Task 3-SubTask D

**Primary submission.** The QQA data setup was used in generating the average word embedding features; and the MART algorithm (Multiple Additive Regression Trees, a.k.a. Gradient boosted regression tree) was used to train the L2Rank model. This submission has attained a MAP score of 38.63 which placed it in the fourth position among the other primary submissions of other participating teams. It achieved a 29.7% improvement over the baseline (29.79).

**Contrastive-1 submission.** The QA data setup was used in generating the features; and the Random Forests algorithm was deployed in training the L2Rank model. This submission has attained a MAP score of 37.80 which is lower than our other two submissions (Table 1). This suggests that using

the QA data setup in feature generation (i.e. using the original question and **answers** of the QApairs while leaving out the questions of the QApairs), is not as good as using the QQA data setup (i.e. using the original questions and their **QApairs**). Further experiments might be needed to assert this finding.

**Contrastive-2 submission.** The QQA data setup was used in generating the features, and again the Random Forests algorithm was deployed in training the L2Rank model. Another difference in the setup of this submission was using 20% of the training data in validating the trained model while using the remaining 80% for training. This submission has performed better than our primary and contrastive-1 submissions; it attained a MAP score of 39.07 and an improvement of 31.3% over the baseline.

It is worth noting that feature values in the primary and contrastive-1 submissions were normalized using zscore and sum, respectively. In the primary submission, each feature was normalized by its *mean/standard deviation*, while in the contrastive-1 submission, each feature was normalized by the *sum* of all its values.

Although Subtask D at the surface is a re-ranking task, it has also embedded a classification task where answers need to be ranked and labeled with either *true* or *false*; the former designates a *Direct* or *Relevant* answer, and the latter designates an *Irrelevant* answer. In all submissions, we have adopted a simple heuristic of labeling the top 10 ranked answers with the label *true*, and the remaining answers with *false* otherwise. Alternatively, a supervised classifier can be used to predict the answer labels, or find a good cutoff threshold point (such as the average or median of answers rank scores) to label those exceeding that threshold with *true*, and *false* otherwise.

#### 3.3.2 Post-Submission Experiments

Further experiments were conducted to explore the performance of Covariance Word Embedding (CovWE) and unigram features as compared to the Average Word Embedding (AvgWE) features. In Table 2, we report the MAP scores achieved by these features using a dimensionality of 50 and 100, respectively, for representing the vectors of word embeddings. In our post-submission experiments, we only extracted features using the QQA data setup.

As such, we only include the results of our primary and contrastive-2 submissions in Table 2 because their features were also extracted using the QQA data setup, unlike the contrastive-1 submission.

| Experiment/Features       | Normalization | MAP          |
|---------------------------|---------------|--------------|
| AvgWE-50                  | -             | 36.01        |
| AvgWE-100 (primary)       | Zscore        | 38.63        |
| AvgWE-100 (contrastive-2) | -             | 39.07        |
| AvgWE-100 and Unigrams    | -             | 37.71        |
| CovWE-50                  | Linear        | <b>41.07</b> |
| CovWE-100                 | Linear        | <b>40.68</b> |
| CovWE-100 and Unigrams    | -             | 37.51        |
| Baseline                  | -             | 29.79        |

**Table 2:** Post-submission experiments comparing the performance of Covariance Word Embedding (CovWE) features and Unigrams to that of Average Word Embedding (AvgWE) features. The suffix numbers 50 and 100 designate the dimensionality of the vectors representing the word embeddings. Best scoring features are boldfaced.

In most of the experiments reported in Table 2, the MART algorithm was used for training the L2Rank models; whereas, for the AvgWE-100 and Unigrams experiment, the Random Forests algorithm was used. In general, the MART algorithm performed better in the majority of our experiments that we have conducted but have not reported. The main observations worth mentioning regarding the experiments in Table 2 are:

- Using tf.idf weighted uni-grams of the most frequent 5000 words along with word2vec features (AvgWE and CovWE) did not mark an improvement over using word2vec features solely.
- Normalization of feature values seem to have a tendency of enhancing the achieved MAP scores when applied. For this reason, we include in Table 2 the normalization scheme (if any) that was adopted in each experiment.
- The discriminant potential of the covariance word embedding features seem to be relatively stronger than that of average word embedding features. For example, the features CovWE-50 and CovWE-100 have achieved relatively higher MAP scores than AvgWE-50 and

AvgWE-100, respectively. With their 41.07 and 40.68 MAP scores, CovWE features have achieved an improvement of about 37.9% over the baseline. AvgWE-100 and AvgWE-50 followed with the MAP scores of 38.63 (primary submission score) and 36.01, respectively; hence, attaining lower improvements (29.7% and 20.9%) over the baseline.

- The covariance word embedding features CovWE-50 and CovWE-100 have attained comparable MAP scores of 41.07 and 40.68, respectively. Interestingly, the CovWE-50 experiment consumed 44.5 minutes to learn the L2Rank model, while the CovWE-100 experiment consumed 5.27 hours. This finding is also suggesting that covariance word embedding features seem to have a relatively higher discriminating potential even with lower dimensions.

More rigorous benchmarking experiments might be needed to further verify the merit of the above implications.

## 4 Conclusion

This paper describes the system we have developed to participate in SemEval-2016 Task 3 on Community Question Answering. Our system has focused on the Arabic Subtask which is confined to Answer Selection in Community Question Answering, i.e. finding good answers for a given new question. The training data provided by the organizers were extracted from Arabic medical forums (*webteb* and *al-tibbi*) and *consult islamweb*.

We have adopted a supervised learning approach where learning-to-rank models were trained over word2vec features generated from the training data. In our primary submission, average word embedding features were used; our system ranked fourth among the other participating teams. It achieved a 29.7% improvement over the baseline. Post-submission experiments were further conducted to enhance the system and integrate covariance word embedding features. The enhanced system marked an improvement of 37.9% over the baseline.

Our experiments have provided preliminary evidence regarding the discriminant potential of the

covariance word embedding features over the average word embedding features; the former type of word2vec features enabled the learned model to attain a relatively better MAP score.

Furthermore, the highly comparable MAP scores attained by the covariance word embedding features for 50 and 100 dimensions (Table 2) suggest another interesting finding: the covariance word embedding features seem to have a relatively higher discriminating potential even with lower dimensions.

In future work, we intend to integrate more semantic features extracted from richer and larger semantic Arabic resources.

## Abstract

This paper describes the system we submitted to the task 3 (Community Question Answering) in SemEval 2016, which contains three subtasks, i.e., Question-Comment Similarity (subtask A), Question-Question Similarity (subtask B), and Question-External Comment Similarity (subtask C). For subtask A, we employed three different methods to rank question-comment pair, i.e., supervised model using traditional features, Convolutional Neural Network and Long-Short Term Memory Network. For subtask B, we proposed two novel methods to improve semantic similarity estimation between question-question pair by integrating the rank information of question-comment pair. For subtask C, we implemented a two-step strategy to select out the similar questions and filter the unrelated comments with respect to the original question.

## 1 Introduction

The purpose of Community Question Answering task in SemEval 2016 (Nakov et al., 2016) is to provide a platform for finding good answers to new questions in a community-created discussion forum, where the main task (subtask C) is defined as follows: given a new question and a large collection of question-comment threads created by a user community, participants are required to rank the comments that are most useful for answering the new question. Obviously, this main task consists of two optional subtasks, i.e., Question-Comment Similarity (subtask A, also known as *answer ranking*), which is to re-rank comments/answers according to their

relevance with respect to the question, and Question-Question Similarity (i.e., subtask B, also known as *question retrieval*), which is to retrieve the similar questions according to their semantic similarity with respect to the original question.

To address subtask A, we explored a traditional machine learning method which uses multiple types of features, e.g., Word Match Features, Translation-based Features, and Lexical Semantic Similarity Features. Additionally, for subtask A, we also built a Convolutional Neural Network (CNN) model and a bidirectional Long Short-Term Memory (BLSTM) model to learn joint representation for question-comment (*Q-C*) pair. For subtask B, besides IR method and traditional machine learning method, we also proposed two novel methods to improve semantic similarity estimation between question-question (*Q-Q*) pairs by integrating the rank information of *Q-C* pairs. Since subtask C can be regarded as a joint work of the two above-mentioned subtasks, we implemented a two-step strategy to first select out similar questions and then to filter out the unrelated comments with respect to the original question.

The rest of this paper is organized as follows. Section 2 describes our system. Section 3 describes experimental setting. Section 4 and 5 report results on training and test sets. Finally, Section 6 concludes this work.

## 2 System Description

For subtask A, we presented three different methods i.e., using traditional linguistic features, learning a CNN model and a bidirectional LSTM model to represent question and comment sentences. For sub-

task B, besides traditional methods, we proposed two novel methods to improve semantic similarity estimation between  $Q$ - $Q$  pairs by integrating the rank information of  $Q$ - $C$  pairs. The first is to adopt general ranking evaluation metrics of  $Q_0$ - $C$  and  $Q_1$ - $C$  (i.e., Spearman, Pearson, and Kendall Coefficient) as additional ranking scores or features of  $Q_0$ - $Q_1$  where  $Q_0$  and  $Q_1$  represent original question and its related question, respectively. The second is to extract features on  $Q_0$ - $C$  and  $Q_1$ - $C$  and to regard the cosine values which are calculated on these two feature vectors as additional features for  $Q_0$ - $Q_1$ .

## 2.1 Features Engineering

All three subtasks can be regarded as an estimation task of sentence semantic measures which can be modeled by various types of features. In this work, we employed the following four types of features borrowed from previous work, i.e., Word Match Features, Translation Based Features, Topic Model Based Features, and Lexical Semantic Similarity Features. The details of these four types of features are described as follows. Note that the following four feature types are adopted in both  $Q$ - $Q$  and  $Q$ - $C$  pairs, here we took the  $Q$ - $Q$  pair for example.

**Word Matching Feature (WM):** This feature records the proportions of co-occurred words between a given sentence pair. Given a  $Q$ - $Q$  pair, this feature type is calculated using five measures:  $|Q_0 \cap Q_1|, |Q_0 \cup Q_1|/|Q_0|, |Q_0 \cap Q_1|/|Q_1|, |Q_1 - Q_0|/|Q_1|, |Q_0 - Q_1|/|Q_0|$ , where  $|Q_0|$  and  $|Q_1|$  denote the number of the words of  $Q_0$  and  $Q_1$ .

**Translation Based Feature (TB):** The above WM feature only considers the overlapped words between  $Q_0$  and  $Q_1$  and thus it may fail to “bridge the lexical gap” between  $Q$ - $Q$  pair. One possible solution is to regard this task as a statistic machine translation problem between question and answer by using the IBM Model 1(Brown et al., 1993) to learn the word-to-word probabilities. Following (Xue et al., 2008; Surdeanu et al., 2011), we regarded  $P(Q_0|Q_1)$ , i.e., the translation probability of  $Q_1$  when given  $Q_0$ , as a translation based feature. The probabilities are calculated as:

$$P(Q_0|Q_1) = \prod_{w \in Q_0} P(w|Q_1)$$

$$P(w|Q_1) = (1 - \lambda)P_{tr}(w|Q_1) + \lambda P_{ml}(w|C)$$

$$P_{ml}(w|Q_1) = \sum_{a \in Q_1} P(w|a)P_{ml}(a|Q_1)$$

where  $P(Q_0|Q_1)$  is the probability that the  $Q_0$  word  $w$  is generated from  $Q_1$ ,  $\lambda$  is a smoothing parameter,  $C$  is a background collection.  $P_{ml}(w|C)$  is computed by maximum likelihood estimator.  $P(w|a)$  denotes the translation probability from  $Q_1$  word  $a$  to  $Q_0$  word  $w$ . The GIZA++ Toolkit<sup>1</sup> is used to compute these probabilities.

**Topic Model Based Feature (TMB):** We used the LDA (Blei et al., 2003) model to transform  $Q_0$  and  $Q_1$  into topic-based vectors and then took the *cosine* value of two topic vectors as feature. We use the *GibbsLDA++* (Phan and Nguyen, 2007) Toolkit to train the topic model.

**Lexical Semantic Similarity Feature (LSS):** Inspired by (Yih et al., 2013), we included the lexical semantic similarity features in our model. We used three different word vectors to represent LSS feature, i.e., the 300-dimensional version of word2vec (Mikolov et al., 2013) vectors, 300-dimensional Glove vectors (Pennington et al., 2014) and 300-dimensional vectors which are pre-trained with the unsupervised neural language model (Mikolov et al., 2013) on the Qatar Living data<sup>2</sup>. Words not present in the set of pre-trained words are initialized randomly. There are two ways to calculate the LSS features. One is to calculate the cosine similarity by summing up all word vectors in  $Q_0$  and  $Q_1$ . Another is to adopt averaged pairwise cosine similarity between each word in  $Q_0$  and  $Q_1$ .

Besides above four types of features, for  $Q$ - $Q$  pair, we also extracted following two question information features (**QI**) to describe the informativeness of related question  $Q_1$ : (1) the number of words in  $Q_1$  (2) the position of  $Q_1$  in all related questions. For  $Q$ - $C$  pair, we also extracted following two comment information features (**CI**) to measure the informativeness of a comment text: (1) the number of words in comment (2) the number of nouns, verbs and adjectives in comment.

## 2.2 Two Methods to address subtask A

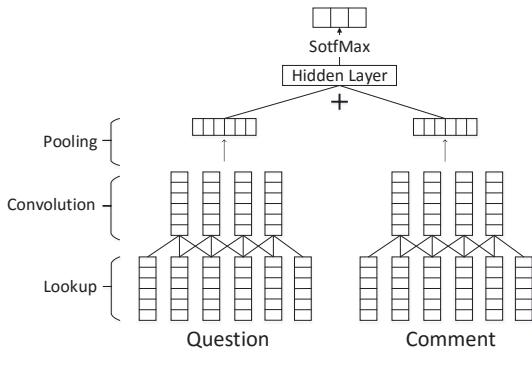

### 2.2.1 Method 1: CNN

We proposed a convolutional neural network to model question-comment sentence. As illustrated in

<sup>1</sup><http://www.statmt.org/moses/giza/GIZA++.html>

<sup>2</sup><http://alt.qcri.org/semeval2015/task3/index.php?id=data-and-tools>

Figure 1, we first input word embeddings (here we used 300-dimensional Glove vectors in (Pennington et al., 2014)) of question and comment words and then learn the meaning (i.e., feature vector) of question and comment through convolution and pooling operation. After a simple concatenation layer connecting question and comment vectors, we final obtain a relevant score through a softmax operation.

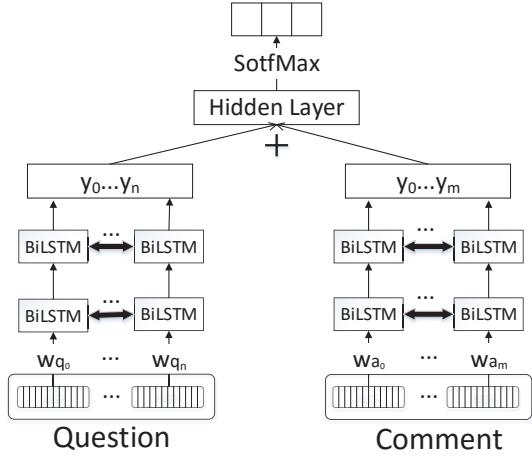

**Figure 1:** An illustration of CNN for question-comment similarity estimation.

## 2.2.2 Method 2: BLSTM

Figure 2 shows a multiple-layer BLSTM network model we used for question and comment sentences modeling. The procedure of BLSTM is similar to that of CNN. The words of question and comment sentences are first converted into vectors by looking up publicly available 300-dimensional Glove vectors. Then they are sequentially read by BLSTM from both directions. In this way, the contextual information across words in both question and comment sentences is modeled by employing temporal recurrence in BLSTM. Like CNN, finally it outputs a relevant score between question and comment by a simple concatenation operation on these two output vectors and a softmax operation.

## 2.3 Two Methods for subtask B

To calculate semantic similarity between  $Q_0$  and  $Q_1$  pair, previous work extracted features only from the  $Q-Q$  sentence pair. We stated that the comment set  $C$  and its rank with respect to  $Q_1$  also provide useful information for question-question similarity. To address it, we propose two novel methods to improve

**Figure 2:** An illustration of BLSTM model for question-comment similarity estimation.

semantic similarity estimation between  $Q-Q$  pair by integrating the rank information of  $Q-C$  pair.

### 2.3.1 Method 1: adopt $Q-C$ Ranking Evaluation Metrics as Similarity Score

The first method is to adopt rank evaluation metrics, i.e., *Spearman*, *Pearson*, and *Kendall* Ranking Coefficient directly as similarity scores for question similarity estimation.

Generally, these three nonparametric metrics are to measure the statistical dependence between two variables and to assess how similar between two variables. In comment ranking, they are used to measure how similar the two rankings  $Q_0-C$  and  $Q_1-C$  are. Based on our consideration, given one comment set  $C$ , if the two ranks of  $Q_0-C$  and  $Q_1-C$  are similar, the semantic similarity between  $Q_0-Q_1$  is high. These three ranking correlation coefficients (i.e., *Spearman*, *Pearson*, and *Kendall* Coefficient) can be used directly as question similarity scores or used as additional ranking scores in combination with other features (described in Section 2.1) extracted from  $Q_0-Q_1$  pair.

### 2.3.2 Method 2: add new features extracted from $Q-C$ pair

We presented two methods to add new features extracted from  $Q-C$  pair. The first is to extract the features from  $Q_0-C$  and  $Q_1-C$  pair and then use the *cosine* scores calculated on the two feature vec-

tors as additional features for  $Q_0$ - $Q_1$ . We extracted traditional NLP features described in Section 2.1 from  $Q_0$ - $C$  and  $Q_1$ - $C$  pairs, respectively, denoted as two feature vectors, i.e.,  $F_0$  and  $F_1$ . Then we calculated the *cosine* similarity on these two vectors respectively, and obtain two *cosine* scores, i.e.,  $\cos(Q_0-C)$ , and  $\cos(Q_1-C)$ . After that, we calculated the absolute difference between these two *cosine* scores. Finally, the obtained scores (denoted as  $[\cos_1, \cos_2, \dots]$ ) are ranked as additional features.

The second is to calculate the ranking scores of  $Q_0$ - $C$  and  $Q_1$ - $C$  by using comment ranking model firstly, then use the *Manhattan Distance* of two lists of ranked scores as an additional feature.

## 2.4 A Two-Step Filtering for Subtask C

To overcome the error propagation from question-question similarity step to question-comment similarity step, we employed a two-step filtering strategy for subtask C. The first step is to choose the top  $N$  similar questions with the aid of the  $Q$ - $C$  ranking. The second step is to re-rank the comment and choose the top  $M$  comments with integration of the previous  $Q$ - $Q$  results.

## 3 Experimental Setting

### 3.1 Datasets

Table 1 shows the statistics of training, development and test data sets, where the #\_original, #\_related, and #\_answers represent the number of original questions, related questions and answers, respectively. The types of comments with respect to original question and related question fall into three classes: *Good*, *PotentiallyUseful* and *Bad*. The types of related question with respect to original question fall into three classes: *PerfectMatch*, *Relevant* and *Irrelevant*.

| Subtask | Data  | #_original | #_related | #_answers |
|---------|-------|------------|-----------|-----------|
| A       | train | –          | 5,898     | 37,848    |
|         | dev   | –          | 500       | 5,000     |
|         | test  | –          | 327       | 3,270     |
| B       | train | 267        | 2,669     | 26,690    |
|         | dev   | 50         | 500       | 5,000     |
|         | test  | 70         | 700       | 7,000     |
| C       | train | 267        | 2,669     | 26,690    |
|         | dev   | 50         | 500       | 5,000     |
|         | test  | 70         | 700       | 7,000     |

**Table 1:** Statistics of datasets.

### 3.2 Preprocessing

We first removed stop words and punctuation, and changed all words to lowercase. After that, we performed tokenization and stemming using NLTK<sup>3</sup> Toolkit.

### 3.3 Evaluation Metrics

To evaluate performance of the tasks, the *Mean Average Precision* (MAP) is adopted as official evaluation measure by the organizers which the MAP is defined as the mean of the averaged precision scores for queries.

### 3.4 Learning Algorithm

We compared two ranking strategies in traditional method. One is to train a pairwise-based ranking model, i.e., *Learning-to-rank* (Trotman, 2005), and use the output of model as a ranking score directly. Another is to first train a supervised classification model and then use the confidence score of probability as a ranking score. To train a supervised classifier, two algorithms implemented in SKLearn<sup>4</sup> have been examined, i.e., Logistic Regression (LR) and Support Vector Machine (SVM). Finally, Logistic Regression classifier (penalized argument  $c = 1$ ) is adopted for all three subtasks for its good performance in preliminary experiments.

## 4 Experiments on Training Data

### 4.1 Results on Subtask A

For the experiments of subtask A, the hyper-parameters of CNN model are set as follows: the number of filter windows is 2, feature maps are set to 100, learning rate is set to 0.01. And the hyper-parameters of BLSTM model are set as follows: memory size is set to 500 and the learning rate is 0.01. Table 2 shows the results of subtask A with three different methods.

Firstly, all CI, TB, TMB, and LSS features significantly over WM baseline. Since CI is a measure of the informativeness of comment text, this indicates that users tend to choose the comment with more information. TB can learn word alignment between different words. Unlike the surface word matching features which only consider the surface word, the

<sup>3</sup><http://www.nltk.org/>

<sup>4</sup><http://scikit-learn.org/stable/>

| Methods                  | Features | MAP(%)       |
|--------------------------|----------|--------------|
| Traditional NLP Features | WM       | 57.13        |
|                          | .+TB     | 58.91        |
|                          | .+TMB    | 61.37        |
|                          | .+CI     | 63.03        |
|                          | .+LSS    | <b>65.37</b> |
| CNN                      | -        | 65.04        |
| BLSTM                    | -        | 65.13        |
| Tra + CNN + BLSTM        | -        | <b>66.84</b> |

**Table 2:** Results of subtask A using different methods. “.+” means to add current feature to the previous feature set.

LSS features are obtained by integrating context of the word. Therefore, the LSS features show that this particular word embedding seems to complement the surface word matching information. Secondly, the combination of five types of features achieve the best performance for traditional method. Thirdly, the model based CNN and BLSTM achieve comparable performance with traditional method. Finally, the combination of three methods achieve the best performance which shows that CNN and BLSTM catch complementary information for  $Q$ - $C$  pair with traditional method.

## 4.2 Results on Subtask B

Table 3 summarizes the results of subtask B with NLP features and integrating the rank information of  $Q$ - $C$  pair. Here *Lucene* represents using Lucene

| Method                   | Features              | MAP(%)       |
|--------------------------|-----------------------|--------------|
| <i>Lucene</i>            | BM25                  | 69.95        |
| Traditional NLP Features | WM                    | 69.91        |
|                          | .+TB                  | 70.72        |
|                          | .+TMB                 | 71.05        |
|                          | .+LSS                 | 72.13        |
|                          | .+QI                  | <b>74.03</b> |
| Method 1                 | <i>Pearson</i>        | 61.18        |
|                          | <i>Spearman</i>       | 62.86        |
|                          | <i>Kendall</i>        | 62.95        |
|                          | <i>Pearson + NLP</i>  | 68.15        |
|                          | <i>Spearman + NLP</i> | 68.49        |
|                          | <i>Kendall + NLP</i>  | <b>68.95</b> |
| Method 2                 | NLP                   | 74.03        |
|                          | .+ARC                 | 74.25        |
|                          | .+ARR                 | <b>75.04</b> |

**Table 3:** Results of subtask B using different methods.

Toolkit<sup>5</sup> with the original question as query with BM25 ( $K_1 = 1.2$  and  $B = 0.75$ ). ARC and ARR

<sup>5</sup><https://lucene.apache.org/>

are the first and second methods presented in Section 2.3.2. According to the results of Table 3, we can make following three observations:

(1) Traditional NLP features significantly improve the performance of question-question similarity over *Lucene* baseline.

(2) The *Pearson*, *Spearman*, and *Kendall* get similar performance and do not perform well versus traditional NLP method. The three rank correlations all take down the performance of traditional NLP method when combined with it. The possible reason is that the ranked scores of comments are obtained by pre-trained comment ranking model which has a limitation of performance.

(3) Both *ARC* and *ARR* make contributions to the performance which means combining the information of  $Q$ - $C$  pair is helpful to find related questions.

## 4.3 Results on Subtask C

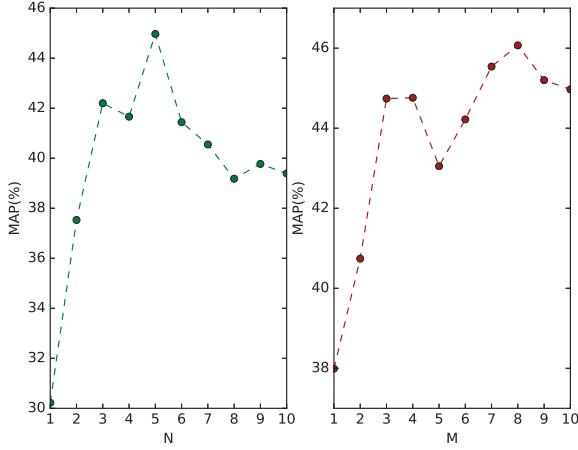

Table 4 depicts the results on subtask C, where *WMQ*, *TMBQ* and *TBQ* represent extracting word matching, topic model based and translation based features on original question and related question. From Table 4, we observe the similar results with those in subtask A, i.e., traditional features make contribution to comment ranking. Moreover, the performance is improved by adding features extracted from  $Q$ - $Q$  pair, which indicates that the information extracted from  $Q$ - $Q$  pair makes significant contribution to answer ranking subtask.

| Method                   | Features | MAP(%)       |
|--------------------------|----------|--------------|
| <i>Lucene</i>            | BM25     | 24.59        |
| Traditional NLP Features | WM       | 30.15        |
|                          | .+CI     | 33.13        |
|                          | .+TB     | 34.27        |
|                          | .+TMB    | 35.80        |
|                          | .+LSS    | <b>36.82</b> |
| $Q$ - $Q$ Features       | NLP      | 36.82        |
|                          | .+WMQ    | 38.14        |
|                          | .+TMBQ   | 38.51        |
|                          | .+TBQ    | <b>39.39</b> |

**Table 4:** Results of subtask C with different traditional NLP features.

However, above results are evaluated using MAP on top 10 comments. Therefore the errors introduced in question retrieval (subtask B) would be propagated to answer ranking (subtask A) and finally reduce the whole performance of CQA (subtask C).

To solve this problem, we investigated a two-step method to first filter unrelated comments and then filter unrelated answers. Figure 3 shows the results of two filtering methods on MAP metric, where  $N$  represents the number of top related questions and  $M$  represents the number of top ranked answers.

**Figure 3:** The results of subtask C using two-step filtering operation.

From left subplot of the Figure 3, we see that the best performance with filtering operation are much higher than the best score ( $MAP = 39.39\%$ ) without any filtering. The best performance  $44.97\%$  is obtained when  $N = 5$  and  $M = 10$ . The reason may be that the filtering operation of unrelated questions can take away many unrelated comments for original question. The right subplot of the Figure 3 shows the performance curve ( $N = 5$ ) when increasing the values of  $M$ . Similarly, the performance increases with  $M$  increasing from 7 to 9 and it achieves the best score of  $46.07\%$  when  $N = 5$  and  $M = 8$ .

#### 4.4 System Configuration

Based on above experimental analysis, the three system configurations are as followings:

(1) subtask A: We used the combination of traditional method, CNN and BLSTM as the primary run in the test set. Traditional method and BLSTM serve as contrastive1 run and contrastive2 run.

(2) subtask B: Traditional method with Method 2 is used as primary run in the test set. The combination of traditional method with Method 2 and *Lucene* is contrastive1 run and traditional method alone is

contrastive2 run.

(3) subtask C: The two-step filtering operation with  $N = 5$  and  $M = 8$  serves as primary run in the test set. The two-step filtering operation with  $N = 4$  and  $M = 7$  is contrastive1 run. Traditional features adding  $Q$ - $Q$  pair information is used as contrastive2 run.

## 5 Results on Test Data

Table 5 shows the results on test set which are released by the organizers.

| subtask               | run(rank)           | MAP(%) |
|-----------------------|---------------------|--------|
| A                     | ECNU-primary(4)     | 77.28  |
|                       | ECNU-contrastive1   | 71.34  |
|                       | ECNU-contrastive2   | 75.71  |
| B                     | Kelp-primary(1)     | 79.19  |
|                       | ECNU-primary(7)     | 73.92  |
|                       | ECNU-contrastive1   | 73.25  |
|                       | ECNU-contrastive2   | 71.62  |
| C                     | UH-PRHLT-primary(1) | 76.70  |
|                       | ECNU-primary(7)     | 46.47  |
|                       | ECNU-contrastive1   | 48.49  |
|                       | ECNU-contrastive2   | 47.24  |
| Super team-primary(1) |                     | 55.41  |

**Table 5:** Our results and the best results on three subtask test sets.

From the results, we find: (1) In subtask A, the combination of three methods significantly improve the performance over the traditional method and BLSTM, which is consistent with the results on training data as our expectation. (2) In subtask B, the result using traditional features is higher than *Lucene* but still has a certain gap with the best result. The possible reason may be because several traditional features do not work well in the test set. (3) In subtask C, beyond our expectation, the method using two-step filtering operation does not make obvious contribution. The possible reason may be that the values of  $M$  and  $N$  are not suitable for test set.

## 6 Conclusion

In this paper, we proposed multiple strategies (i.e., traditional method of extracting features and deep learning models) to address Community Question Answering task in SemEval 2016. For subtask A, we trained a classifier and learned the question-comment representation based CNN and BLSTM. The combination of three models obtains the best

results. For subtask B, we proposed two novel methods to improve semantic similarity estimation between  $Q$ - $Q$  pairs by utilizing the information of  $Q$ - $C$  ranking. For subtask C, we employed a two step filtering strategy to reduce the noise which taking from unrelated comments. The results on test set show the effectiveness of our methods.

## Abstract

We describe our system for finding good answers in a community forum, as defined in SemEval-2016, Task 3 on Community Question Answering. Our approach relies on several semantic similarity features based on fine-tuned word embeddings and topics similarities. In the main Subtask C, our primary submission was ranked third, with a MAP of 51.68 and accuracy of 69.94. In Subtask A, our primary submission was also third, with MAP of 77.58 and accuracy of 73.39.

## 1 Introduction

Posting questions that have already been asked and answered in a community forum is annoying to users as it usually ends up with them being referred to a previously asked question. The SemEval-2016 Task 3 on Community Question Answering<sup>1</sup>(Nakov et al., 2016) aims to solve this real-life problem. The main subtask (Subtask C) asks to find an answer that already exists in the forum and will be appropriate as a response to a newly-posted question. There is also a secondary, Subtask A, which focuses on Question-Comment Similarity and asks to rank the comments within a question-comment thread based on their relevance with respect to the thread’s question.

Here, we examine the performance of using different word embeddings obtained with the Word2Vec tool (Mikolov et al., 2013), which we use to build vectors for the questions and the answers. We train classifiers using features derived from these embeddings to solve subtasks A and C.

<sup>1</sup><http://alt.qcri.org/semeval2016/task3/>

Our contribution is in producing good word embeddings based on empirical evaluation of different configurations working in the Community Question Answering domain; as they perform well, we make them freely available to the research community.<sup>2</sup>

## 2 Related Work

This year’s SemEval-2016 Task 3 is a follow up of SemEval-2015 Task 3 on Answer Selection in Community Question Answering (Nakov et al., 2015). The 2015 subtask A asked to determine whether an answer was relevant, potentially useful, or bad, while this year this is about ranking.

Here we focus on features that use semantic knowledge such as word embeddings, various features extracted from word embeddings, and topic models. Word embeddings and word embeddings similarities have been used by teams in the 2015 edition of the task (Belinkov et al., 2015; Zamanov et al., 2015; Tran et al., 2015; Nicosia et al., 2015). LDA topic have also been used (Tran et al., 2015).

Many other features have been tried for the task. For example, Tran et al. (2015) used metadata about the question and the comment. User profile statistics such as number of *Good*, *Bad* and *Potentially Useful* comments by a given user have been used to model user likelihood of posting different types of comment (Nicosia et al., 2015). Vo et al. (2015) and Nicosia et al. (2015) used syntactic tree similarities to compare questions to comments. The problem of selecting relevant answers has even been approached as a spam filtering task (Vo et al., 2015).

### 3 Data

In our experiments, we used annotated training, development and testing datasets, as well as a large unannotated dataset, all provided by the SemEval-2016 Task 3 organizers. We further collected some additional unannotated in-domain data from some other sources, as explained below; finally, we used some models pretrained on out-of-domain data.

**Training, development, and testing data.** For Subtask A, there are 6,398 questions and 40,288 comments from their question-answer threads, and for Subtask C, there are 317 original questions, 3,169 related questions, and 31,690 comments. For both subtasks, the comments are annotated as *Good*, *PotentiallyUseful* and *Bad*; for subtask A, the annotation is with respect to the question in whose thread the comment appeared, while for subtask C, it is with respect to a new question. For both subtasks, a successful ranking is one that ranks all *Good* comments before all *PotentiallyUseful* and *Bad* ones (without distinguishing between the latter two).

**Unannotated data.** We performed experiments with Word2Vec embeddings trained on different unannotated data sources. We wanted to find the best performing embeddings and to use them in our system. In Table 1, we list the various data sources we used for training our Word2Vec models, and their vocabulary size.

**Qatar Living Forum** is the original Qatar Living.<sup>3</sup> unannotated data containing 189,941 questions and 1,894,456 comments. It is limited to the forums section of the Qatar Living website.

**Qatar Living Forum + Ext** includes the *Qatar Living Forum* dataset, i.e., the forums, but also some other sections of Qatar Living: Jobs, Classifieds, Pages, Wiki and Events posts.

**Doha News** is a dataset that we built by crawling about 7,000 news publications about the life in Doha, Qatar from the DohaNews website.<sup>4</sup>

We also used an out-of-domain, general model, which is readily-pretrained using Word2Vec on **Google News**,<sup>5</sup> as provided by Mikolov et al. (2013).

<sup>3</sup>[www.qatarliving.com](http://www.qatarliving.com) is an online community for everyone living in or interested in the State of Qatar.

<sup>4</sup>dohanews.co covers breaking news, politics, business, culture and more in and around Qatar.

<sup>5</sup>[code.google.com/archive/p/word2vec/](http://code.google.com/archive/p/word2vec/)

| Features               | Train size | Vocab |

**Table 1: Data used for training word embedding vectors.**

Shown are training source size (word tokens) and vocabulary size (word types).

### 4 Method

Below we focus our explanation on subtask A; for subtask C, we combine the predictions for subtask A with the Google’s reciprocal rank for the related question (see below).

We approach subtask A as a classification problem. For each comment, we extract variety of features from both the question and the comment, and we train a classifier to label comments as Good or Bad with respect to the thread question. We rank the comments in each question according to the classifier’s score of being classified as Good with respect to the question.

We first train several word embedding vector models and we fine-tune them using different configurations. For fine-tuning the parameters of the word embeddings training configuration, we setup a simple baseline system and we evaluate it on the official MAP score. We then use the best-performing embeddings in our further experiments. Our main features are semantic similarity based on word embeddings and topics, but we also use some metadata features.

#### 4.1 Preprocessing

Before extracting features, we preprocessed the input text using several steps. We first replaced URLs in text with TOKEN\_URL, numbers with TOKEN\_NUM, images with TOKEN\_IMG, and emoticons with TOKEN\_EMO. We then tokenized the text by matching only continuous alphabet characters including \_ (underscore). Next, we lowercased the result. For the training, the development, and the test datasets, we removed the stopwords using the English stopwords lexicon from the NLTK toolkit (Bird and Loper, 2004).

## 4.2 Features

We used several semantic vector similarity and metadata feature groups. For the similarity measures mentioned below, we used cosine similarity:

$$1 - \frac{u \cdot v}{\|u\| \cdot \|v\|} \quad (1)$$

**Semantic Word Embeddings.** We used semantic word embeddings obtained from Word2Vec models trained on different unannotated data sources including the QatarLiving and DohaNews. We also used a model pre-trained on Google News text. For each piece of text such as comment text, question body and question subject, we constructed the centroid vector from the vectors of all words in that text (excluding stopwords).

$$\text{centroid}(w_{1..n}) = \frac{\sum_{i=1}^n w_i}{n} \quad (2)$$

We built centroid vectors (2) from the question body and the comment text. We then examined different Word2Vec models in terms of training source and training configuration including word vector size, training window size, minimum word occurrence in the corpus, and number of skip-grams.

**Semantic Vector Similarities.** We used various similarity features calculated using the centroid word vectors on the question body, on the question subject and on the comment text, as well as on parts thereof:

**Question to Answer similarity.** We assume that a relevant answer should have a centroid vector that is close to that for the question. We used the question body to comment text, and question subject to comment text vector similarities.

**Maximized similarity.** We ranked each word in the answer text to the question body centroid vector according to their similarity and we took the average similarity of the top  $N$  words. We took the top 1,2,3 and 5 words similarities as features. The assumption here is that if the average similarity for the top  $N$  most similar words is high, then the answer might be relevant.

**Aligned similarity.** For each word in the question body, we chose the most similar word from the comment text and we took the average of all best word pair similarities as suggested in (Tran et al., 2015).

### Part of speech (POS) based word vector similarities.

We performed part of speech tagging using the Stanford tagger (Toutanova et al., 2003), and we took similarities between centroid vectors of words with a specific tag from the comment text and the centroid vector of the words with a specific tag from the question body text. The assumption is that some parts of speech between the question and the comment might be closer than other parts of speech.

**Word clusters (WC) similarity.** We clustered the word vectors from the Word2Vec vocabulary in 1,000 clusters (with 200 words per cluster on average) using K-Means clustering. We then calculated the cluster similarity between the question body word clusters and the answer text word clusters. For all experiments, we used clusters obtained from the Word2Vec model trained on QatarLiving forums with vector size of 100, window size 10, minimum words frequency of 5, and skip-gram 1.

**LDA topic similarity.** We performed topic clustering using Latent Dirichlet Allocation (LDA) as implemented in the *gensim* toolkit (Řehůřek and Sojka, 2010) on Train1+Train2+Dev questions and comments. We built topic models with 100 topics. For each word in the question body and for the comment text, we built a bag-of-topics with corresponding distribution, and calculated similarity. The assumption here is that if the question and the comment share similar topics, they are more likely to be relevant to each other.

**Metadata.** In addition to the semantic features described above, we also used some common sense metadata features:

**Answer contains a question mark.** If the comment has an question mark, it may be another question, which might indicate a bad answer.

**Answer length.** The assumption here is that longer answers could bring more useful detail.

**Question length.** If the question is longer, it may be more clear, which may help users give a more relevant answer.

**Question to comment length.** If the question is long and the answer is short, it may be less relevant.

**The answer's author is the same as the corresponding question's author.** If the answer is posted by the same user who posted the question and it is relevant, why has he/she asked the question in the first place?

**Answer rank in the thread.** Earlier answers could be posted by users who visit the forum more often, and they may have read more similar questions and answers. Moreover, discussion in the forum tends to diverge from the question over time.

**Question category.** We took the category of the question as a sparse binary feature vector (a feature with a value of 1 appears if question is in the category). The assumption here is that the question-comment relevance might depend on the category of the question.

### 4.3 Classifier

For each Question+Comment pair, we extracted the features explained above from the *Question* body and the subject text fields, and from the *Comment* text; we also extracted the relevant metadata. We concatenated the extracted features in a bag of features vector, scaling them in the 0 to 1 range, and feeding them to a classifier. In our experiments, we used different feature configurations. We used L2-regularized logistic regression classifier as implemented in Liblinear (Fan et al., 2008). For most of our experiments, we tuned the classifier with different values of the C (cost) parameter, and we took the one that yielded the best accuracy on 5-fold cross-validation on the training set. We used binary classification *Good* vs. *Bad* (including both *Bad* and *Potentially Useful* original labels). The output of the evaluation for each test example was a label, either *Good* or *Bad*, and the probability of being *Good* in the 0 to 1 range. We then used this output probability as a relevance rank for each *Comment* in the *Question* thread.

## 5 Experiments and Evaluation

As explained above, we rely mainly on semantic features extracted from Word2Vec word embeddings. Thus, we ran several experiments looking for the best embeddings for the task.

Table 2 shows experiments with Word2Vec models trained on the unannotated datasets described above. The Google News Word2Vec model comes pretrained with vector size of 300, window 10, minimum word frequency of 10 and skip-gram 1. We started with training our three Word2Vec models using the same parameters.

| Dataset                | Dev2016       |               |
|------------------------|---------------|---------------|
|                        | MAP           | Accuracy      |
| Qatar Living Forum     | <b>0.6311</b> | 0.7078        |
| Qatar Living Forum+Ext | 0.6269        | <b>0.7131</b> |
| Google News            | 0.6113        | 0.6996        |
| Doha News              | 0.5769        | 0.6844        |

**Table 2:** Semantic vectors trained on different unannotated datasets as the only features for subtask A: training on train2016-part1, testing on dev2016.

| Vector size | Test2016     |              |
|-------------|--------------|--------------|
|             | MAP          | Accuracy     |
| 800         | <b>78.45</b> | 74.22        |
| 700         | 78.12        | 73.98        |
| 600         | 77.31        | 73.15        |
| 500         | 77.61        | 73.30        |
| 400         | 78.36        | 74.19        |
| 300         | 77.25        | 74.50        |
| 200         | 77.90        | 73.88        |
| 100         | 77.08        | <b>74.53</b> |
| 50          | 77.22        | 73.85        |
| 20          | 75.44        | 72.42        |
| Baseline    | 59.53        | -            |

**Table 3:** Semantic vectors of different vector sizes, trained on Qatar Living Forum+Ext as features for subtask A (together with all other features): training on train2016-part1, testing on test2016.

Table 2 shows results using raw word vectors as features, together with an extra feature for question body to comment cosine similarity. We can see that training on *Qatar Living Forum* data performs best followed by using *Qatar Living Forum+Ext*, *Google News*, and *Doha News*. This is not surprising as the first two datasets are in-domain, while the latter two cover more topics (as they are news) and more formal language. Overall, Doha News contains topics that largely overlap with the topics discussed in the *Qatar Living* forum; yet, it uses more formal language and contains very little conversational word types (mostly in quotations and interviews); moreover, being smaller in size, it covers much less vocabulary. Based on these preliminary experiments on Dev2016, we concluded that the domain-specific word vectors trained on *Qatar Living Forum* were the best for this task, and we used them further in our experiments.

After we have selected the best dataset for training our semantic vectors, we continued with various experiments to select the best training parameters for Word2Vec. Below we present the results of these experiments on Test2016, but we experimented with Dev2016 when developing our system.

In Table 3, we present experiments with different vector sizes. We trained our classifier with all features mentioned above, extracted for the corresponding word vector model. We can see that word vectors of size 800 perform best followed by sizes 400 and 700. However, we should note that using word vectors of size 800 generates more than 1,650 features (800+800+other features), which slows down training and evaluation. Moreover, in our experiments, we noticed that using large word vectors blurs the impact of the other, non-vector features.

Thus, next we tried to achieve the MAP for the 800-size vector by using better parameters for smaller vector sizes. Table 4 shows the results, where we used vectors of size 100 and 200. We can see that the configuration with word vector size 200, window size 5, minimum word frequency 1 and skip-gram 3 performed best improving the 200 vectors MAP by 0.31 (compared to Table 3). However, the experiments with word vector size 100 improved its MAP score by 0.85, which suggests that there might be potential for improvement when using vectors of smaller size. We also tried to use Doc2Vec (Le and Mikolov, 2014) instead of Word2Vec, but this led to noticeably lower performance.

We further experimented with Word2Vec models trained with different configurations and different feature groups. Tables 5 and 6 show the results for ablation experiments using the best-performing configuration for Subtask A and C, respectively.

For Subtask A we achieved the best score with semantic vectors of size 200, trained with window size 5, minimum word frequency 1 and skip-grams 3. The best score we achieved (MAP 78.52) is slightly better than the best score from Table 3 (MAP 78.45), which means that it may be a good idea to use smaller word vectors in combination with other features. We can see that the features that contribute most (the bottom features are better) are the raw word centroid vectors and metadata features, followed by various similarities such as LDA topic similarity and POS-tagged-word similarity.

| Size | Window | Freq | Skip | Test2016     |              |
|------|--------|------|------|--------------|--------------|
|      |        |      |      | MAP          | Acc          |
| 200  | 5      | 1    | 3    | <b>78.21</b> | 74.25        |
| 200  | 5      | 5    | 1    | 78.19        | 73.49        |
| 200  | 5      | 5    | 3    | 78.13        | 74.01        |
| 200  | 5      | 1    | 1    | 78.01        | <b>74.53</b> |
| 100  | 5      | 1    | 1    | 77.93        | 74.19        |
| 200  | 10     | 5    | 1    | 77.90        | 73.88        |
| 100  | 5      | 1    | 3    | 77.81        | 73.94        |
| 100  | 10     | 1    | 1    | 77.72        | 74.43        |
| 200  | 10     | 1    | 1    | 77.58        | 74.25        |
| 100  | 5      | 5    | 1    | 77.53        | 74.07        |
| 200  | 10     | 1    | 3    | 77.43        | 73.73        |
| 100  | 10     | 10   | 1    | 77.18        | 73.79        |
| 100  | 10     | 5    | 1    | 77.08        | <b>74.53</b> |

**Table 6: Subtask C. Using all features without some feature groups.** Word2Vec is trained with word vector size 100, context window 5, minimum word frequency 1, and skip-grams 1.

For Subtask C, we achieved the best score with vectors of size 100, trained with window size 5, minimum word frequency 1, and skip-grams 1. The features that contributed most were mostly the same as for Subtask A. One difference is the maximized similarity features group, which now yields worse results when excluded, which indicates its importance.

Our *Primary*, *Contrastive 1* and *Contrastive 2* submissions were built with the same feature set: *All features - POS similarity & Meta Category*, but were trained with fixed C=0.55 on different datasets: *Primary* was trained on Train2016-part1, *Contrastive 1* was trained on Train2016-part1 + Train2016-part2, and *Contrastive 2* was trained on Train2016-part2.

## 6 Conclusion and Future Work

We have described our system for SemEval-2016, Task 3 on Community Question Answering. Our approach relied on several semantic similarity features based on fine-tuned word embeddings and topics similarities.

In the main Subtask C, our primary submission was ranked third, with a MAP of 51.68 and accuracy of 69.94. In Subtask A, our primary submission was also third, with MAP of 77.58 and accuracy of 73.39. After the submission deadline, we improved our MAP score to 78.52 for Subtask A, and to 53.39 for Subtask C, which would rank our system second.

In future work, we plan to use our best performing word embeddings models and features in a deep learning architecture, e.g., as in the MTE-NN system (Guzmán et al., 2016a; Guzmán et al., 2016b), which borrowed an entire neural network framework and architecture from previous work on machine translation evaluation (Guzmán et al., 2015). We also want to incorporate several rich knowledge sources, e.g., as in the SUper Team system (Mihaylova et al., 2016), including troll user features as inspired by (Mihaylov et al., 2015a; Mihaylov et al., 2015b; Mihaylov and Nakov, 2016), and PMI-based goodness polarity lexicons as in the PMI-cool system (Balchev et al., 2016), as well as sentiment polarity features (Nicosia et al., 2015).

We further plan to use information from entire threads to make better predictions, as using thread-level information for answer classification has already been shown useful for SemEval-2015 Task 3, subtask A, e.g., by using features modeling the thread structure and dialogue (Nicosia et al., 2015; Barrón-Cedeño et al., 2015), or by applying thread-level inference using the predictions of local classifiers (Joty et al., 2015; Joty et al., 2016). How to use such models efficiently in the ranking setup of 2016 is an interesting research question.

Finally, we would like to address subtask C in a more solid way, making good use of the data, the gold annotations, the features, the models, and the predictions for subtasks A and B.

## Abstract

We present a system for answer ranking (SemEval-2016 Task 3, subtask A) that is a direct adaptation of a pairwise neural network model for machine translation evaluation (MTE). In particular, the network incorporates MTE features, as well as rich syntactic and semantic embeddings, and it efficiently models complex non-linear interactions between them. With the addition of lightweight task-specific features, we obtained very encouraging experimental results, with sizeable contributions from both the MTE features and from the pairwise network architecture. We also achieved good results on subtask C.

## 1 Introduction

We present a system for SemEval-2016 Task 3 on Community Question Answering (cQA), subtask A (English). In that task, we are given a question from a community forum and a thread of associated text comments intended to answer the question, and the goal is to rank the comments according to their appropriateness to the question. Since cQA forum threads are noisy, as many comments are not answers to the question, the challenge lies in learning to rank all *good* comments above all *bad* ones.<sup>1</sup>

In this work, we approach subtask A from a novel perspective: by using notions of machine translation evaluation (MTE) to decide on the *quality* of a comment. In particular, we extend the MTE neural network framework from Guzmán et al. (2015).

<sup>1</sup>More detail and examples can be found on the task website (<http://alt.qcri.org/semeval2016/task3/>) and in the associated task description paper (Nakov et al., 2016).

We believe that this neural network is interesting for the cQA problem because: (i) it works in a pairwise fashion, i.e., given two translation hypotheses and a reference translation to compare to, the network decides which translation hypothesis is better; this is appropriate for a ranking problem; (ii) it allows for an easy incorporation of rich syntactic and semantic embedded representations of the input texts, and it efficiently models complex non-linear relationships among them; (iii) it uses a number of MT evaluation measures that have not been explored for the cQA task (e.g., TER, Meteor and BLEU).

The analogy we apply to adapt the neural MTE architecture to the cQA problem is the following: given two comments  $c_1$  and  $c_2$  from the question thread—which play the role of the two translation hypotheses—we have to decide whether  $c_1$  is a better answer than  $c_2$  to question  $q$ —which plays the role of the translation reference.

The two tasks seem similar: both reason about the similarity of two competing texts against a reference text, to decide which one is better. However, there are some profound differences. In MTE, the goal is to decide whether a hypothesis translation conveys the same meaning as the reference translation. In cQA, it is to determine whether the comment is an appropriate answer to the question. Furthermore, in MTE we can expect shorter texts, which are much more similar among them. In cQA, the question and the intended answers might differ significantly both in length and in lexical content. Thus, it is not clear a priori whether the MTE network can work well for cQA. Here, we show that the analogy is convenient, allowing to achieve competitive results.

At competition time, we achieved the sixth best result on the task from a set of twelve systems. Right after the competition we introduced some minor improvements and extra features, without changing the fundamental architecture of the network, which improved the MAP result by almost two points. We also performed a more detailed experimental analysis of the system, checking the contribution of several features and parts of the NN architecture. We observed that every single piece contributes important information to achieve the final performance. While task-specific features are crucial, other aspects of the framework are relevant too: syntactic embeddings, MT evaluation measures, and pairwise training of the network.

Finally, we used our system for subtask A to solve subtask C, which asks to find good answers to a new question that was not asked before in the forum by reranking the answers to related questions. For the purpose, we weighted the subtask A scores by the reciprocal rank of the related questions (following the order given by the organizers, i.e., the ranking by Google). Without any subtask C specific addition, we achieved the fourth best result in the task.

## 2 Related Work

Recently, many neural network (NN) models have been applied to cQA tasks: e.g., *question-question similarity* (Zhou et al., 2015; dos Santos et al., 2015; Lei et al., 2016) and *answer selection* (Severyn and Moschitti, 2015; Wang and Nyberg, 2015; Shen et al., 2015; Feng et al., 2015; Tan et al., 2015). Also, other participants in the SemEval 2016 Task 3 applied NNs to solve some of the subtasks (Nakov et al., 2016). However, our goal was different: we were interested in extending an existing pairwise NN framework from a different but related problem.

There is also work that uses scores from machine translation models as features for cQA (Berger et al., 2000; Echihabi and Marcu, 2003; Jeon et al., 2005; Soricut and Brill, 2006; Riezler et al., 2007; Li and Manandhar, 2011; Surdeanu et al., 2011; Tran et al., 2015), e.g., a variation of IBM model 1, to compute the probability that the question is a “translation” of the candidate answer. Unlike that work, here we use machine translation *evaluation* (MTE) instead of machine translation models.

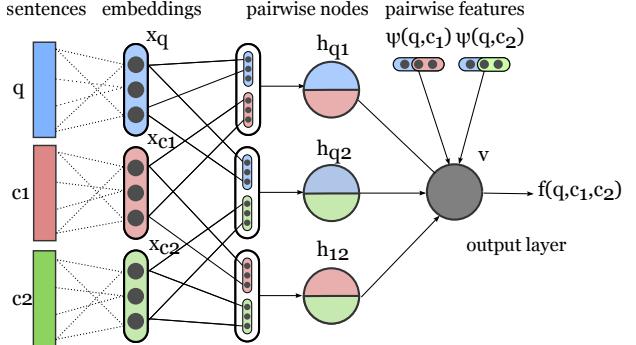

Figure 1: Overall architecture of the NN.

Another relevant work is that of Madnani et al. (2012), who applied MTE metrics as features for paraphrase identification. However, here we have a different problem: cQA. Moreover, instead of using MTE metrics as features, we port an entire MTE framework to the cQA problem.

## 3 Neural Model for Answer Ranking

The NN model we use for answer ranking is depicted in Figure 1. It is a direct adaptation of the feed-forward NN for MTE described in (Guzmán et al., 2015). Technically, we have a binary classification task with input  $(q, c_1, c_2)$ , which should output 1 if  $c_1$  is a better answer to  $q$  than  $c_2$ , and 0 otherwise.<sup>2</sup> The network computes a sigmoid function  $f(q, c_1, c_2) = \text{sig}(\mathbf{w}_v^T \phi(q, c_1, c_2) + b_v)$ , where  $\phi(x)$  transforms the input  $x$  through the hidden layer,  $\mathbf{w}_v$  are the weights from the hidden layer to the output layer, and  $b_v$  is a bias term.

We first map the question and the comments to a fixed-length vector  $[\mathbf{x}_q, \mathbf{x}_{c_1}, \mathbf{x}_{c_2}]$ , using syntactic and semantic embeddings. Then, we feed this vector as input to the neural network, which models three types of interactions, using different groups of nodes in the hidden layer. There are two *evaluation* groups  $\mathbf{h}_{q1}$  and  $\mathbf{h}_{q2}$  that model how good each comment  $c_i$  is to the question  $q$ . The input to these groups are the concatenations  $[\mathbf{x}_q, \mathbf{x}_{c_1}]$  and  $[\mathbf{x}_q, \mathbf{x}_{c_2}]$ , respectively. The third group of hidden nodes  $\mathbf{h}_{12}$ , which we call *similarity* group, models how close  $c_1$  and  $c_2$  are. Its input is  $[\mathbf{x}_{c_1}, \mathbf{x}_{c_2}]$ . This might be useful as highly similar comments are likely to be comparable in appropriateness, irrespective of whether they are good or bad answers in absolute terms.

<sup>2</sup>In this work, we do not learn to predict ties.

In summary, the transformation  $\phi(q, c_1, c_2) = [\mathbf{h}_{\mathbf{q}1}, \mathbf{h}_{\mathbf{q}2}, \mathbf{h}_{12}]$  can be written as follows:

$$\begin{aligned}\mathbf{h}_{\mathbf{q}i} &= g(\mathbf{W}_{\mathbf{q}i}[\mathbf{x}_q, \mathbf{x}_{c_i}] + \mathbf{b}_{\mathbf{q}i}), i = 1, 2 \\ \mathbf{h}_{12} &= g(\mathbf{W}_{12}[\mathbf{x}_{c_1}, \mathbf{x}_{c_2}] + \mathbf{b}_{12}),\end{aligned}$$

where  $g(\cdot)$  is a non-linear activation function (applied component-wise),  $\mathbf{W} \in \mathbb{R}^{H \times N}$  are the associated weights between the input layer and the hidden layer, and  $\mathbf{b}$  are the corresponding bias terms. We use tanh as an activation function, rather than sig, to be consistent with how parts of our input vectors (the word embeddings) are generated.

The model further allows to incorporate external sources of information in the form of *skip arcs* that go directly from the input to the output, skipping the hidden layer. These arcs represent pairwise *similarity* feature vectors between  $q$  and either  $c_1$  or  $c_2$ . In these feature vectors, we encode MT evaluation measures (e.g., TER, Meteor, and BLEU), cQA task-specific features, etc. See Section 4.3 for details about the features implemented as skip arcs. In the figure, we indicate these pairwise external feature sets as  $\psi(q, c_1)$  and  $\psi(q, c_2)$ . When including the external features, the activation at the output is  $f(q, c_1, c_2) = \text{sig}(\mathbf{w}_v^T[\phi(q, c_1, c_2), \psi(q, c_1), \psi(q, c_2)] + b_v)$ .

## 4 Learning Features

We experiment with three kinds of features: (i) input embeddings, (ii) features motivated by previous work on Machine Translation Evaluation (MTE) (Guzmán et al., 2015) and (iii) task-specific features, mostly proposed by participants in the 2015 edition of the task (Nakov et al., 2015).

### 4.1 Embedding Features

We use the following vector-based embeddings of  $(q, c_1, c_2)$  as input to the NN:

- **GOOGLE\_VEC**: We use the pre-trained, 300-dimensional embedding vectors, which Tomas Mikolov trained on 100 billion words from Google News (Mikolov et al., 2013).
- **SYNTAX\_VEC**: We parse the entire question/comment text using the Stanford neural parser (Socher et al., 2013), and we use the final 25-dimensional vector that is produced internally as a by-product of parsing.

Moreover, we use the above vectors to calculate pairwise similarity features. More specifically, given a question  $q$  and a pair of comments  $c_1$  and  $c_2$  for it, we calculate the following features:  $\psi(q, c_1) = \cos(q, c_1)$  and  $\psi(q, c_2) = \cos(q, c_2)$ .

### 4.2 MTE features

**MTEFEATS** (in MTE-NN-improved only). We use (as skip-arc pairwise features) the following six machine translation evaluation features, to which we refer as MTEFEATS, and which measure the similarity between the question and a candidate answer:

- **BLEU**: This is the most commonly used measure for machine translation evaluation, which is based on  $n$ -gram overlap and length ratios (Papineni et al., 2002).
- **NIST**: This measure is similar to BLEU, and is used at evaluation campaigns run by NIST (Doddington, 2002).
- **TER**: Translation error rate; it is based on the edit distance between a translation hypothesis and the reference (Snover et al., 2006).
- **METEOR**: A measure that matches the hypothesis and the reference using synonyms and paraphrases (Lavie and Denkowski, 2009).
- **PRECISION**: measure, originating in information retrieval.
- **RECALL**: another measure coming from information retrieval.

**BLEUCOMP**. Following (Guzmán et al., 2015), we further use as features various components that are involved in the computation of BLEU:  $n$ -gram precisions,  $n$ -gram matches, total number of  $n$ -grams ( $n=1,2,3,4$ ), lengths of the hypotheses and of the reference, length ratio between them, and BLEU’s brevity penalty. We will refer to the set of these features as BLEUCOMP.

### 4.3 Task-specific features

**QL\_VEC** (in MTE-NN-improved only). Similarly to the GOOGLE\_VEC, but on task-specific data, we train word vectors using WORD2VEC on all available cQA training data (Qatar Living) and use them as input to the NN.

**QL+IWSLT\_VEC** (in MTE-NN-{primary, contrastive1/2} only). We also use trained word vectors on the concatenation of the cQA training data and the English portion of the IWSLT data, which consists of TED talks (Cettolo et al., 2012) and is thus informal and somewhat similar to cQA data.

**TASK\_FEAT.** We further extract various task-specific skip-arc features, most of them proposed for the 2015 edition of the task (Nakov et al., 2015). This includes some comment-specific features:

- number of URLs/images/emails/phone numbers;
- number of occurrences of the string *thank*;<sup>3</sup>
- number of tokens/sentences;
- average number of tokens;
- type/token ratio;
- number of nouns/verbs/adjectives/adverbs/pro-nouns;
- number of positive/negative smileys;
- number of single/double/triple exclamation/interrogation symbols;
- number of interrogative sentences (based on parsing);
- number of words that are not in word2vec’s Google News vocabulary.<sup>4</sup>

And also some question-comment pair features:

- question to comment count ratio in terms of sentences/tokens/nouns/verbs/adjectives/adverbs/pronouns;
- question to comment count ratio of words that are not in word2vec’s Google News vocabulary.

We also have two meta features:

- is the person answering the question the one who asked it;
- reciprocal rank of the comment in the thread.

---

<sup>3</sup>When an author thanks somebody, this post is typically a bad answer to the original question.

<sup>4</sup>Can detect slang, foreign language, etc., which would indicate a bad answer.

## 5 Experiments and Results

Below we explain which part of the available data we used for training, as well as our basic settings. Then, we present in detail our experiments and the evaluation results.

### 5.1 Data and Settings

We experiment with the data from SemEval-2016 Task 3 (Nakov et al., 2016). The task offers a higher quality training dataset TRAIN-PART1, which includes 1,412 questions and 14,110 answers, and a lower-quality TRAIN-PART2 with 382 questions and 3,790 answers. We train our model on TRAIN-PART1 with hidden layers of size 3 for 63 epochs with minibatches of size 30, regularization of 0.0015, and a decay of 0.0001, using stochastic gradient descent with adagrad (Duchi et al., 2011); we use Theano (Bergstra et al., 2010) for learning. We normalize the input feature values to the  $[-1; 1]$  interval using minmax, and we initialize the network weights by sampling from a uniform distribution as in (Bengio and Glorot, 2010). We train the model using all pairs of good and bad comments, ignoring ties. At test time we get the full ranking by scoring all possible pairs, and accumulating the scores at the comment level.

We evaluate the model on TRAIN-PART2 after each epoch, and ultimately we keep the model that achieves the highest Kendall’s Tau ( $\tau$ ); in case of a tie, we prefer the parameters from a later epoch. We selected the above parameter values on the DEV dataset (244 questions and 2,440 answers) using the full model, and we use them for all experiments below, where we evaluate on the official TEST dataset (329 questions and 3,270 answers).

For evaluation, we use mean average precision (MAP), which is the official evaluation measure. We further report scores using average recall (AvgRec), mean reciprocal rank (MRR), Precision (P), Recall (R), F-measure (F1), and Accuracy (Acc). Note that the first three are ranking measures, to which we directly give our ranking scores. However, the latter four measures require Good vs. Bad categorical predictions. We generate them based on the ranking scores using a threshold: if the score is above 0.95 (chosen on the DEV set), we consider the comment to be Good, otherwise it is Bad.

## 5.2 Contrastive Runs

We submitted two contrastive runs, which differ from the general settings above as follows:

- MTE-NN-contrastive1: a different network architecture with 50 units in the hidden layer (instead of 3 for each of  $h_{q1}, h_{q2}, h_{12}$ ) and higher regularization (0.03, i.e., twenty times bigger). On the development data, it performed very similarly to those for the primary run, and we wanted to try a bigger NN.
- MTE-NN-contrastive2: the same architecture as the primary but different training. We put together TRAIN-PART1 and DEV and randomly split them into 90% for training and 10% for model selection. The idea here was to have some training examples from development, which was supposed to be a cleaner dataset (and so more similar to the test set).

## 5.3 Official Results

Table 1 shows the results for our submissions for subtask A. Our primary submission was ranked sixth out of twelve teams on MAP. Note, however, that it was third on MRR and  $F_1$ . It is also 3 and 14 points above the average and the worst systems, respectively, and well above the baselines. Both our contrastive submissions performed slightly better, but neither of them is strong enough to change the overall ranking if we had chosen one of them as primary.

For subtask C, we multiplied (i) our scores for subtask A for the related question by (ii) the given reciprocal rank of the related question in the list of related questions. That is, we did not try to address question-question similarity (subtask B). We achieved 4th place with a MAP of 49.38, which is well above the baseline of 40.36. Our contrastive2 run performed slightly better at 49.49.

## 5.4 Post-submission Analysis on the Test Set

After the competition, we produced a refined version of the system (**MTE-NN-improved**) where the settings changed as follows: (i) using QL\_VEC instead of QL+IWSLT\_VEC, (ii) adding MTFEATS to the set of features, (iii) optimizing accuracy instead of Kendall’s tau, (iv) training for 100 epochs instead of 63, and (v) regularization of 0.005 instead of 0.0015.

| System                 | MAP          | AvgRec       | MRR          | $\Delta_{\text{MAP}}$ |
|------------------------|--------------|--------------|--------------|-----------------------|
| <b>MTE-NN-improved</b> | <b>78.20</b> | <b>88.01</b> | <b>86.93</b> |                       |
| –TASK_FEATS            | 72.91        | 84.06        | 78.73        | -5.29                 |
| –COMMENT_RANK          | 76.08        | 86.41        | 84.42        | -2.12                 |
| –SAME_AUTHOR           | 76.60        | 86.75        | 83.71        | -1.60                 |
| –QL_VEC                | 75.83        | 86.57        | 83.90        | -2.37                 |
| –GOOGLE_VEC            | 76.96        | 87.66        | 84.72        | -1.24                 |

Table 2: Ablation study of our improved system on the test data.

Note that the training and development set remained unchanged. **MTE-NN-improved** showed notable improvements on the DEV set over our primary submission. In Table 2, we present the results on the TEST set. To gain additional insight about the contribution of various features and feature groups to the performance of the overall system, we also present the results of an ablation study where we removed different feature groups one by one. For this purpose, we study  $\Delta_{\text{MAP}}$ , i.e., the absolute change in MAP when the feature or feature group is excluded from the full system. Not surprisingly, the most important turn out to be the TASK\_FEATS (contributing over 5 MAP points) as they handle important information sources that are not available to the system from other feature groups, e.g., the reciprocal rank of the comment in the comment thread, which alone contributes 2.12 MAP points, and the feature checking whether the person who asked the question is the one who answered, which contributes 1.60 MAP points. Next in terms of importance come word embeddings, QL\_VEC (contributing over 2 MAP points), trained on text from the target forum, Qatar-Living. Then come the GOOGLE\_VEC (contributing over 1 MAP point), which are trained on 100 billion words, and thus are still useful even in the presence of the domain-specific QL\_VEC, which are in turn trained on four orders of magnitude less data. Interestingly, the MTE-motivated SYNTAX\_VEC vectors contribute half a MAP point, which shows the importance of modeling syntax for this task. Next, we can see that using just the vectors is not enough, and adding cosines as pairwise features for the three kinds of vectors contributes over one MAP point.

Table 1: **Comparison to the official results on SemEval-2016 Task 3, subtask A.** The first column shows the rank of the primary runs with respect to the official MAP score. The subindices in the results columns show the rank of the primary runs with respect to the evaluation measure in the respective column.

Finally, the two MTE features, MTFEATS and BLEUCOMP, together contribute 0.8 MAP points. It is interesting that the BLEU components manage to contribute on top of the MTFEATS, which already contain several state-of-the-art MTE measures, including BLEU itself. This is probably because the other features we have do not model  $n$ -gram matches directly.

We further used the output of our MTE-NN-improved system to generate predictions for subtask C, as explained above. This yielded improvements from 49.38 to 49.87 on MAP, from 55.44 to 56.08 on AvgRec, and from 51.56 to 52.16 on MRR.

## 6 Conclusion

We have explored the applicability of machine translation evaluation metrics to answer ranking in community Question Answering, a seemingly very different task (compared to MTE). In particular, with ranking in mind, we have adopted a pairwise neural network architecture, which incorporates MTE features, as well as rich syntactic and semantic embeddings of the input texts that are non-linearly combined in the hidden layer.

Our post-competition improvements have shown state-of-the-art performance (Guzmán et al., 2016), with sizeable contribution from both the MTE features and from the network architecture. This is an encouraging result as it was not a priori clear that an MTE approach would work well for cQA.

In future work, we plan to incorporate fine-tuned word embeddings as in the SemanticZ system (Mihaylov and Nakov, 2016b), and information from entire threads (Nicosia et al., 2015; Barrón-Cedeño et al., 2015; Joty et al., 2015; Joty et al., 2016). We also want to add more knowledge sources, e.g., as in the SUper Team system (Mihaylova et al., 2016), including veracity, sentiment, complexity, troll user features as inspired by (Mihaylov et al., 2015a; Mihaylov et al., 2015b; Mihaylov and Nakov, 2016a), and PMI-based goodness polarity lexicons as in the PMI-cool system (Balchev et al., 2016).

We further plan to explore the application of our NN architecture to subtasks B and C, and to study the interactions among the three subtasks in order to solve the primary subtask C. Furthermore, we would like to try a similar neural network for other semantic similarity problems, such as textual entailment.

## Acknowledgments

This research was performed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation. It is part of the Interactive systems for Answer Search (Iyas) project, which is developed in collaboration with MIT-CSAIL.

## Abstract

We describe our system, ConvKN, participating to the SemEval-2016 Task 3 “Community Question Answering”. The task targeted the reranking of questions and comments in real-life web fora both in English and Arabic. ConvKN combines convolutional tree kernels with convolutional neural networks and additional manually designed features including text similarity and thread specific features. For the first time, we applied tree kernels to syntactic trees of Arabic sentences for a reranking task. Our approaches obtained the second best results in three out of four tasks. The only task we performed averagely is the one where we did not use tree kernels in our classifier.

## 1 Introduction

SemEval-2016 Task 3 challenged the participants on the different steps of the full task of Community Question Answering (cQA).<sup>1</sup> Given a set of existing forum questions  $Q$ , where each existing question  $q \in Q$  is associated with a set of answers  $C_q$ , and a new user question  $q'$ , the ultimate task is to determine whether a comment  $c \in C_q$  represents a pertinent answer to  $q'$  or not. This task can be subdivided into three tasks, namely: (A) to assign a relevance (*goodness*) score to each answer  $c \in C_q$  with respect to the existing question  $q$ ; (B) to re-rank the set of questions  $Q$  according to their relevance against the new question  $q'$ ; and finally (C) to predict the appropriateness of the answers  $c \in C_q$  against  $q'$ .

<sup>1</sup><http://alt.qcri.org/semeval2016/task3>

Task 3 included these three tasks for English, whereas an adaptation of Task C was proposed for Arabic (Task D). The reader can refer to (Nakov et al., 2016) for a more detailed description of the tasks. Task A was also proposed in the SemEval-2015 edition (Nakov et al., 2015).<sup>2</sup>

We designed systems for all tasks. We used the feature vectors designed by Barrón-Cedeño et al. (2015) and Nicosia et al. (2015) for tasks A, B and C, whereas we just used a basic feature vector derived from the system of Belinkov et al. (2015) for Task D.

Most importantly, for tasks A, B and D, we combined feature vectors with tree kernels (Moschitti, 2006) for relational learning from short text (Moschitti et al., 2007; Moschitti, 2008). In particular, we used the improved models that have been successfully applied for several tasks and datasets in standard QA, see for example, (Severyn and Moschitti, 2012; Severyn and Moschitti, 2013; Severyn et al., 2013b; Severyn et al., 2013a; Tymoshenko et al., 2014; Tymoshenko and Moschitti, 2015).

Additionally, we used Convolutional Neural Networks (CNNs) (Severyn and Moschitti, 2015) and combined them with vectors and tree kernels for Task A as we did in (Tymoshenko et al., 2016).

We acknowledge that the automatic feature engineering of tree kernels was very useful to tackle the new challenges of the SemEval-2016 Task 3. Indeed, all our three systems using relational models based on tree kernels achieved the second official

<sup>2</sup>Note that in that paper the naming convention is slightly different. The fresh user question and the forum question are called “original” and “related”, respectively.

position. In contrast, for Task C, we did not have time for using the relational model in our submitted system, this has probably caused our average performance in such task, i.e., our system was ranked at the eighth position. For similar reasons, we could apply CNNs to only Task A.

The rest of the paper is organized as follows. Section 2 describes the four CQA tasks and gives a brief overview of the corpora. Section 3 describes the features used. Section 4 discusses our models and our official results. Section 6 presents final remarks.

## 2 Tasks Description

In this section we sketch the four proposed tasks.

**Task A: Question–Comment Similarity.** Given a user question and a thread of ten comments associated with it, re-rank the comments in the thread according to their pertinence. Three classes exist in this case: (i) good: the comment is definitely relevant; (ii) potentially useful: the comment is not good, but it still contains related information worth checking; and (iii) bad: the comment is irrelevant (e.g., it is part of a dialogue or unrelated to the topic). For evaluation purposes, both potentially useful and bad comments were considered as bad.

**Task B: Question–Question Similarity.** Given a new question and a set of ten forum questions, re-rank the forum questions by assessing if they are (i) perfect match: the new and forum questions request roughly the same information, (ii) relevant: the new and forum questions ask for similar information, or (iii) irrelevant: the new and forum questions are completely unrelated. For evaluation purposes, both perfect match and relevant forum questions are considered as relevant.

**Task C: New Question–Comment Similarity.** Similar to task A, but in this case the relevance of one-hundred comments is assessed against a new out-of-the-forum question. Same evaluation considerations as in task A apply.

**Task D: Question–{Forum Question+Comment}.** A new question and a set of thirty forum question-answer pairs are provided (it is known in advance

that the answer is correct with respect to the forum question). Re-rank the question+comment pairs according to three classes: (i) direct: a direct answer to the new question; (ii) relevant: not a direct answer to the question but with information related to the topic; and (iii) irrelevant: an answer to another question, not related to the topic. For evaluation purposes, both direct and relevant forum questions are considered as good.

Tasks A, B, and C use English instances extracted from *Qatar Living*, a forum for people to pose questions on multiple aspects of daily life in Qatar.<sup>3</sup> Task D uses Arabic instances extracted from three medical fora: *webteb*, *altibbi*, and *consult islamweb*.<sup>4</sup>

As this is a reranking task, mean average precision (MAP) is the referring evaluation metric. We also evaluate our models in terms of average Recall (AvgRec), Precision (P), Recall (R), F-measure (F<sub>1</sub>), and Accuracy.

Further details about the corpora, evaluation and other settings can be found in (Nakov et al., 2016).

## 3 Approach

In order to re-rank the comments according to their relevance, either against the forum questions or against the new questions, we train a binary SVM classifier and use its score as a measure of relevance. The classifier uses partial tree kernels (Moschitti, 2006) defined over shallow syntactic trees, along with other numeric features.

We used the DKPro Core toolkit (Eckart de Castilho and Gurevych, 2014)<sup>5</sup> for pre-processing the texts in English. More precisely, we used OpenNLP’s tokenizer, POS-tagger and chunk annotator<sup>6</sup>, and Stanford’s lemmatizer (Manning et al., 2014), all accessible through DKPro Core.

We used the MADAMIRA toolkit (Pasha et al., 2014) for segmenting Arabic texts. In order to split the texts into sentences, we used the Stanford splitter.<sup>7</sup> For parsing Arabic texts into syntactic trees, we

<sup>3</sup><http://www.qatarliving.com/forum>

<sup>4</sup><https://www.webteb.com/>, <http://www.altibbi.com/>, and <http://consult.islamweb.net>.

<sup>5</sup><https://dkpro.github.io/dkpro-core/>

<sup>6</sup><https://opennlp.apache.org/>

<sup>7</sup><http://stanfordnlp.github.io/CoreNLP>

used the Berkeley parser (Petrov and Klein, 2007). Following, we briefly describe the numeric features used in different tasks.

### 3.1 SemEval-2015 Features

For English texts, we consider three kinds of similarity measures: lexical, syntactic, and semantic (Barrón-Cedeño et al., 2015; Nicosia et al., 2015)

In the case of Task A, the context of a comment is a relevant factor. Comments are organized sequentially according to the time line of the comment thread. Important factors to assess the value of a comment is whether the thread includes further comments by the person who originally asked the question, if the same user is behind various comments in the thread, or what forum category the thread belongs to. Therefore, we consider a set of features that try to describe a comment in the context of the entire thread. Other Boolean context features characterize different situations including the identification of potential dialogues, which usually represent a bunch of bad comments, or the position of the comment in the thread. We also considered the categories of the questions in the forum (as some of them tend to include more open-ended questions and even invite for discussion on ambiguous topics), as well as the occurrence of specific strings or the length of a comment. In-depth descriptions of these features are available in (Nicosia et al., 2015).

For Arabic texts, we utilize the embedding vectors as obtained by Belinkov et al. (2015): employing word2vec (Mikolov et al., 2013) on the Arabic Gigaword corpus (Parker et al., 2011). More specifically, we concatenate the vectors representing a new question and an existing question in the question-answer pair, which is then fed to the SVM classifier.

### 3.2 Rank Feature

The meta-information in the English corpus includes the position of the forum threads in the rank generated by the Google search engine for a given new question. We exploit this information in tasks B and C. We employ the inverse of such position as a feature and refer to it as the rank feature.

### 3.3 Tree Kernels

Tree kernels are similarity functions that measure the similarity between tree structures. We con-

structed a syntactic tree for each comment or question. Each task involves a pair of trees, question and comment (tasks A and C) and new and forum questions (tasks B and D). Replicating Severyn and Moschitti (2012), we link the two trees by connecting (i) part-of-speech nodes with a lexical match between the corresponding non-stop words; and (ii) chunk nodes such as NP, PP, VP, when there is a link above between POS-tags. Such links are marked with the presence of a specific tag. We then apply the partial tree kernel (PTK) or the syntactic tree kernels<sup>8</sup> (STK) both defined in (Moschitti, 2006) on the pairs as:

$$K((t_1, t_2), (u_1, u_2)) = TK(t_1, u_1) + TK(t_2, u_2), \quad (1)$$

where  $t$  and  $u$  are parse trees extracted from the text pair, i.e., either question and comment for task A or question and question for tasks B and D.

## 4 Submissions and Results

We describe our primary submissions for the four tasks in Section 4.1. The contrastive submissions are discussed in Section 4.2. Table 1 shows our official competition results for both primary and contrastive submissions.

In all submissions we employed Support Vector Machines (SVM) (Joachims, 1999) using either SVM-Light (Joachims, 1999), KeLP<sup>9</sup> (Filice et al., 2015), or SVM-light-TK<sup>10</sup> (Moschitti, 2006) (only the last two can handle tree kernels).

### 4.1 Primary Submissions

**Task A.** The submission consists in an SVM operating on two kernels: (i) the tree kernel described in Section 3.3, applied to the structures described by Tymoshenko and Moschitti (2015) without question and focus classification; (ii) a polynomial kernel of degree 3 applied to the feature vector that is a concatenation of the feature vector described in Section 3.1, and question and answer embeddings learned on the training set by the Convolutional Neural Network (CNN) described in (Severyn and Moschitti, 2015). More details about the used

<sup>8</sup>Also called SST.

**Table 1:** Performance of our official primary and contrastive submissions to SemEval-2016 Task 3 for tasks A, B, C, and D. Best-performing and baseline systems included for comparison. The super-index in the primary submission stands for the position in the challenge ranking. The baselines are as provided by the task organizers; they are based on search engine rankings (except for task D, which is random).

embeddings and the resulting kernels can be seen in (Tymoshenko et al., 2016). The SVM was trained on the union of both training and development sets.

**Task B.** The submission consists in an SVM operating on three kernels: (i) an RBF kernel on the features described in Section 3.1, (ii) an RBF kernel on the features described in Section 3.2; and (iii) the tree kernel described in Section 3.3. The  $C$  parameter of the SVM was set to 1. Both the tree and the RBF kernels use default values for the parameters. The SVM was trained on the union of the training and development sets.

**Task C.** The submission consists in an SVM operating on two RBF kernels (with default parameter values): the first one is on the features described in Section 3.1. The second one is on the features described in Section 3.2 plus the score obtained from

the prediction of a comment according to a classifier built for task A, computed by cross-validation. The SVM is trained on the union of the training part 2 and development sets.

**Task D.** The submission consists in an SVM operating on two kernels: (i) the syntactic tree kernel (SST) (Moschitti, 2006), applied as described in Section 3.3, to the constituency trees of the question texts; (ii) a linear kernel applied to the features in (Belinkov et al., 2015). In tasks A and B we used PTK, which is slower but more accurate. However, the trees of the Arabic data were rather large and very noisy. Thus we used SST, which is faster and uses less features. The value 0.1 for parameter L served the purpose of removing noise. The SVM was trained on the union of the training and development sets.

## 4.2 Contrastive Submissions

**Task A.** We submitted a contrastive run ( $\text{cont}_1$ ), where we use a joint learning and inference approach based on a Fully-connected Conditional Random Field (FCCRF) (Joty et al., 2016) to classify all the comments in a thread collectively. We used the numeric (non-tree) features used previously in (Joty et al., 2015; Barrón-Cedeño et al., 2015), and also the predictions of the SVM used in our primary run. The FCCRF model uses an Ising-like edge potential, which distinguishes between only *same* and *different* (as opposed to all four possibilities) state transitions to model all pair dependencies.

The second contrastive run ( $\text{cont}_2$ ) is as the primary submission, but without tree kernels.

**Task B.** We submitted one contrastive submission which is identical to the primary one, with the only exception that SVM is trained on the training part 2 and development sets only.

**Task C.** We submitted one contrastive submission which is identical to the primary one, with the exception that SVM is trained on all training and development sets.

The second contrastive submission consists of a rule-based system which relies on the outputs from tasks A and B. A comment is labeled as *good* if it is considered *good* with respect to the related question (Task A) and the related question is considered *relevant* with respect to the new question (Task B). The comment is considered *bad* otherwise.

**Task D.** The contrastive systems did not use tree kernels. Our first contrastive run used only feature vectors. Our second contrastive run also used additional features borrowed from machine translation evaluation: BLEU (Papineni et al., 2002), TER (Snover et al., 2006), Meteor (Lavie and Denkowski, 2009), NIST (Doddington, 2002), Precision and Recall, and length ratio between the question and the comment.

## 5 Results and Discussion

Table 1 shows the results obtained in the four tasks. We achieved the second position for tasks A, B, and D. In Task A, tree kernels give no major boost, but without them our model would be  $\text{cont}_2$ , which

achieved the third position on the test set. The joint model  $\text{cont}_1$ , run on top of our primary system, was able to improve it by more than one point. We were not sure about the outcome of this model, thus we preferred not to use it as our primary submission, even though we got an improvement also on the development set.

Our  $\text{cont}_1$  system for Task B, trained only on the train part 2 and development sets, scored less than our primary one. Even if our preliminary observations had suggested that the distributions of the different training and development sets were too different and potentially damaging the model learning, having more diverse data ended up as a better solution to the task.

Our submission for Task C is very limited as it does not include tree kernel models. The use of our feature vectors only (the same used for tasks A and B), results in an average performance in the challenge.

Regarding Task D,  $\text{cont}_1$ , using embedding features from (Belinkov et al., 2015), is an average system. When we add the machine translation evaluation (MTE) features the MAP increases from 38.33 to 39.98. We did not trust the MTE features as in the development set they obtained a lower result than the simple embedding features. This resulted to be a mistake from the competition viewpoint as they could have been combined with tree kernels. Indeed, our Primary system just combines tree kernels with the embedding features improving them by more than 7 absolute points, achieving the second position with a MAP of 45.50, very close to the best system, i.e., 45.83.

## 6 Conclusions

In this paper, we have presented the systems developed by the teams of the Qatar Computing Research Institute (QCRI) and the University of Trento for participating in SemEval-2016 Task 3 on Community Question Answering.

We used supervised machine learning approaches based on various combinations of the convolution tree kernels, text embedding features, including those learned by the convolutional neural networks, and a number of task-specific features from our previous work for SemEval-2015, Task 3.

For each task we submitted one primary and two contrastive runs incorporating various combinations of the above components. Our primary runs scored second for tasks A, B and D and eighth for task C. Finally, we analyzed the performance of our runs and discussed which components are more beneficial for a specific task/language.

In future work, we plan to devise better ways of combining convolution tree kernels with CNNs, e.g. by embedding the CNN similarities into the structural kernels, and encoding more complex relations into the structural representations of the text snippets.

## Acknowledgments

This research is developed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, Qatar Foundation in collaboration with MIT. It is part of the Interactive sYstems for Answer Search (IYAS) project. This work has been partially supported by the EC project CogNet, 671625 (H2020-ICT-2014-2, Research and Innovation action) and by an IBM Faculty Award.

duxk@huilan.com

## Abstract

Community Question Answering (CQA) systems play an important role in people's lives due to the huge knowledge accumulated in them. In order to take full advantage of the huge knowledge, the target of semeval2016 task3 is to find the best answers to a new question in CQA. This work proposes to use rich semantic text similarity (STS) features to complete the task. We address the task as a ranking problem and Support Vector Regression (SVR) model is chosen to combine rich semantic similarity features and context features. Finally, we used genetic algorithm to do feature selection. Our method achieves an MAP (mean average precision) of 71.52%, 71.43% and 48.49% in subtask A, B and C respectively. It ranked 8<sup>th</sup> in subtask A and subtask B, and 7<sup>th</sup> in subtask C.

## 1 Introduction

The CQA system with interactive and open character, can better adapt to the diversity of needs of users. With the growth of the number of users, community question answering system has accumulated a lot of QA pair archives. It has presented new challenges to analyze user's requirement and recommends high-quality answers to users.

In response to this problem, Semeval2015 Task3 - "Answer Selection in Community Question Answering"<sup>1</sup> (Nakov et al., 2015) proposed a task to divide the answers into three

levels in accordance with the relevance of the question. However, the classification system does not fully comply with the question requirement, as it does not implement the recommending function.

Semeval2016 Task3 - "Community Question Answering"<sup>2</sup> (Nakov et al., 2016) puts forward new requirements to automate the process of finding good answers to new questions in a community-created discussion forum based on the Semeval2015 Task3. The task is divided into three parts: subtask A - "Question-Comment Similarity", subtask B - "Question-Question Similarity" and subtask C - "Question-External Comment Similarity".

In our work, we focus on using features that employ STS knowledge, such as extracting text similarity features from word vectors, structured resource and topic models, to deal with the task. Word vectors has been used in (Liu, Sun, Lin, Zhao, & Wang, 2015) and (Nicosia et al., 2015) to compute STS, and (Jin, Sun, Lin, & Wang, 2014) has evaluated word-phrase semantic similarity with structured resource.

## 2 Feature

The main idea of our method is to find the similarity between most similar words in two sentences to estimate sentence similarity. Our features include the following categories: WordNet-based features, vector features, word matching features, topic features and answer features.

<sup>1</sup> <http://alt.qcri.org/semeval2015/task3/>

<sup>2</sup> <http://alt.qcri.org/semeval2016/task3/>

## 2.1 Vector Features

There are three approaches that we are applying to measure sentence similarity with word vector.

The first one uses the sum of all the words' vectors in sentence  $s$  as the representative of  $s$ , and calculate the distance of two sentences' vector.

$$\text{vec}(s) = \sum_{w_i \in s} \text{vec}(w_i) \quad (1)$$

$$\text{sim}(s_1, s_2) = c\_sim(\text{vec}(s_1), \text{vec}(s_2)) \quad (2)$$

Where  $s$  is a sentence,  $\text{vec}(w)$  is the vector of word  $w$ , and  $c\_sim(v, u)$  is cosine similarity which will be mentioned below.

$$c\_sim(v, u) = \frac{\sum_i^n v_i \times u_i}{\sqrt{\sum_i^n (v_i)^2} \times \sqrt{\sum_i^n (u_i)^2}} \quad (3)$$

Where  $v$  and  $u$  are two  $N$ -dimensional vectors.  $v_i$  is the  $i$ -th element of  $v$ .

The second and the third are similar to each other. The procedure that computing sentence pair similarity includes the following three steps.

First, given two sentences  $s_1$  and  $s_2$ , and for each word  $v$  in sentence  $s_1$ , we find the most similarity word  $u$  in sentence  $s_2$ , to word  $v$ . And we do the same to sentence  $s_2$ .

$$sc(v, u \in s_1) = \max_{u \in s_2} (\text{sim}(v, u)) \quad (4)$$

Second, we calculate the similarity of a sentence-sentence pair based on each sentence respectively:

$$\text{sim}(s) = \frac{\sum_{w \in s} sc(w)}{l} \quad (5)$$

$$idfsim(s) = \frac{\sum_{w \in s} sc(w) \times idf(w)}{\sum_{w \in s} idf(w)} \quad (6)$$

Where  $l$  is the number of the words with stopwords removed from sentence  $s$ , and  $idf(w)$  is the inverse document frequency (Sparck Jones, 1972) of word  $w$  in the Wikipedia data.

Third, the value is averaged over the two sentence:

$$\text{sim\_ag}(s_1, s_2) = \frac{\text{sim}(s_1) + \text{sim}(s_2)}{2} \quad (7)$$

$$idfsim\_ag(s_1, s_2) = \frac{idfsim(s_1) + idfsim(s_2)}{2} \quad (8)$$

We trained two word2vec<sup>3</sup> models using Gensim toolkit<sup>4</sup> (Řehůřek & Sojka, 2010). The first one is trained on the training data, and the second one on Wikipedia data<sup>5</sup>. Only these latter two ways are used in both models.

In addition, we also make use of existing word vectors mentioned by earlier researchers (Nicosia et al., 2015), Glove<sup>6</sup> (Pennington, Socher, & Manning, 2014) and COMPOSES<sup>7</sup> (Baroni, Dinu, & Kruszewski, 2014), which have been proved to be helpful in many NLP applications.

## 2.2 WordNet-based Features

WordNet (Fellbaum, 2005) is widely used in semantic similarity computing in the field of natural language processing. WordNet provides six ways to calculate the similarity of words depending on the meanings: path-similarity (Resnik, 1999), Leacock-Chodorow Similarity (Leacock & Chodorow, 1998), Wu-Palmer Similarity (Wu & Palmer, 1994), Resnik Similarity (Resnik, 1995), Jiang-Conrath Similarity (Jiang & Conrath, 1997) and Lin Similarity (Lin, 1998).

In our systems, the six methods are all used to measure word similarity. The WordNet-based features are computed using the same formulas as the last two methods of vector features.

## 2.3 Word Match Features

Longest Common Subsequence (Allison & Dix, 1986) can retain the words' position information when computing the sentence similarity:

$$\text{sim}(s_1, s_2) = \frac{\frac{lcs(s_1, s_2)}{l_1} + \frac{lcs(s_1, s_2)}{l_2}}{2} \quad (9)$$

Where  $lcs(s_1, s_2)$  is the length of the longest common subsequence,  $l_1$  and  $l_2$  are the numbers of the words in  $s_1$  and  $s_2$ .

We also use the bag of word to search the hidden relationship between words and sentences,

<sup>3</sup> The size is 400.

<sup>4</sup> <http://scikit-learn.org/stable/index.html>

<sup>5</sup> <https://dumps.wikimedia.org>

<sup>6</sup> <http://nlp.stanford.edu/projects/glove/>

<sup>7</sup> <http://clic.cimec.unitn.it/composes/semantic-vectors.html>

and the cosine similarity is used to be the measure of vector similarity.

Besides, we use Stanford CoreNLP toolkit (Finkel, Grenager, & Manning, 2005) to get the two sentences' nouns and measure their similarity by bag of word.

## 2.4 Topic Features

All the features mentioned above are based on lexical similarity. In order to overcome the limitation of the lexical features, we build Latent Dirichlet Allocation (Blei, Ng, & Jordan, 2003) model and Latent Semantic Analysis (Hofmann, 2001) model using the Gensim toolkit (Řehůřek & Sojka, 2010), which are both trained on Wikipedia data.

The topic models<sup>8</sup> can get sentence vector directly, and we calculate the vector distance by cosine similarity.

## 2.5 Answer Features

Closely analyzing the train data, we noticed that many “Good” comments would like to suggest questioners to visit a web site or ask further questions by email, and many “Good” comments prefer to contain pictures or numbers to explain themselves more clearly. Moreover, “Good” comments’ sentence length is much longer than “PotentiallyUserful” comments and “Bad” comments’.

In addition, respondents themselves have a great influence on the quality of the answers. It may lead to a “Bad” comment if the respondent is also the questioner, and if the respondent is not the questioner but asks a question, it may also lead to a “Bad” comment. If a respondent was accustomed to submit high-quality comments, he/she has a high likelihood of offering a “Good” suggestion in the current question. So, we have voted the accuracy and error rates of comments for all users.

The answer features are only applied in subtask A.

---

<sup>8</sup> The size of both models are 100.

## 3 Method and Result

### 3.1 Feature generation

Each question has brief description and detailed description. Take the following question as an example:

*OrgQSubject: What is the purpose of heaven?*

*OrgQBody: What is the point? What is in it for the ones that get there? Let's leave the purpose of hell for another thread. I invite you to ponder. You can quote scripture or Sura's etc if you want but you must expand upon them with your own thoughts.*

As we can see, people can get a broad understanding on the question by reading the brief description, and experiments show that the features of brief description lead to a better result.

| Features | F1 score |
|----------|----------|
| Sub      | 0.4898   |
| Body     | 0.4476   |
| Sub+Body | 0.5316   |

**Table 1: Experiments for subtask B.** A classification model is trained on training dataset and tested on development dataset.

We assume that if the features come off well on a classification model, they would do a good job on ranking model.

So, we extracted eigenvalue from both brief description and detailed description for subtask B. The subtask A is trained models with all the characteristics mentioned above. We multiply the subtask A’s results by the subtask B’s as subtask C’s. And eventually we got 38 features for subtask A and 56 features for subtask B. Table 2 lists all the features.

### 3.2 Feature Selection

Considering that there may be a feature subset performing better than other subset of all features, we designed a genetic algorithm (Renna, 2000) to find the best one. The genetic algorithm (GA) can be described as follows:

**Encoding:** Assuming that there are  $n$  features,  $n$ -bit binary will be needed to encode a chromosome then. The process of feature selection is as the Figure 1 shows.

|                         | Category               | Feature  |
|-------------------------|------------------------|--|
| Subtask A and Subtask B | Vector features        | W2V_wiki, W2V_wiki_idf, W2V_qatar, W2V_qatar_idf, Glove_sp, Glove_w2w, Glove_w2w_idf, COMPOSES_sp, COMPOSES_w2w, COMPOSES_w2w_idf    |
|                         | WordNet-based features | PATH_sim, LCH_sim, WUP_sim, RES_sim, JCN_sim, LIN_sim, PATH_sim_idf, LCH_sim_idf, WUP_sim_idf, RES_sim_idf, JCN_sim_idf, LIN_sim_idf |
|                         | Topic features         | LDA_sim, LSA_sim   |
|                         | Word match features    | LCS_sim, BagOfW_sim, NOUN_sim, NOUN_sim_idf  |
| Subtask A               | Answer features        | IS_QUsr, IS_Thank, IS_Ask, IS_Other_Ask, IS_Email, IS_URL, U_BestRate, U_GoodRate, U_BadRate, Sen_Lenght, IS_NUM, IS_IMG,            |

Table 2: The features we extracted

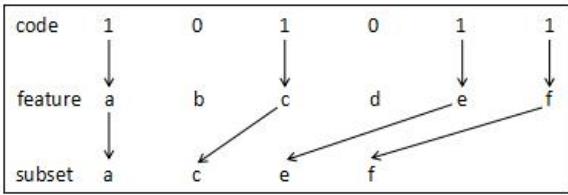

Figure 1: Feature subset selection. If the  $i$ -th feature is added into the subset, the value of the  $i$ -th binary is 1, and if not is 0.

**Individual creation:** Relying on the hypothesis that a feature can make a feature subset work better if it is added to the current feature subset, we increase the probability<sup>9</sup> that each feature is selected.

**Fitness:** We employ SVR as the evaluation function of feature selection.

**Selection:** The reproduction operator just selects the top individuals of fitness as a part of the next generation, instead of adopting a probability selection algorithm to select superior individuals.

**Crossover:** Here we use the single-point crossover.

**Mutation:** Get a probability, and if the value is less than the preset threshold, an individual will be selected and a binary will be changed randomly. In order to retain the best feature subset, all operations mentioned above are among the superiors, and the aberration rate is set to a larger value<sup>10</sup> to escape the local minimum.

Figure 2 is the flowchart of GA. Where  $n$  is quorum,  $m$  is selection scale, and  $thresh$  is fitness-threshold.

GA can lead to different results for each run, so we run the selection function several times and choose the best one. Table 3 and Table 4 show the results of subtask A and subtask B in 20 runs of GA respectively. All experiments below train models on training dataset, and test them on development dataset.

| Operation      | Statistics         | Result |
|----------------|--------------------|--------|
| Undo selection | —                  | 0.5263 |
| Do selection   | max                | 0.6182 |
|                | min                | 0.6121 |
|                | average            | 0.6163 |
|                | Standard deviation | 0.0014 |
|                |                    |        |

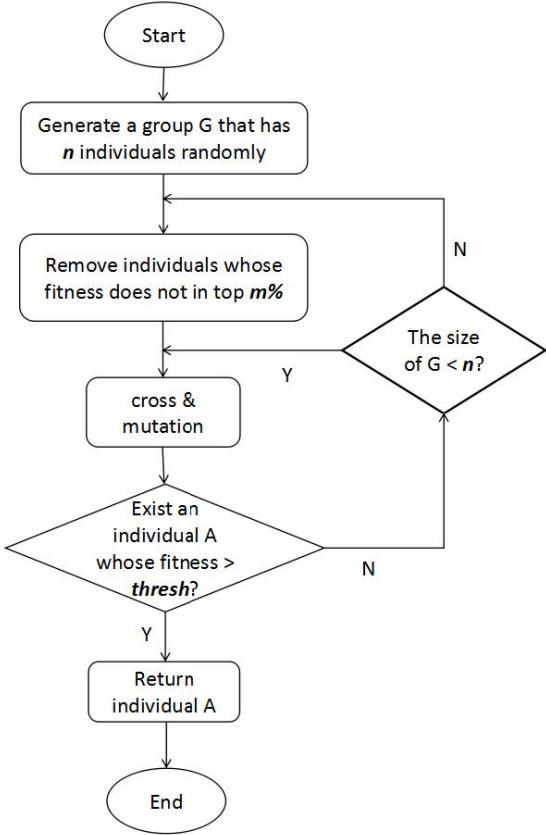

Table 3: 20 runs' results of GA for subtask A.

| Operation      | Statistics         | Result |
|----------------|--------------------|--------|
| Undo selection | —                  | 0.5889 |
| Do selection   | max                | 0.7801 |
|                | min                | 0.7320 |
|                | average            | 0.7627 |
|                | Standard deviation | 0.0137 |
|                |                    |        |

Table 4: 20 runs' results of GA for subtask B.

<sup>9</sup> The value is 0.75.

<sup>10</sup> The value we set is 0.3.

**Figure 2:** genetic algorithm

### 3.3 Training Model

We trained a Maximum Entropy Modeling using the maxent toolkit (Le, 2004) and a SVR model (Smola & Schölkopf, 2004) using scikit-learn toolkit (Pedregosa et al., 2011).

Table 5 and Table 6 show the results of different models.

| Runs             | MAP           |
|------------------|---------------|
| random baselines | 0.4556        |
| IR baselines     | 0.5384        |
| Maxent           | 0.5826        |
| SVR              | <b>0.6179</b> |

**Table 5:** Experiments for Subtask A

| Runs             | MAP           |
|------------------|---------------|
| random baselines | 0.5595        |
| IR baselines     | 0.7135        |
| Maxent           | 0.7135        |
| SVR              | <b>0.7801</b> |

**Table 6:** Experiments for Subtask B

### 3.4 Result

We just submit one time, and our system perform better in subtask A and subtask C than subtask B.

|        | IR     | SYS           |
|--------|--------|---------------|
| MAP    | 0.5953 | <b>0.7152</b> |
| AvgRec | 0.7260 | 0.8267        |
| MRR    | 67.83  | 80.26         |

**Table 7:** System performance for subtask A.

|        | IR     | SYS           |
|--------|--------|---------------|
| MAP    | 0.7475 | <b>0.7143</b> |
| AvgRec | 0.8830 | 0.8731        |
| MRR    | 83.79  | 81.28         |

**Table 8:** System performance for subtask B.

|        | IR     | SYS           |
|--------|--------|---------------|
| MAP    | 0.4036 | <b>0.4849</b> |
| AvgRec | 0.4597 | 0.5516        |
| MRR    | 45.83  | 55.21         |

**Table 9:** System performance for subtask C

## 4 Conclusion and Future Work

We have tested the system by taking part in SemEval2016 Task 3 on English sub tasks, and our system works better on subtask A and subtask C than the IR system provided by organizers.

Aware our method's shortcomings that the features center on lexical similarity, we will pay attention to process long sentence similarity in further work.

## Acknowledgments

We thank reviewers for their helpful comments on an earlier version of this work. This work is supported by National Natural Science Foundation of China (61572151 and 61300114).

## Abstract

This paper presents our approach towards the SemEval-2016 Task 10 – Detecting Minimal Semantic Units and their Meanings. Systems are expected to provide a representation of lexical semantics by (1) segmenting tokens into words and multiword units and (2) providing a supersense tag for segments that function as nouns or verbs. Our pipeline rule-based system uses no external resources and was implemented using the `mwetoolkit`. First, we extract and filter known MWEs from the training corpus. Second, we group input tokens of the test corpus based on this lexicon, with special treatment for non-contiguous expressions. Third, we use an MWE-aware predominant-sense heuristic for supersense tagging. We obtain an F-score of 51.48% for MWE identification and 49.98% for supersense tagging.

## 1 Introduction

Accurate segmentation and semantic disambiguation of minimal text units is a major challenge in the general pipeline of NLP applications. A machine translation system, for example, needs to decide what is the intended meaning for a given word or phrase in its context, so that it may translate it into an equivalent meaning in the target language.

While determining the meaning of single words is a difficult task on its own, the problem is compounded by the pervasiveness of Multiword Expressions (MWEs). MWEs are semantic units that span over multiple lexemes in the text (e.g. dry run, look up, fall flat). Their meaning cannot be inferred by applying regular composition rules on the meanings

of their component words. The task of semantic tagging is thus deeply intertwined with the identification of multiword expressions.

This paper presents our solution to the DiMSUM shared task (Schneider et al., 2016), where the evaluated systems are expected to perform both semantic tagging and multiword identification. Our pipeline system first detects and groups MWEs and then assigns supersense tags, as two consecutive steps. For MWE identification, we use a task-specific instantiation of the `mwetoolkit` (Ramisch, 2015), handling both contiguous and non-contiguous MWEs with some degree of customization (Cordeiro et al., 2015). Additionally, MWE type-level candidates are extracted without losing track of their token-level occurrences, to guarantee that all the MWE occurrences learned from the training data are projected onto the test corpus. For semantic tagging we adopted a predominant-sense heuristic.

In the remainder of this paper, we present related work (§ 2), then we present and discuss the results of the MWE identification subsystem (§ 3) and of the supersense tagging subsystem (§ 4). We then conclude and share ideas for future improvements (§ 5).

## 2 Related Work

Practical solutions for rule-based MWE identification include tools like jMWE (Kulkarni and Finlayson, 2011), a library for direct lexicon projection based on preexisting MWE lists. Finite-state transducers can also be used to take into account the internal morphology of component words and perform efficient tokenization based on MWE dictionaries (Savary, 2009). The problem of MWE identification

has also been modeled using supervised machine learning. Probabilistic MWE taggers usually encode the data using a begin-inside-outside scheme and learn CRF-like taggers on it (Constant and Sigogne, 2011; Schneider et al., 2014). The `mwe toolkit` (Ramisch, 2015) provides command-line programs that allow one to discover new MWE candidate lists, filter them and project them back on text according to some parameters. Our system uses the latter as basis for MWE identification.

Word sense disambiguation (WSD) methods can be roughly classified into knowledge-based, supervised and unsupervised. Knowledge-based methods use lexico-semantic taxonomies like WordNet to calculate the similarity between context and target words (Lesk, 1986). Supervised approaches generally use context-sensitive classifiers (Cabezas et al., 2001). Unsupervised approaches using clustering and distributional similarity (Brody and Lapata, 2008; Goyal and Hovy, 2014) can also be employed for WSD. Both supervised and unsupervised WSD techniques have also been used to distinguish literal from idiomatic uses of MWEs (Fazly et al., 2009; Diab and Bhutada, 2009). Nonetheless, systematically choosing the most frequent sense is a surprisingly good baseline, not always easy to beat (McCarthy et al., 2007; Navigli, 2009). This was also verified for MWE disambiguation (Uchiyama et al., 2005). Thus, in this work, we implemented a simple supervised predominant-sense heuristic and will investigate more sophisticated WSD techniques as future work.

### 3 MWE Identification

Our MWE identification algorithm uses 6 different rule configurations, targeting different MWE classes. Three of these are based on data from the training corpus, while the other three are unsupervised. The parameters of each configuration are optimized on a held-out development set, consisting of  $\frac{1}{9}$  of the training corpus. The final system is the union of all configurations.<sup>1</sup>

For the 3 supervised configurations, annotated MWEs are extracted from the training data and then filtered: we only keep combinations that have been annotated often enough in the training corpus. In

---

<sup>1</sup>When there is an overlap, we favor longer MWEs.

other words, we keep MWE candidates whose proportion of annotated instances with respect to all occurrences in the training corpus is above a threshold  $t$ , discarding the rest. The thresholds were manually chosen based on what seemed to yield better results on the development set. Finally, we project the resulting list of MWE candidates on the test data, that is, we segment as MWEs the test token sequences that are contained in the lexicon extracted from the training data. These configurations are:

**CONTIG** Contiguous MWEs annotated in the training corpus are extracted and filtered with a threshold of  $t = 40\%$ . That is, we create a lexicon containing all contiguous lemma+POS sequences for which at least 40% of the occurrences in the training corpus were annotated. The resulting lexicon is projected on the test corpus whenever that contiguous sequence of words is seen.

**GAPPY** Non-contiguous MWEs are extracted from the training corpus and filtered with a threshold of  $t = 70\%$ . The resulting MWEs are projected on the test corpus using the following rule: an MWE is deemed to occur if its component words appear sequentially with at most a total of 3 gap words in between them.

**NOUN<sup>2</sup>-KN** Collect all noun-noun sequences in the test corpus that also appear at least once in the training corpus (known compounds), and filter them with a threshold of  $t = 70\%$ . The resulting list is projected onto the test corpus.

We further developed 3 additional configurations based on empirical findings. We identify MWEs in the test corpus based on POS-tag patterns, without any filtering (and thus without looking at the training corpus)<sup>2</sup>:

**NOUN<sup>2</sup>-UKN** Collect all noun-noun sequences in the test corpus that never appear in the training corpus (unknown compounds), and project all of them back on the test corpus.

**PROPN<sup>2..∞</sup>** Collect sequences of two or more contiguous words with POS-tag PROPN and project all of them back onto the test corpus.

---

<sup>2</sup>For NOUN<sup>2</sup>-UKN, we exclude known compounds, as otherwise that would undo the filtering work done by NOUN<sup>2</sup>-KN.

**VP** Collect verb-particle candidates and project them back onto the test corpus. A verb-particle candidate is a pair of words under these constraints: the first word must have POS-tag VERB and cannot have lemma *go* or *be*. The two words may be separated by a N<sup>3</sup> or PROPN. The second word must be in a list of frequent non-literal particles<sup>4</sup>. Finally, the particle must be followed by a word with one of these POS-tags: ADV, ADP, PART, CONJ, PUNCT. Even though we might miss some cases, this final delimiter avoids capturing regular verb-PP sequences.

Table 1 presents the results for each isolated configuration (evaluated on the test corpus, with all MWEs). These results are calculated based on the fuzzy metrics of the shared task (Schneider et al., 2014), where partial MWE matches are taken into account. Our final MWE identification system is the union of all rule configurations described above. The final recall of the system is not the sum of coverage values because MWE candidate lexicons may overlap (multiple configurations may have identified the same MWE).

| Configuration          | Precision | Coverage |
|------------------------|-----------|----------|
| CONTIG                 | 57.9%     | 11.6%    |
| GAPPY                  | 36.0%     | 0.9%     |
| NOUN <sup>2</sup> -KN  | 100.0%    | 1.6%     |
| NOUN <sup>2</sup> -UKN | 80.2%     | 18.9%    |
| PROPN <sup>2..∞</sup>  | 96.0%     | 8.5%     |
| VP                     | 71.2%     | 4.2%     |

**Table 1:** Precision and coverage per MWE annotation. Coverage is the recall of each configuration applied independently.

### 3.1 Error Analysis

Table 2 presents the system results for the most common POS-tag sequences in the test corpus, using an exact match (a MWE is either correct or incorrect). Overall results are presented in both exact and fuzzy metrics.

**N\_N errors** Since our system looks for all occurrences of adjacent noun-noun pairs, we obtain a high

<sup>3</sup>In the remainder of the paper, we abbreviate the POS tag NOUN as N.

<sup>4</sup>The 13 most frequent non-literal particles: *about*, *around*, *away*, *back*, *down*, *in*, *into*, *off*, *on*, *out*, *over*, *through*, *up* (Sinclair, 2012).

| POS-tags        | Precision                | Recall                    | F <sub>1</sub> |
|-----------------|--------------------------|---------------------------|----------------|
| N_N             | $\frac{170}{278} = 61\%$ | $\frac{170}{181} = 94\%$  | 74.0%          |
| VERB_AD彭        | $\frac{43}{60} = 72\%$   | $\frac{43}{73} = 59\%$    | 64.9%          |
| ADJ_N           | $\frac{5}{6} = 83\%$     | $\frac{5}{69} = 7\%$      | 12.9%          |
| PROPN_PROPN     | $\frac{65}{82} = 79\%$   | $\frac{65}{66} = 98\%$    | 87.5%          |
| VERB_PART       | $\frac{31}{37} = 84\%$   | $\frac{31}{49} = 63\%$    | 72.0%          |
| PROPN_N         | $\frac{1}{1} = 100\%$    | $\frac{1}{34} = 3\%$      | 5.8%           |
| N_N_N           | $\frac{0}{0} = 100\%$    | $\frac{0}{22} = 0\%$      | 0.0%           |
| ADP_N           | $\frac{10}{14} = 71\%$   | $\frac{10}{22} = 45\%$    | 55.1%          |
| VERB_N          | $\frac{1}{5} = 20\%$     | $\frac{1}{16} = 6\%$      | 9.2%           |
| DET_N           | $\frac{4}{23} = 17\%$    | $\frac{4}{16} = 25\%$     | 20.2%          |
| ADJ_N_N         | $\frac{0}{0} = 100\%$    | $\frac{0}{11} = 0\%$      | 0.0%           |
| Overall (exact) | $\frac{364}{613} = 59\%$ | $\frac{364}{837} = 43\%$  | 50.2%          |
| Overall (fuzzy) | $\frac{460}{635} = 72\%$ | $\frac{461}{1115} = 41\%$ | 52.6%          |

**Table 2:** MWE identification results on test set per POS-tag.

recall for N\_N compounds. The most common false positive errors are presented below.

- **Not in the same phrase** In 19 cases, our system has identified two Ns that are not in the same phrase; e.g. *\*when I have a problem customer services don't want to know*. In order to realize that these nouns are not related, we would need parsing information. Nonetheless, it is not clear whether an off-the-shelf parser could solve these ambiguities in the absence of punctuation.
- **Partial N\_N\_N** 17 cases have been missed due to only the first two nouns in the MWE being identified; e.g. *\*Try the memory foam pillows!* – instead of *memory foam pillows*.
- **Partial ADJ\_N\_N** 10 cases have been missed; e.g. *\*My sweet pea plants arrived 00th May completely dried up and dead!* – instead of *sweet pea plants*. These cases are a consequence of the fact that we do not look for adjective-noun pairs (see ADJ\_N errors below).
- **Compositional N\_N** In 24 cases, our system identified a compositional compound; e.g. *\*Quality gear guys, excellent!* Semantic features would be required to filter such cases out.
- **Questionable N tags** 10 false noun compounds were found due to words such as *today* being tagged as nouns (e.g. *\*I'm saving gas today*). Another 5 cases had adjectives classified as nouns: *\*Maybe this is a kind of an artificial way to read an e-book*.

**VERB<sub>\_</sub>ADP errors** Most of the VERB<sub>\_</sub>ADP expressions were caught by the VP configuration, but we still had some false negatives. In 7 cases, the underlying particle was not in our list (e.g. *I regret ever going near their store*), while in 9 other cases, the particle was followed by a noun phrase (e.g. *Givin out Back shots*). 5 of the missed MWEs could have been found by accepting the particle to be followed by a SCONJ, or to be followed by the end of the line as delimiters. Most of the false positives were due to the verb being followed by an indirect object or prepositional phrase. We believe that disambiguating these cases would require valency information, either from a lexicon or automatically acquired from large corpora (Preiss et al., 2007).

**ADJ<sub>\_</sub>N errors** While the few ADJ<sub>\_</sub>N pairs that our system identified were usually correct MWEs, most of the annotated cases were missed. This is because we do not specifically look for adjective-noun pairs, due to the high likelihood of them being compositional. For example, a simple ADJ<sub>\_</sub>N annotation scheme (as performed in NOUN<sup>2</sup>-UKN) would have achieved a precision of only  $69/505 = 14\%$ .

Out of all annotated sentences, in 23 cases the noun is transparent, and we could replace the adjective by a synonym; e.g. *I guess people are going again next week, do you think you'll go?* (which could be replaced by *the following week*). In another 17 cases, the noun is transparent and the adjective suggestive of the global meaning, even though it is fixed; e.g. *23 is the lucky number* (but not *\*fortunate number*, albeit related to *luck*).

These cases could be dealt with using fixedness tests such as substitution and permutation (Fazly et al., 2009; Ramisch et al., 2008).

**PROPN<sub>\_</sub>PROPN errors** Since our system looks for all occurrences of adjacent PROPN pairs, we obtain near-perfect recall for PROPN<sub>\_</sub>PROPN compounds. Most false positives were caused by possessives or personal titles, which were annotated as part of the MWE in the gold standard.

**VERB<sub>\_</sub>PART errors** The results for VERB<sub>\_</sub>PART are similar to the ones found for VERB<sub>\_</sub>ADP: 3 false negatives are due to the particle not being in our list, and in another 7 cases they are followed by a noun phrase. Additionally, in 6 cases the particle was fol-

lowed by a verb (e.g. *Stupid Kilkenny didn't get to meet @Royseven*). 4 false positives were CONTIG cases of *go to* being identified as a MWE (e.g. *\*In my mother's day, she didn't go to college*). In the training corpus, this MWE had been annotated 57% of the time, but in future constructions (e.g. *Definitely not going to purchase a car from here*). Canonical forms would be easy to model with a specific contextual rule of the form *going to* verb.

**PROPN<sub>\_</sub>N errors** While the few PROPN<sub>\_</sub>N pairs we found were all correct MWEs, most of the annotated cases were missed. These cases did not earn special attention during the development of the system due to an incorrectly perceived infrequency. However, using only an annotation scheme such as NOUN<sup>2</sup>-UKN, we could have achieved a precision of 72% for these MWEs.

**N<sub>\_</sub>N<sub>\_</sub>N errors** The occurrence of N<sub>\_</sub>N<sub>\_</sub>N sequences is rare in the training corpus, and we did not specifically look for them, which explains our recall of 0%. By annotating the longest sequence of Ns in the corpus (NOUN<sup>2..∞</sup>), we could have obtained a precision of 56% and recall of 91% for N<sub>\_</sub>N<sub>\_</sub>N. The precision of N<sub>\_</sub>N would also increase to 70% (with a recall of 93%). If we then replace NOUN<sup>2</sup> by NOUN<sup>2..∞</sup>, the full-system's F-score increases to 56.23%.

**ADP<sub>\_</sub>N errors** The false positives were ambiguous determinerless PPs that can be compositional or not according to the context. For instance, the system identified *\*Try them all, in order* after seeing *The Big Lebowski is in order tonight*. False negatives were mainly due to threshold-based filters, like *at all* and *in peace*. Unsupervised MWE discovery on large corpora using context-sensitive association measures could have helped in these cases.

**VERB<sub>\_</sub>N errors** We only generated 4 false positives, which look like light-verb constructions missed by the annotators (*give ride, place order*). False negatives include 8 cases of gerunds POS-tagged as verbs (e.g. *to listen to flying saucers*), which are actually similar to ADJ<sub>\_</sub>N cases discussed above. We also found 7 false negatives, mainly light-verb constructions, that were not present in the training corpus (*take place, take control*).

**DET\_N errors** 8 false negatives were compositional time adjuncts (e.g. *this morning*, *this season*). False positives are mainly cases that seem inconsistent between training and test data concerning frequent quantifiers (e.g. *a lot*, *a bit*, *a couple*).

Noun compounds (two or more Ns in a row) account for a significant proportion of MWEs in the training corpus ( $601/4232 = 14\%$ ) and an even larger amount of the testing corpus ( $203/837 = 24\%$ ). The NOUN<sup>2</sup> rule sets were essential to obtaining good results. If we remove NOUN<sup>2</sup> from our system, its global performance would drop to a fuzzy  $F_1 = 33.79\%$ .

The domain of the corpus does not seem to have a great influence on our method’s performance. Our lowest performance is on the Reviews subcorpus (fuzzy  $F_1 = 49.57\%$ ) and our best performance is on TED (fuzzy  $F_1 = 56.76\%$ ).

Some of the missed MWEs are questionable and we feel that our system should not annotate them. These include regular verbal chains (*shouldn’t have*, *have been*), infinitival and selected preposition *to* (*to take*, *go to*) and compositional noun phrases (*this Saturday*). Fortunately, these cases correspond to a small proportion of the data.

## 4 Supersense Tagging

Supersense tagging takes place after MWE identification. Sense tags are coarse top-level Wordnet synsets. The tagset for nouns and verbs has respectively 26 and 15 supersense tags. We use a predominant-sense heuristic to perform WSD.

Before tagging the test data, our system collects all annotated supersense tags from MWEs in the training corpus. We create a mapping with entries of the form  $(w_1, w_2, \dots, w_N) \mapsto S$ , where each MWE component  $w_i = (\text{lemma}_i, \text{POStag}_i)$ . This mapping indicates the most frequent tag  $S$  associated a given MWE. Single words are treated as length-1 MWEs and are also added to this mapping.

The supersense tagging algorithm then goes through all segmented units (MWEs or single words) in the test corpus and annotates them according to the most common tag seen in the training set. If a tag has not been seen for a given word or MWE, we do not tag it at all. This heuristic is very simple and not very realistic. Nonetheless, it allowed us to

have a minimal supersense tagger quickly and then focus on accurate MWE identification as the main contribution of our system.

### 4.1 Error Analysis

Tables 3 and 4 show the confusion matrices of our system for the 10 most common tags. Each row corresponds to a gold tag and contains the distribution of predicted tags. The perfect system would have numbers only in the main diagonal and zeros everywhere else. The skewed distribution of supersense tags makes our simple heuristic quite effective when the MWE/word has been observed in the training data.

Known nouns seem easy to tag. Most of our errors come from the fact that we did not observe instances of a noun in the training data, and thus did not assign it any tag (column “skipped”). Some distinctions seem harder than others due to similar semantic classes: attributive/cognition and event/time.

The occurrence of verbs in the training data is less of a problem than their polysemy. Stative verbs correspond to the large majority of verbs in the dataset. This is magnified by the nature of the corpus: reviews tend to use stative verbs to talk about product characteristics, tweets often use them to describe the state of the author. While very frequent, stative verbs are also difficult to disambiguate: most false negatives were tagged as change verbs while most false positives were tagged as social verbs. Some distinctions seem extremely hard to make, specially for less frequent supersense tags like contact/motion and perception/cognition.

## 5 Conclusions and Future Work

We developed a simple rule-based system that was able to obtain competitive results. Its main advantage is that it was very quick to implement in the context of the generic framework of the mwetoolkit. The system is freely available as part of the official mwetoolkit release.<sup>5</sup> The main limitation of our system is that it cannot properly take unseen MWEs into account and generalize from seen instances. Moreover, most of our rule sets are highly language dependent.

Ideas for future improvements include:

**Table 4:** Confusion matrix for verb supersense tagging. Skipped segments are those absent in training data.

- Adding specific rules for verb-particle constructions, probably based on a lexicon of idiomatic combinations.
- Replacing the CONTIG method by a sequence tagger for contiguous MWEs (e.g. using a CRF), in order to identify unknown MWEs based on generalizations made from known MWEs (Constant and Sigogne, 2011; Schneider et al., 2014).
- Taking parse trees into account to distinguish MWEs from accidental cooccurrences (Nasr et al., 2015).
- Using semantic-based association measures and semantic-based features based on word embeddings to target idiomatic MWEs (Salehi et al., 2015).
- Using fixedness features to identify and disambiguate very productive patterns like ADJ\_N (Ramisch et al., 2008; Fazly et al., 2009).
- Developing a more realistic WSD algorithm for supersense tagging, able to tag unseen words and MWEs and to take context into account.

## Acknowledgments

This work has been funded by the French Agence Nationale pour la Recherche through projects PARSEME-FR (ANR-14-CERA-0001) and ORFEO (ANR-12-CORP-0005), and by French-Brazilian cooperation projects CAMELEON (CAPES-COFECUB #707/11) and AIM-WEST (FAPERGS-INRIA 1706-2551/13-7). Part of the results presented in this paper were obtained through research on a project titled "Simplificação Textual de Expressões Complexas", sponsored by Samsung Eletrônica da Amazônia Ltda. under the terms of Brazilian federal law No. 8.248/91.

## Abstract

This paper describes our approach towards the SemEval-2016 Task 10: Detecting Minimal Semantic Units and their Meanings (DiMSUM). We consider that the two problems are similar to multiword expression detection and supersense tagging, respectively. The former problem is formalized as a sequence labeling problem solved by first-order CRFs, and the latter one is formalized as a classification problem solved by Maximum Entropy Algorithm. To carry out our pilot study quickly, we extract some simple features such as words or part-of-speech tags from the training set, and avoid using external resources such as WordNet or Brown clusters which are allowed in the supervised closed condition. Experimental results show that much further work on feature engineering and model optimization needs to be explored.

## 1 Introduction

In the community of natural language processing, multiword expressions (MWEs) detection (Schneider et al., 2014b; Schneider et al., 2014a) and supersense tagging (Ciaramita and Johnson, 2003; Ciaramita and Altun, 2006) have received much research attention due to their various applications such as syntactic parsing (Candito and Constant, 2014; Bengoetxea et al., 2014), semantic parsing (Banarescu et al., 2013), and machine translation (Carpuat and Diab, 2010). However, not much attention has been paid to the relationship between MWEs and supersenses (Piao et al., 2005; Schneider and Smith, 2015).

**Output:** Security<sub>n.state</sub> increased<sub>v.change</sub> in

Mumbai<sub>n.location</sub> amid

terror\_threats<sub>n.communication</sub>

ahead of Ganshotsav<sub>n.event</sub>

---

Figure 1: An DiMSUM Example. Given a tokenized and POS-tagged sentence, outputs will be a representation annotated with MWEs and supersenses. Noun and verb supersenses start with “n.” and “v.”, respectively. “\_” joins tokens within a MWE.

The DiMSUM shared task (Schneider et al., 2016) at SemEval 2016 aims to predict a broad-coverage representation of lexical semantics giving an English sentence. This representation consists of two facets: a segmentation into minimal semantic units, and a labeling of some of those units with semantic classes. Based on the task descriptions, we consider the concepts of minimal semantic units and semantic classes are identical to those of MWEs and supersenses, respectively. Figure 1 shows an input example and its corresponding outputs of DiMSUM task.

Prior work on MWE detection using unsupervised methods includes lexicon lookup (Bejček et al., 2013), statistical association measures (Ramisch et al., 2012), parallel corpora (Tsvetkov and Wintner, 2010), or hybrid methods (Tsvetkov and Wintner, 2011). More sophisticated methods use supervised techniques such as conditional random fields (CRFs) (Shigeto et al., 2013; Constant et al., 2012; Vincze et al., 2013) or structured perceptron

(Schneider et al., 2014a), and usually achieve better performance. Compared to most aforementioned systems, MWEs in the DiMSUM task may be not contiguous or restricted by syntactic construction, which increases the detection difficulty.

Supersense tagging has been studied on diverse languages such as English (Ciaramita and Johnson, 2003; Ciaramita and Altun, 2006; Johannsen et al., 2014; Schneider and Smith, 2015), Italian (Attardi et al., 2010), Chinese (Qiu et al., 2011) and Arabic (Schneider et al., 2012). It is usually formalized as a multi-classification problem solved by supervised approaches such as perceptron. In the DiMSUM task, both single-word and multiword expressions that holistically function as noun or verb, can be considered as units for supersense tagging.

Following prior work using supervised approaches, we divide DiMSUM task into two subtasks: first, MWEs detection is treated as a sequence labeling task using first-order CRFs; second, supersense tagging is treated as a multi-classification task using Maximum Entropy Algorithm. We focus on the supervised closed condition, so only the training set are used for training both submodels separately. Then results generated on the test set are submitted for official evaluation. The evaluation results show that our system performance are not as good as those of other teams, since we leverage only some simple features such as words, POS, etc. Syntactic features and semantic resources such as WordNet (Miller, 1995) and Brown clusters (Brown et al., 1992) are not used. This suggests that further work needs to be done on feature engineering and model optimization.

## 2 Multiword Expression Detection

In the training set, sentences are tokenized into words, and every word has been annotated with POS and lemma. We formalize MWE detection as a sequence labeling problem, so Mallet (McCallum, 2002), Off-the-shelf implementation of CRFs, is used to handle this task. All the labels of our CRF model, extracted from the training set, are listed as follows:

- O, which indicates that the current word does not belong to a MWE.

|   |  |
|---|--|
| 1 | current word $w_i$   |
| 2 | whether current word $w_i$ is in the beginning of a sentence |
| 3 | whether current word $w_i$ is in the end of a sentence       |
| 4 | previous word $w_{i-1}$                                      |
| 5 | next word $w_{i+1}$  |
| 6 | POS of current word $t_i$                                    |
| 7 | POS of previous word $t_{i-1}$                               |
| 8 | POS of next word $t_{i+1}$                                   |
| 9 | whether current word $w_i$ is the only word of a sentence    |

Table 1: Feature templates for MWE Detection.

- B, which indicates that the current word is the first token of a MWE.
- I, which denotes that the current word continues a MWE.
- o, which indicates that the current word does not belong to a MWE, but inside the gap of another MWE.
- b, which denotes that the current word is the first token of a MWE and inside the gap of another MWE.
- i, which indicates that the current word continues a MWE and inside the gap of another MWE.

Compared with prior work on MWE detection, one difference in DiMSUM is that gaps may exist in MWEs, which increases difficulty to recognize them correctly. For example, given “Bramen Honda was a bit of a hassle .” as input, the output labels will be “Bramen<sub>B</sub> Honda<sub>I</sub> was<sub>B</sub> a<sub>b</sub> bit<sub>i</sub> of<sub>o</sub> a<sub>I</sub> hassle<sub>I</sub> .O”. Tag “B” and tag “I” can be discontinuous and there may be several “b”, “i” or “o” between them.

In order to implement a system for our pilot study quickly, we only use some simple features which are shown in Table 1. The values of these features are discrete, namely 0 or 1. The motivation of Feature 7 and 8 is to help our model to generate correct label sequences which satisfy some constraints. For example, only “B” and “O” can be located in the beginning of a sentence, and “b”, “i” and “o” cannot be in the end of a sentence. Feature 9 is added since most of words which is the only one of a sentence, are tagged as “O” in the training set.

## 3 Supersense Tagging

We treat supersense tagging as a multi-classification problem using Maximum Entropy Algorithm, and

| noun                       | verb              |
|----------------------------|-------------------|
| act, animal, artifact      | body, change      |
| attribute, body, cognition | cognition, social |
| communication, event       | communication     |
| food, group, location      | competition       |
| motive, natural\_object    | consumption       |
| other, person, phenomenon  | contact, weather  |
| plant, possession, process | creation, motion  |
| quantity, relation, shape  | emotion, stative  |
| state, substance, time     | perception        |
| feeling                    | possession        |

Table 2: Supersense Categories.

|   |   |
|---|---|
| 1 | $w_1 w_2 \dots w_n$ of $mwe_i$ or $swe_i$         |
| 2 | $w_1 w_2 \dots w_n$ of $mwe_{i-1}$ or $swe_{i-1}$ |
| 3 | $w_1 w_2 \dots w_n$ of $mwe_{i+1}$ or $swe_{i+1}$ |
| 4 | $t_1 t_2 \dots t_n$ of $mwe_i$ or $swe_i$         |
| 5 | $t_1 t_2 \dots t_n$ of $mwe_{i-1}$ or $swe_{i-1}$ |
| 6 | $t_1 t_2 \dots t_n$ of $mwe_{i+1}$ or $swe_{i+1}$ |

Table 3: Feature templates for Supersense Tagging.  $swe$  or  $mwe$  denotes a single or multiple word expression.  $mwe_i$ ,  $mwe_{i-1}$  and  $mwe_{i+1}$  denote current, previous and next multiple word expressions, respectively.  $w_1 w_2 \dots w_n$  and  $t_1 t_2 \dots t_n$  denote word and POS combinations, respectively.

Mallet is also used to implement our supersense tagging subsystem. Based on the task description, single-word or multiword expressions can receive supersenses, so both of them are treated as classification units. This suggests that supersense tagging does not totally depend on the results of MWE detection. According to Schneider and Smith (2015), supersense categories are listed as Table 2.

Given “Bramen<sub>B</sub> Honda<sub>I</sub> was<sub>B</sub> a<sub>b</sub> bit<sub>i</sub> of<sub>o</sub> a<sub>j</sub> hassle<sub>I</sub> .<sub>O</sub>” as input, our model will firstly transform it into classification units based on the labels, “[Bramen Honda], [was a hassle], [a bit], [of], [.]”. Since the span of “[was a hassle]” includes “[a bit]” and “[of]”, it is located before “[a bit]” and “[of]”. Then these units will be classified into supersense categories and an empty class which receives the units which do not belong to any category.

Supersense tagging features are shown in Table 3. The values of these features are also discrete.

| Features | F <sub>1</sub> | Features | F <sub>1</sub> |
|----------|----------------|----------|----------------|
| Baseline | 28.9           | Baseline | 50.3           |
| +4       | 36.5           | +2       | 42.2           |
| +5       | 31.4           | +3       | 40.1           |
| +6       | 51.5           | +4       | 55.5           |
| +7       | 50.4           | +5       | 50.7           |
| +8       | 19.9           | +6       | 52.2           |
| +9       | 34.8           |          |                |

(a)

(b)

Table 4: Subtable (a) and (b) denote contributions of features in Table 1 and 3, respectively. “+” denotes that only the feature in the current line is added. The numbers in the first column correspond to the ones in Table 1 and 3, respectively.

## 4 Experiments

### 4.1 Experimental Settings

There are three conditions in the DiMSUM<sup>1</sup> shared task at SemEval 2016. In the supervised closed condition, only the training set, WordNet and Brown clusters are allowed to be used. In the semi-supervised closed condition, all of the above are permitted, plus the Yelp Academic Dataset. In the open condition, all available resources can be used. We carry out our experiments according to the demands in the supervised closed condition, but WordNet and Brown clusters are not used. The test set consists of 16,500 words in 1,000 English sentences which are drawn from the following sources: reviews from the TrustPilot corpus (Hovy et al., 2015), tweets from the Tweebank corpus (Kong et al., 2014), TED talks from the WIT3 archive (Cettolo et al., 2012).

During the development period, we split 30% data from the training set as our development set and use the remainder for training. The maximum training iteration is set as 500. The evaluation scripts (v1.5) released by task organizers are used for tuning parameters and features. During the official evaluation period, we use all the training set to train our CRF and Maximum Entropy models, and prediction results on the test set are submitted.

### 4.2 Development Results

The contributions of features are shown in Table 4. The baseline in Table 4a does not only use Feature 1

Table 5: Official Evaluation Results (in %) of DiMSUM 2016.

in Table 1, but also Feature 2 and 3 since they help to generate correct label sequences. The baseline in Table 4b uses only Feature 1 in Table 3. It can be seen that Feature 8 in Table 1, Feature 2 and 3 in Table 3 lead to decreases of  $F_1$  scores, so they should be excluded<sup>2</sup>.

### 4.3 Final Results

Table 5 shows official evaluation results. The columns “ $\mu\text{-M}$ ”, “ $\mu\text{-S}$ ” and “ $\mu\text{-C}$ ” denote microaverages of F1 scores for MWEs (-M), supersenses (-S) and combined (-C), respectively. “Tw”, “R” and “TED” indicate F1 scores for tweets, reviews and TED talks, respectively. The results in the last column denote macroaverages of F1 scores across three domains. Compared with other supervised closed condition systems, the performance of our system is not good. This suggests that that there is substantial work to be done on exploring more features to improve our system.

Apart from using simple features, another reason that leads to poor performance of our system is that we use a pipeline model. Since errors generated in the first step are inherited by the second step, the performance of supersense tagging further decreases. Error propagation can be reduced by leveraging joint models. Previous work (Schneider and Smith, 2015) has already leveraged joint models on this issue, so we plan to follow this approach in our future work.

Moreover, it is worth noting that UW-CSE system in the supervised closed condition, achieves competitive results compared with the best scoring systems in the open condition. This suggests that good performance can still be obtained without too much external resources or data.

<sup>2</sup>In the official evaluation, these features are included due to our coding problems, so this may be one of the reasons due to poor performance.

| MWE Features   | Improved $F_1$ |
|--|----------------|
| prefix of $w_i$  | 11.2           |
| suffix of $w_i$  | 10.4           |
| whether the first character of $w_i$ is uppercase          | 12.1           |
| whether $w_i$ contains non-alpha or non-numeric characters | 7.4            |
| context POS bigram ( $t_i t_{i+1}$ )                       | 21.4           |
| word + context POS ( $t_{i-1} w_i t_{i+1}$ )               | 11.4           |
| Supersense Features  | Improved $F_1$ |
| whether $swe_i$ is a noun                                  | 2.9            |
| whether $swe_i$ is a verb                                  | 5.1            |
| first character and POS combinations of $swe_i$ or $mwe_i$ | 6              |

Table 6: Expanded Feature templates and their improved performance on the development set.  $w_i$  denotes the current word and  $t_i$  denotes the POS of current word.  $swe_i$  or  $mwe_i$  denotes the current single or multiple word expression.

### 4.4 Feature Enrichment

After the evaluation results are released, we expand our feature templates to improve the performance. Table 6 shows the contributions of these expanded features evaluated on the development set and some of them are inspired by (Schneider et al., 2014a). Compared with the performance improvements of MWE detection, the performance of supersense tagging increases less. On the test set, “ $\mu\text{-M}$ ”, “ $\mu\text{-S}$ ” and “ $\mu\text{-C}$ ” can achieve 45.6%, 46.1% and 46.0% using all the features proposed in this paper.

### 4.5 Error Analysis

We calculate false positive (FP) and false negative (FN) errors on the test set. For MWE detection errors in Table 7, a MWE is counted as FP if its boundary is incorrectly identified, and a MWE is counted as FN if it has not been recognized. Table 7 shows that “\*\*\*\_NOUN” is the most difficult pattern to be

| False Positive |       | False Negative |       |
|----------------|-------|----------------|-------|
| POS Pattern    | Count | POS Pattern    | Count |
| NOUN_NOUN      | 25    | NOUN_NOUN      | 100   |
| VERB_NOUN      | 20    | ADJ_NOUN       | 59    |
| DET_NOUN       | 17    | VERB_ADP       | 34    |
| VERB_ADP       | 16    | NOUN_NOUN_NOUN | 19    |
| ADP_NOUN       | 14    | PROPN_NOUN     | 15    |
| ADJ_NOUN       | 12    | DET_NOUN       | 15    |
| ADJ_ADP        | 11    | VERB_NOUN      | 14    |
| VERB_PART      | 10    | PROPN_PROPN    | 13    |
| ADV_ADV        | 8     | ADJ_NOUN_NOUN  | 11    |
| VERB_ADP_NOUN  | 7     | ADP_NOUN       | 11    |

Table 7: Top 10 false positive and false negative patterns for MWE detection.

| False Positive  |       | False Negative  |       |
|-----------------|-------|-----------------|-------|
| Supersense      | Count | Supersense      | Count |
| n.artifact      | 783   | n.person        | 216   |
| v.statative     | 629   | n.communication | 172   |
| n.person        | 499   | n.artifact      | 168   |
| n.cognition     | 493   | v.change        | 165   |
| v.social        | 441   | n.act           | 161   |
| v.cognition     | 373   | v.statative     | 154   |
| v.communication | 303   | n.group         | 136   |
| n.group         | 269   | n.attribute     | 117   |
| n.communication | 253   | v.cognition     | 98    |
| n.time          | 237   | n.location      | 82    |

Table 8: Top 10 false positive and false negative supersenses.

recognized. One reason might be that noun phrases often consist of weak MWEs, while weak MWEs are harder to be detected since their vocabularies are more flexible and their meanings are more ambiguous than those of strong MWEs.

For supersense tagging errors in Table 8, a predicted supersense is counted as FP if it is not identical to its corresponding gold supersense, and a gold supersense is counted as FN if it has not been recognized. The single or multiple word expression without a supersense is not taken into account. Table 8 shows that “n.artifact” and “n.person” are more difficult to be tagged. One reason might be “n.artifact” is usually associated with abstract nouns such as “thing” or polysemous words such as “watch”. “n.person” recognition might be difficult since various person names lead to many out-of-vocabulary words. This problem may be more serious in the supervised closed condition. In addition, stative verbs are very frequent and also difficult to be disambiguated.

## 5 Conclusion

We attend the DiMSUM shared task at SemEval 2016 which aims to predict MWEs and supersenses when an English sentence is given. Two submodels, namely CRFs and Maximum Entropy, are explored to detect multiword expressions and supersenses, respectively. Experimental results in the official evaluation suggest that there is substantial work to be done to improve the performance of our system.

In future work, we plan to extend our work in two directions. Firstly, feature templates need to be further expanded and finetuned. Secondly, joint models, which may not only reduce error propagation, but also utilize relations between MWEs and supersenses, can be used to facilitate both subtasks.

## Abstract

The SemEval 2016 DiMSUM Shared Task concerns the detection of minimal semantic units from text and prediction of their coarse lexical categories known as supersenses. Our approach is to define this task as a binary classification problem approachable by straightforward machine learning methods.

We start by detecting semantic units by matching text spans against several large dictionaries, including the English WordNet, expressions derived from the Yelp Academic Dataset and concepts from the English Wikipedia, generating a set of potential supersenses for each matched span. For each potential supersense and text span pair a binary machine learning example is defined. We classify these examples using an ensemble method, taking as the final predicted supersense the one with the highest confidence score.

Our system achieves good performance on the supersense classification task but has limited performance for detection of multi-word semantic units. We show that the task of supersense prediction can be effectively defined as a binary classification task.

## 1 Introduction

The SemEval 2016 DiMSUM Shared Task<sup>1</sup> concerns the detection of *minimal semantic units* and their semantic classification using *supersenses* (Schneider et al., 2016). The minimal semantic units can consist of either single words or *multiword expressions (MWE)* in cases where multiple words

form a lexical item. The concept of MWE as used in the DiMSUM task is described in detail in Schneider et al. (2014). The *supersenses* are broad-coverage, coarse lexical categories, 26 for nouns and 15 for verbs. These supersenses mostly correspond to the WordNet lexicographer files. A detailed description of the supersenses is in Schneider and Smith (2015). Automated supersense tagging has previously been explored by e.g. Curran (2005), Ciaramita and Altun (2006) and Johannsen et al. (2014).

In the DiMSUM task systems must both detect the minimal semantic units and assign correct supersenses for them. The final metric of the shared task is the averaged performance on these tasks, which are also evaluated independently. The systems can approach these tasks either independently (e.g. in a pipeline) or through a joint model.

We approach the DiMSUM task as a machine learning classification task where examples are generated for all semantic units found in a pre-defined dictionary. These semantic units are classified into one of the 41 supersenses by generating an example for each possible semantic unit + supersense pair, turning the task of assigning one of many supersenses into a binary classification problem. In this manner, the task becomes a generalized machine learning task for which almost any classifier can be used.

The DiMSUM shared task defines three subtasks or data conditions in which the systems can participate, varying in the amount of resources that are allowed to be used. The *supervised closed* condition defines the most limited case where participants can use the labeled training corpus, the English Word-

<sup>1</sup><http://dimsum16.github.io/>

Net lexicon and two sets of Brown word clusters. In the *semi-supervised closed* condition the Yelp Academic Dataset can also be used, and in the *open* condition systems may use any and all resources available.

## 2 Data and Methods

### 2.1 Datasets

The DiMSUM corpus and evaluation tools, version 1.5, were provided by the task organizers. The corpus consists of a training and test set. The training set is a unified combination of the STREUSLE 2.1 corpus of web reviews, and the Ritter and Lowlands Twitter datasets, and consists of 4,799 sentences with tokenization, POS, MWE and supersense annotation. The test set consists of 1,000 sentences from online reviews, tweets and TED talk transcripts, with only tokenization and POS annotation.

The Yelp’s Academic Dataset<sup>2</sup>, which consists of JSON objects describing 13,490 businesses, 330,071 reviews and 130,873 users, was used with permission from Yelp Inc. WordNet version 3.0 (Fellbaum, 1998) was used through NLTK version 3.1 (Bird et al., 2009). For the English Wikipedia, the dump of titles in the main namespace *enwiki-20160113-all-titles-in-ns0.gz* was used<sup>3</sup>. Wikipedia page categories were downloaded using the Wikipedia Python library<sup>4</sup> by Jonathan Goldsmith.

### 2.2 System Overview

Our system follows a straightforward machine learning approach where examples are first generated and then classified using a standard classifier library. The task specific code is in the example generation part, which consists of two steps: 1) detection of minimal semantic units and 2) assignment of candidate supersenses for these units.

The detection of minimal semantic units is a rule-based step consisting mostly of dictionary matching. One sentence is processed at a time, one token at a time. For each token, the token itself and the following five tokens are first tested for a match, then the

token and the next four tokens, and so on until just the token on its own. A set of *taggers* are applied for each span of tokens, and if any of the taggers finds a match, one or more examples are generated.

All tokens that are part of the matched set are then “consumed” and example generation continues from the next free token. In this manner, each token is assigned to the longest matched minimal semantic unit. As a consequence, each token may belong to a maximum of one candidate semantic unit. We do not attempt to detect disjoint MWEs.

A tagger will provide for each positive match a list of potential supersenses. A feature vector is built for each combination of the matched span of tokens and potential supersenses, with the example containing the correct supersense labeled as a positive and the rest as negatives.

### 2.3 Taggers

In our system taggers are the modules that detect minimal semantic units among the tokens in the sentence. For each set of consecutive tokens each tagger can generate zero or more candidate supersenses. Each unique candidate supersense will then be used to produce one example for classification.

The *WordNet tagger* is used in all three conditions as the primary tagger. Tested tokens are joined to a span by first using their lemmas and if no match is found by using their exact words. For the joined span all synsets are retrieved from WordNet and for each synset the corresponding lexicographer file name is added as a potential supersense. In the case of the *noun.Tops* file name the span itself is added as a supersense if it directly matches a known supersense.

The *Out-of-Vocabulary (OoV) tagger* is used in all three conditions to match semantic units not detected by the other taggers, providing a fuzzy matching system for common positive spans not included in any of the dictionaries. It detects such constructs as Twitter @-codes (*n.person*), possessive suffix tokens starting with an apostrophe (*v.stative*) and words whose DiMSUM supersense differs from their WordNet lexicographer file name, commonly businesses such as “restaurant”, “store” or “hotel” (*n.group*). Cases for the OoV tagger were determined manually using the DiMSUM training corpus.

<sup>4</sup><https://github.com/goldsmith/Wikipedia>

### 2.3.1 The Yelp Tagger

The *Yelp tagger* is used in the *semi-supervised closed* and *open* conditions. First, three types of information are extracted from the Yelp Academic Dataset. For business objects the name of the business itself is used, but businesses also contain information on nearby schools and neighborhoods, and these are likewise added to the dictionary. When matching token sets, the businesses provide the *n.group* supersense and schools and neighborhoods the *n.location* supersense. Exact matches are tested for all of these cases.

Many business names have a common last noun, as in “Harvard Square Cafe” or “Minami Sushi”. Thus, for token sets consisting only of nouns and proper nouns (POS tags *NOUN* or *PROPN*) a match is generated if the last token in the set matches the last token of any Yelp business or location. Candidate supersenses are generated based on all Yelp objects in which a token from the set is found in a corresponding position (first, middle or last). In addition to the *n.group* and *n.location* supersenses the additional supersense *n.food* is generated for the token “Restaurants”.

Yelp user objects contain the first name and the last initial of the user. All first names are added to a dictionary. When detecting potential matches, first names of more than two characters are used as matches for the *n.person* supersense, tested against the first token in sets of no more than two upper-cased tokens.

### 2.3.2 The Wikipedia Tagger

The *Wikipedia tagger* is used only in the *open* condition. All token sets for which a match cannot be provided by the WordNet tagger are compared against the list of Wikipedia page titles. Before matching the parenthesized disambiguation parts are removed from the titles. For matching titles, potential supersenses are provided according to the categories of that page. A page category can match zero or more DiMSUM supersenses.

Common Wikipedia page categories, present in pages for titles matching the DiMSUM training set, are manually assigned to supersenses if they are relevant for the DiMSUM task. For example, a category ending in “births” (e.g. “1968 births”) corresponds to the *n.person* supersense, common media

categories such as “album”, “game”, “television” or “comics” correspond to *n.communication* and any category ending in “companies” to *n.group*.

Based on these rules, the page categories of all matched Wikipedia titles are automatically mapped to supersenses. This mapping is done only for the subset of Wikipedia page titles found in the entire DiMSUM corpus, as processing the large Wikipedia dataset is quite time consuming. In this way, the resulting subset of 1,110 page titles and categories linked to corresponding DiMSUM supersenses can also be easily distributed alongside our source code.

## 2.4 Feature Representation

For each candidate token set + supersense pair a feature vector is built for machine learning. The same feature representation is used in all three DiMSUM task conditions.

For each token in the set a feature is built for the *lemma*, *POS* and *word* values. For the first and last tokens in the set, additional copies of these features are built, marked with the token’s position. If the set consists of only a single token, an additional copy of these features is likewise built, marking that they come from a single-token example.

For the whole set of tokens, the consecutive *lemma*, *POS* and *word* values of the entire set are catenated together as features. The supersense of the token set + supersense pair is added as a feature. The supersenses of all the other examples generated for the same token set are also added as features distinct from the supersense feature of the current pair.

## 2.5 Machine Learning

For machine learning we use the scikit-learn library version 0.16.1 (Pedregosa et al., 2011). After examples are generated for each token set + supersense pair a binary classifier is used to classify them as either positives or negatives. We classify the examples with the Extra Trees Classifier ensemble method (Geurts et al., 2006) using its *predict\_proba* function which gives probability estimates. For each token set, the final prediction is the supersense with the highest probability estimate among all supersenses predicted as positive for that token set.

### 3 Results and Discussion

The official results for the six teams participating in the DiMSUM shared task are shown in Table 1. Using the primary metric of the shared task, macro-averaged performance over both the minimal semantic unit detection and supersense assignment tasks, our system (BCED) was ranked third out of four participants in the *supervised closed* condition, fourth out of four participants in the *open* condition and was the only participating system in the *semi-supervised closed* condition.

#### 3.1 Minimal Semantic Units

Compared to the other systems, the major limitation in our system was in the detection of the minimal semantic units. Our approach of detecting known MWEs, even using a very large dictionary such as the Wikipedia, was not sufficient to cover the scope of the DiMSUM MWEs, which consist of not only compound words and common idioms, but also more generalized noun phrases.

The numbers of generated examples are shown in Table 2. The vast majority of examples are detected by the WordNet tagger. It's notable how few additional positives are detected with the Wikipedia and Yelp dictionaries, even though the Wikipedia tagger considers only examples missed by the WordNet tagger. The number of examples detected by the OoV tagger doesn't change much between the conditions, as it mostly matches special cases not in any of the dictionaries.

The primary issue with the dictionary matching approach is that approximately a third of real positive examples are missed in all three conditions. The addition of first the Yelp and then the Wikipedia taggers decreases this number by 392 examples but compared to the total missed this is a relatively small improvement. Looking at the categories of the missed examples, MWEs that are *too long* (longer than six tokens) and those with *gaps* fall outside the scope of the system. Inclusion of the Yelp and Wikipedia taggers reduces the token sets for which *no match* is found by a considerable 718 examples, but there is a corresponding increase of 64 missing *type* examples for which a correct candidate supersense was not found.

Finally, the *nested* category highlights an inter-

|              | Super | Semi  | Open  |

| total -      | 78714 | 78400 | 80158 |
| too long     | 6     | 6     | 6     |
| no match     | 3206  | 2876  | 2488  |
| gaps         | 426   | 426   | 426   |
| type         | 2783  | 2768  | 2847  |
| nested       | 830   | 970   | 1092  |
| total missed | 7251  | 7046  | 6859  |

**Table 2:** Example generation for the training corpus. Each column corresponds to one of the conditions. The uppermost rows show the positive and negative examples generated by each of the four taggers, followed by the combined totals. After these are shown the five categories of false negative examples followed by their totals.

esting issue in example generation. Even while the Yelp and Wikipedia taggers provide more matches, at the same time the number of examples that are undetectable due to being nested within a false, longer MWE increases by 262. The issue of missing nested examples could be solved by generating examples for matched nested spans, but the corpus annotation might not be compatible with this approach, as each token can belong to a maximum of one annotated semantic unit. In the case of strong MWEs, for example in the idiom “close call”, it is not clear what, if any, supersense the “call” token alone could be assigned (Schneider et al., 2014). However, in an MWE such as “cricket bat” (*n.artifact*) it is clear what the meaning of “bat” is, and likewise, “cricket” refers to the sport. Nevertheless, there is no annotation within MWEs, so while “cricket” alone has the supersense *n.act*, nested in “cricket bat” it has no supersense of its own. Thus, examples generated for nested spans would be inconsistent with non-nested examples.

#### 3.2 Supersense classification

While MWE detection performance was very low due to the issues in example generation, supersense

**Table 1:** The results of the DiMSUM 2016 shared task (provided by task organizers). Micro- and macro-averaged F-scores are shown for (M) MWE detection, (S) supersense assignment and (C) their combination. EB refers to embeddings.

assignment worked quite well (See Table 1). For supersenses, our approach reached F-scores of around 51% while the best performing systems were at 57%. Thus, our system placed 2nd and 3rd in terms of supersenses in the *supervised closed* and *open* conditions. As only 19% of all annotated minimal semantic units have more than one token the impact of MWE detection on supersense classification is limited.

The supersense classification is the only machine learning step in our system. Like most classifiers, the parameters of the Extra Trees Classifier must be optimized on known data for best performance. For parameter optimization, we used three-fold cross-validation on the training corpus, using one of the STREUSLE, Ritter and Lowlands datasets for performance estimation at a time and the other two for training.

Parameter optimization highlighted a conflict in using one binary classification step for both detecting MWEs and assigning the supersenses. Generally, the performance of the Extra Trees Classifier can be increased by increasing the ensemble size, and we noticed such increases while testing sizes from the default of 10 estimators up to 100. However, while the overall classification performance increased, the classifier became increasingly likely to not take any chances with MWE examples, assigning them all as negative. Only by decreasing ensemble size to 2 it became possible to detect at least some MWEs, albeit at the cost of slightly reduced performance on supersense assignment.

## 4 Conclusions

We developed a binary classification system for the DiMSUM 2016 task of detecting minimal semantic units and their supersenses. Our system consists of a customizable dictionary matching step for example generation, followed by a classification step.

The main advantage of this system is its simplicity. Standard machine learning systems can be applied for the classification of the generalized binary examples. As only one machine learning step is used, parameter optimization can likewise be performed in a standard cross-validation loop. The dictionary matching step can be quickly extended by adding new taggers for different vocabularies.

The primary shortcoming of the system is its low performance on MWE detection. This is largely a result of the dictionary matching approach being only partially applicable for the task of detecting the DiMSUM corpus MWEs. We speculate that using machine learning to follow the annotated scope of the MWEs would be a better approach for this part of the task.

Nevertheless, our system achieved good performance on supersense classification, indicating that binarizing this multi-class task is a valid approach. Moreover, even with a simple feature representation consisting only of token attributes and their combinations, comparatively high performance could be achieved.

We publish all of our experimental code, our Wikipedia derived datasets and our detailed results as an open source project<sup>5</sup>.

## **Abstract**

We describe our entry to SemEval 2016 Task 10: Detecting Minimal Semantic Units and their Meanings. Our approach uses a discriminative first-order sequence model similar to Schneider and Smith (2015). The chief novelty in our approach is a factorization of the labels into multiword expression and supersense labels, and restricting first-order dependencies within these two parts. Our submitted models achieved first place in the closed competition (CRF) and second place in the open competition (2-CRF).

## **1 Introduction**

Schneider and Smith (2015) argued that the problems of segmenting a piece of text into minimal semantic units, and of labeling those units with semantic classes (e.g., supersenses), are intimately connected.

We propose to use a double-chained conditional random field (which we refer to as “2-CRF,” an example of a factorial CRF; §3.4) for joint multiword expression identification and supersense tagging. Like other CRFs, 2-CRF is a feature-rich probabilistic model that can represent probabilistic dependencies between features and labels and between the labels of the consecutive words. The 2-CRF models local dependencies between MWE and supersense sequences with two parallel chains of labels, restricting direct interaction between the two to local, single-word positions. Label constraints on tag bigrams ensure a globally consistent tagging.

Our experiments show that 2-CRF outperforms a zero-order baseline, the structured perceptron used

by Schneider and Smith (2015), and a conventional CRF (§4). For SemEval 2016 Task 10: Detecting Minimal Semantic Units and their Meanings, we submitted a CRF for the closed condition and a 2-CRF (incompletely trained) for the open condition, achieving first and second place, respectively.

## **2 Task Description**

For completeness, we briefly review the shared task. The shared task training dataset, called “Detecting Minimal Semantic Units and their Meanings” (DiM-SUM) (Schneider et al., 2016),<sup>1</sup> consists of sentences with multiword expression (MWE) and supersense annotations. The data combine and harmonize the STREUSLE 2.1 corpus of web reviews (Schneider and Smith, 2015)<sup>2</sup> and Ritter and Lowlands Twitter datasets (Johannsen et al., 2014).<sup>3</sup>

Similar to prior work (Schneider and Smith, 2015), the annotation for MWEs extends the conventional BIO scheme (Ramshaw and Marcus, 1995) to include gappy MWEs with one level of nesting.<sup>4</sup> Segmentations are represented using six tags; the lower-case variants indicate that an expression is within another MWE’s gap.

- *O* and *o*: single word expression
- *B* and *b*: the first word of a MWE

<sup>1</sup><https://github.com/dimsum16/dimsum-data/blob/1.5/README.md>

<sup>2</sup><http://www.cs.cmu.edu/~ark/LexSem>

<sup>3</sup><https://github.com/coastalcpb/supersense-data-twitter>

<sup>4</sup>Unlike in Schneider and Smith (2015), there is no notion of weak and strong MWEs.

- $I$  and  $i$ : a word continuing a MWE

We call a tag sequence *valid* if it matches the regular expression  $(O|B(o|bi^+|I)^*I^+)^+$ . Validity can be ensured using label constraints on tag bigrams (Schneider, 2014).

Each noun or verb expression is also annotated with a supersense; there are 26 supersenses for nouns and 15 for verbs. Only the first word of a MWE receives a supersense tag.

One approach to encoding the MWE and supersense tags is to define an extended label set containing both tags (Schneider and Smith, 2015). This will result in 170 potential labels:  $I$ ,  $i$ , and each of  $B$ ,  $b$ ,  $O$  and  $o$  paired with one of the 41 supersenses and no supersense ( $2 + 4 \times 42 = 170$ ). Only 110 of these are attested in the training data, and these are the combinations our approach considers.

There are 4,799 sentences in the training data. For each token, the dataset provides its offset in the sentence, lemma, POS tag, MWE tag, offset of parent, and supersense label (if applicable).

The blind test set consists of 1,000 sentences from three sources: online reviews from the TrustPilot corpus (Hovy et al., 2015), tweets from the Tweebank corpus (Kong et al., 2014) and TED talk transcripts from the IWSLT MT evaluation campaigns, obtained from the WIT<sup>3</sup> archive (Cettolo et al., 2012).

The shared task has three data conditions: supervised closed, semi-supervised closed, and open. In the supervised closed condition, only the labeled data, the English WordNet lexicon, a provided Brown clustering (Brown et al., 1992) on the 21-million-word Yelp Academic Dataset<sup>5</sup> (Schneider et al., 2014), and any of the ARK Tweet NLP clusters<sup>6</sup> are allowed. The semi-supervised closed condition adds the Yelp Academic Dataset to the resources. The open condition allows the use of any available resources. We have participated in the supervised closed and open conditions. The evaluation is based on  $F_1$  score for MWE identification, supersense labeling, and their combination.<sup>7</sup>

### 3 Models

#### 3.1 Input Features

For the open condition, we use all features introduced in Schneider and Smith (2015): a.) Basic MWE features used by Schneider et al. (2014), including lemma, POS tags, word shapes and features indicating whether the token matches entries in any of several multiword lexicons (WordNet, SemCor, SAID, WikiMwe, English Wiktionary and Multiword Entries on the Phrases.net website), b.) the provided Brown clusters and c.) capitalization features, an auxiliary verb vs. main verb feature and unlexicalized WordNet supersense features. Based on the model, these features are conjoined with the MWE, supersense, or extended label set to form zero-order features. For the closed condition, we exclude the features based on multiword lexicons.

#### 3.2 Baseline: Multinomial Logistic Regression

As a baseline, we predict the label of each word based on the features of the word within a sentence. The multinomial logistic regression models the conditional probability of the label of the  $i$ th word, denoted by  $Y_i$ , in a sentence  $x$  as:

$$p(Y_i = y | x, i; \lambda) = \frac{\exp \lambda^\top \mathbf{h}(x, y, i)}{\sum_{y'} \exp \lambda^\top \mathbf{h}(x, y', i)}, \quad (1)$$

where  $\mathbf{h}$  denotes a feature vector that contains features that describe the token  $i$ , and its relationships with some of its adjacent words in  $x$  conjoined with the label  $y$ .  $\lambda$  denotes a vector of feature weights and is learned from data.

Constraints on labels are not taken into account during training. We incorporated these constraints during testing in a greedy manner: For the  $i$ th word, we considered only the labels that make it valid with respect to the bigram label constraints based on the predicted label for the  $(i - 1)$ th word.

#### 3.3 Conditional Random Field

In the linear chain CRF (Lafferty et al., 2001), the conditional probability of a valid label sequence  $y$  of words in a sentence  $x$  is modeled as:

$$p(\mathbf{y} | \mathbf{x}; \boldsymbol{\lambda}) = \frac{\exp \boldsymbol{\lambda}^\top \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}(\mathbf{x}, y_i, y_{i-1}, i)}{\sum_{\mathbf{y}'} \exp \boldsymbol{\lambda}^\top \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}(\mathbf{x}, y'_i, y'_{i-1}, i)}, \quad (2)$$

where  $\boldsymbol{\lambda}$  is a vector of feature weights shared across all positions (i.e., words) and sentences. The feature vector  $\mathbf{h}$  contains the zero-order features described above and the first-order features. The first-order features model the dependencies between the label of  $i$ th word and that of  $(i+1)$ th word. We assume a dummy label  $y_0$  for notational convenience.

In both training and testing, we ensure that the constraints on the consecutive labels are satisfied. The label of the  $i$ th word only depends on the token sequence, its offset in the sentence and the labels of  $(i-1)$ th and  $(i+1)$ th words. Dynamic programming is used for exact inference; runtime is quadratic in the size of the label set and linear in the sequence length. We maximize  $\ell_2$ -regularized log-likelihood using L-BFGS to learn the feature weights  $\boldsymbol{\lambda}$ :

$$\sum_{(\mathbf{x}, \mathbf{y} \in \mathcal{D})} \log p(\mathbf{y} | \mathbf{x}; \boldsymbol{\lambda}) - \alpha_1 \|\boldsymbol{\lambda}_1\|_2^2 - \alpha_2 \|\boldsymbol{\lambda}_2\|_2^2, \quad (3)$$

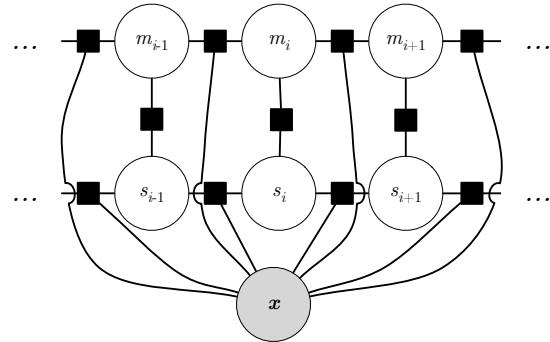

where  $\mathcal{D}$  contains all training instances,  $\boldsymbol{\lambda}_1$  ( $\boldsymbol{\lambda}_2$ ) corresponds to the parameters for zero-order (first-order) features, and  $\alpha_1$  ( $\alpha_2$ ) is the regularization strength for zero-order (first-order) feature weights. In our preliminary experiments, we found that using different regularization strengths for zero-order and first-order features can benefit accuracy.

### 3.4 Double-Chained CRF

We propose a double-chained CRF (2-CRF) that factors the labels into separate MWE and supersense annotations. Such a model has been used for joint POS tagging and noun-phrase chunking by Sutton et al. (2007). The model is illustrated in Fig. 1; the heart of the difference lies in restricting first-order dependencies within MWE or supersense labels, not the combination of the two.

Concretely, the 2-CRF separates the zero-order features for MWE and for supersense tags. Second, while the traditional chain-structured CRF has a feature for each pair of labels in the extended label set, the 2-CRF introduces first-order features capturing

each consecutive pair of MWE labels, and (separately) each consecutive pair of supersense labels. This model removes some repetitive parameters. For example, instead of having parameters to capture the relation between consecutive  $B$  and  $I$  tags paired with all supersenses, 2-CRF will have only one parameter. Moreover, if the feature weights  $\boldsymbol{\lambda}$  for all the features between  $m_i$  and  $s_i$  pairs are zero, the 2-CRF model is equivalent to two separate CRFs for the two tasks. Therefore, it has a flexibility to learn the parameters for the two tasks jointly or separately. Due to this kind of flexibility, we expect that the 2-CRF model has a better generalization ability.

**Figure 1:** Double-chained CRF expressed as a factor graph:  $\mathbf{x}$  is the whole sentence. For a token in position  $i$ , its MWE label is  $m_i$  and its supersense tag is  $s_i$ .

For a sentence  $\mathbf{x}$  with a valid label sequence  $\mathbf{y} = (\mathbf{m}, \mathbf{s})$ , where  $\mathbf{m}$  denotes the MWE tag sequence and  $\mathbf{s}$  denotes supersense tag sequence, the conditional probability of  $(\mathbf{m}, \mathbf{s})$  given  $\mathbf{x}$  is defined as:

$$p(\mathbf{m}, \mathbf{s} | \mathbf{x}) = \frac{\exp \boldsymbol{\lambda}^\top \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}(\mathbf{x}, m_i, s_i, m_{i-1}, s_{i-1}, i)}{\sum_{\mathbf{m}', \mathbf{s}'} \exp \boldsymbol{\lambda}^\top \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}(\mathbf{x}, m'_i, s'_i, m'_{i-1}, s'_{i-1}, i)}, \quad (4)$$

where the feature vector function  $\mathbf{h}$  can be written as:

$$\begin{aligned} \mathbf{h}(\mathbf{x}, m_i, s_i, m_{i-1}, s_{i-1}, i) &= \\ \langle \mathbf{h}^m(\mathbf{x}, m_i, i); \mathbf{h}^s(\mathbf{x}, s_i, i); \\ \mathbf{h}^{mm}(m_i, m_{i-1}); \mathbf{h}^{ss}(s_i, s_{i-1}); \mathbf{h}^{ms}(m_i, s_i) \rangle. \end{aligned} \quad (5)$$

$\mathbf{h}$  contains the following features: two copies of the zero-order features conjoined with the MWE tag  $m_i$  and supersense tag  $s_i$ , first-order features between  $m_i$  and  $m_{i-1}$ ,  $s_i$  and  $s_{i-1}$  and  $m_i$  and  $s_i$ .

Similar to the CRF, we enforce label constraints on the MWE label sequence both at training and prediction time.

Inference can be carried out exactly using similar dynamic programming algorithms to those used for the CRF. Training is carried out as for the CRF (i.e.,  $\ell_2$ -regularized log-likelihood; see Eq. 3).<sup>8</sup>

## 4 Experiments

### 4.1 Experimental Setup

We compare the performance of the following four models that use exactly the same input features §3.1:

- Multinomial logistic regression (MLR) as described in §3.2 (a zero-order model)
- Structured perceptron as used by Schneider and Smith (2015) with the same set of features (first-order, similar to our CRF)
- CRF as described in §3.3
- Double-chained CRF as described in §3.4

We used the AMALGrAM<sup>9</sup> code base for feature extraction (Schneider and Smith, 2015). For hyperparameter tuning, we hold out 30% randomly selected training samples of the DiMSUM dataset as validation data. Using preliminary experiments on validation data, we set the number of L-BFGS iterations for multinomial logistic regression, CRF, and 2-CRF as 100, 120, and 120, respectively. We set the number of iterations of averaged perceptron algorithm for structured perceptron as 10. We also impose a percept cutoff of 3 on the minimum number of occurrences for a zero-order percept to be considered in the models. We use validation data to tune  $\alpha_1$  and  $\alpha_2$  (where applicable) hyperparameters. After tuning the parameters, we use the whole DiMSUM training dataset to train the models.

### 4.2 Results and Discussion

Tables 1 and 2 show the results for the closed and open conditions. The selected hyperparameters  $\alpha_1$  and  $\alpha_2$  are shown for each model. In each table, we

<sup>8</sup>An open source efficient cython implementation of our method will be made publicly available at: <https://github.com/mjhosseini/2-CRF-MWE>.

<sup>9</sup><http://www.cs.cmu.edu/~ark/LexSem>

show the results on our held-out validation data and on the DiMSUM test datasets.

The official submitted systems are marked with \* in the tables.<sup>10</sup> For the closed condition, the 2-CRF had not completed training, so our entry was the CRF; it achieved first place.

For the open condition, training of 2-CRF had only completed 80 iterations at the submission deadline, so that is what was entered (it achieved second place). We report those scores, as well as the slightly improved scores obtained after 120 iterations.

Across the board, there is roughly a 9% decrease in the  $F_1$  score when we move from validation to DiMSUM test datasets. This is not surprising because the validation and DiMSUM datasets represent different text genres and styles.

We measured the statistical significance of the difference between the structured perceptron (SP) and the other methods. We used a randomization test (Yeh, 2000) at the sentence level to estimate the confidence level of the difference ( $p$ -value < 0.05). We indicate in Tables 1 and 2 in italics the cases where the improvement over the structured perceptron is significant.

In the closed condition, the 2-CRF model leads to the highest  $F_1$  scores for all evaluation metrics. Interestingly, the structured perceptron improves on MWE but suffers on supersenses, relative to the zero-order MLR model.<sup>11</sup> CRF and 2-CRF show improvements against MLR on both tasks, with the latter winning overall on validation and (slightly) on test data.

In the open condition, we see similar patterns except a few cases: structured perceptron has the highest  $F_1$  score in MWE identification on validation data and MLR slightly outperforms 2-CRF in supersense tagging on test data. However, the differences are not statistically significant over 2-CRF, and it has the highest combined score.

Finally, we observe that adding the features based

<sup>10</sup>The official results of the shared task are based on the macroaverages of the per-domain scores, while we have done the detailed analysis based on microaverage scores of the whole dataset. Our system got combined macroaverage  $F_1$  score of 57.10% for the closed condition and 57.71% for the open condition.

<sup>11</sup>The MLR model could potentially be improved with dynamic programming instead of greedy prediction.

**Table 2:** Open condition: Results on validation (left) and DiMSUM data (right) for multinomial logistic regression (MLR), structured perceptron, CRF, and 2-CRF models. The hyperparameters and  $F_1$  scores for identifying MWEs, supersenses, and their combination are reported. In the open condition, we have added features using the following lists of English MWEs based on: WordNet, SemCor, SAID, WikiMwe, English Wiktionary, Multiword Entries on the Phrases.net website (Schneider et al., 2014). The best result in each column is bolded. The results that are significant over SP are italicized. The system denoted by \* is our official submission for the open condition.

on multiword lexicons (moving from supervised closed to open condition) improves MWE identification, without harming supersense tagging performance. The increase in the performance of MWE identification is statistically significant across all methods and test datasets.

## 5 Conclusions

We presented the results of four models for the joint prediction of MWE annotations and supersense annotations: multinomial logistic regression, structured perceptron, CRF and double-chained CRF. We found that double-chained CRF performs well on both tasks. We showed that, consistent with past work, adding features based on multiword lexicons improves the performance of all models.

## Abstract

This paper presents our system submitted for SemEval 2016 Task 10: Detecting Minimal Semantic Units and their Meanings (DiMSUM; Schneider, Hovy, et al., 2016). We extend AMALGrAM (Schneider and Smith, 2015) by tapping two additional information sources. The first information source uses a semantic knowledge base (YAGO3; Suchanek et al., 2007) to improve supersense tagging (SST) for named entities. The second information source employs word embeddings (GloVe; Pennington et al., 2014) to capture fine-grained latent semantics and therefore improving the supersense identification for both nouns and verbs. We conduct a detailed evaluation and error analysis for our features and come to the conclusion that both our extensions lead to an improved detection for SST.

## 1 Introduction

The SemEval 2016 Task 10 on Detecting Minimal Semantic Units of Meaning (DiMSUM) is concerned with the identification of semantic classes called supersenses for single words as well as multi-word expressions (MWEs).

Identifying supersenses in text allows for abstractions that characterize word meanings beyond superficial orthography (Schneider and Smith, 2015) as well as inferring representations that move towards language independence (Schneider, Mohit, et al., 2013). It has been used to extend named entity recognition (Ciaramita and Johnson, 2003) and to support supervised word sense disambiguation as it

provides partial disambiguation (Ciaramita and Altun, 2006; Ciaramita and Johnson, 2003) as well as in syntactic parse re-ranking (Koo et al., 2005) as latent semantic features.

The addition of MWEs - idiosyncratic interpretations that cross word boundaries (Sag et al., 2002) - takes into account that the supersense of a MWE is usually not predictable from the meaning of the individual lexemes. The Task moreover distinguishes between continuous MWEs like “*high\_school<sub>n.group</sub>*” and discontinuous (*gappy*) MWEs like “*track people down<sub>v.social</sub>*”. The inventory of supersenses used for the task - 41 supersense classes, consisting of 26 noun and 15 verb supersenses - is derived from WordNet’s top-level hypernyms in the taxonomy. They are designed to be broad enough to encompass all nouns and verbs (Miller, 1990; Fellbaum, 1990).

## 2 Related Work

Schneider and Smith (2015) are the first to approach SST and MWE detection jointly with a discriminative model. Most of the previous work focuses on each of the tasks in separate. Sag et al. (2002) tried to raise attention for the issue of MWEs in general and analyzed different types of MWE. Baldwin et al. (2003) employed latent semantic analysis to determine the decomposability of MWEs. Finally many MWE lexicons have been built for different purposes which is why Schneider et al. picked up the issue to address MWE annotation for general purposes (Schneider, Danchik, et al., 2014; Schneider, Onuffer, et al., 2014).

Ciaramita and Johnson (2003) first trained and tested a discriminative model for SST of unambigu-

ous nouns on data extracted from different versions of WordNet and achieved an accuracy of slightly over 52%. Curran (2005) applied an unsupervised approach based on vector-space word similarity and achieved 63% accuracy on the same data used by Ciaramita and Johnson (2003). When revisiting the task Ciaramita and Altun (2006) achieved between 70% and 77% F-score using a HMM sequence tagger.

### 3 System Description

#### 3.1 Baseline System

We use AMALGrAM 2.0 (Schneider and Smith, 2015) as our baseline system. The model uses a first-order structured perceptron (Collins, 2002) with averaging. It involves a linear scoring function, a Viterbi algorithm that chooses the highest-scoring valid output tag sequence and an online learning algorithm that determines the best tagging given the current model.

We contrast four feature sets for full SST: Schneider and Smith (2015) most effective feature set which is further described in section 3.2, those baseline features plus YAGO feature (3.3), baseline features plus GloVe word embeddings (3.4), and finally a feature set that combines all the above mentioned.

#### 3.2 Baseline Features

The feature set incorporates three components: the first is Schneider, Danchik, et al. (2014) basic MWE features, second is Brown clusters and the last component is WordNet synset features (Schneider and Smith, 2015). Basic MWE features analyze word n-grams, character pre- and suffixes, and POS tags, as well as lexicon entries that match lemmas of MWE in the sentence. We use four of the ten available lookup lexicons: *semcor\_mwes* including all MWEs in SemCor (Miller et al., 1993), *WordNet\_mwes* containing all MWEs from WordNet (Fellbaum, 1998), *phrases\_dot\_net* which is a phrase idiom lexicon<sup>1</sup>, *wikimwe* which is mined from English Wikipedia (Hartmann et al., 2012), and *enwikt* consisting of all MWE entries in English Wiktionary. The second component of the baseline feature set provides unsupervised distributional word clusters in the form

---

<sup>1</sup><http://www.phrases.net/>

of Brown clusters (Brown et al., 1992). Those clusters reflect lexical generalizations that are useful for syntactic and semantic analysis tasks and are therefore suitable for our task. The last component of the feature set helps predicting supersenses by creating possible supersense candidates from WordNet synsets.

#### 3.3 YAGO Feature

We implement a YAGO lookup component that provides semantic information as an additional feature for the AMALGrAM system with the purpose of improving SST for named entities. YAGO (Yet Another Great Anthology; Suchanek et al., 2007) is a knowledge resource that combines the structural benefits from the WordNet taxonomy with the richness of Wikipedia’s categories system. This renders it ideal for our task by enabling us to retrieve WordNet hypernyms for many different named entities. The following part describes how we look up potential concepts in YAGO, how we find potential names of YAGO concepts within the text and how we encode the returned results as a feature for AMALGrAM.

There is no guarantee that the named entities contained in training or test data appear in the same surface form as they are stored in YAGO (e.g. “Elvis” vs. “Elvis\_Presley”). We apply some heuristics should an initial query with a potential named entity not yield a result:

1. Capitalize the initial character of each token<sup>2</sup>
2. Try to retrieve the exact entry via Wikipedias “redirectedFrom” links that are included in YAGO (e.g. ⟨Elvis\_Presley⟩, ⟨redirectedFrom⟩, ⟨“Elvis”@eng⟩)
3. Drop all tokens except the first and repeat the previous steps (only applicable for sequences)

For the detection of named entities during feature extraction we rely on the gold POS tag annotation in the provided data. Whenever a token appears with a “PROPN” tag (e.g. Germany PROPN) we query it on YAGO. If the token is followed by a continuous sequence of further “PROPN” tagged tokens (e.g.

---

<sup>2</sup>We found that we get the best results when capitalizing every candidate expression.

| back            | living_thing | player          |
| causal_agent    | object       | preserver       |
| contestant      | organism     | running_back    |
| defender        | person       | whole           |
| football_player |              |                 |

**Table 1:** WordNet hypernyms contained in the YAGO-Entry: “Jérôme\_Boateng”.

$\text{FC}_{\text{PROPN}} \text{Bayern}_{\text{PROPN}} \text{Munich}_{\text{PROPN}}$ ) the whole sequence linked with underscores is used as the search query.

The feature extraction is done in the following way: In a first step we iterate over all supersense bearing singleton and MWE nouns in our training data and try to query them in YAGO. If we have a match we extract the WordNet hypernyms for the found entity. An example for a successful query can be seen in Table 1. We accumulate a count of observed WordNet hypernyms for each supersense. From the count we calculate a tf-idf whereby the supersenses are seen as the “documents” and the WordNet hypernyms as “words”. What we obtain from this procedure is a tf-idf index that tells us the significance of a WordNet hypernym for a given supersense based on our training data. We require that a WordNet hypernym has to appear at least three times with a supersense otherwise its tf-idf is set to zero for this supersense. During feature extraction we provide the information from extracted WordNet hypernyms in two ways: The straightforward way is to provide each WordNet hypernym as is. With the second feature we make use of our precomputed tf-idf index by calculating a supersense ranking whenever we find a candidate entity in YAGO. For each supersense we add up the tf-idf values of the WordNet hypernyms found with the current candidate entity. If the entity is linked to many WordNet hypernyms with high tf-idf values for a certain supersense the respective supersense will receive a high rank.<sup>3</sup>

### 3.4 GloVe Feature

The second novel feature we provide is based on word embeddings which are representations of the meaning of words in terms of real-valued vectors in

<sup>3</sup>We achieve the best results when using the top ranked supersense as well as all additional supersenses that receive at least half of the top ranked supersense’s tf-idf score.

a low-dimensional vector space. Because such embeddings provide generalizations over the meaning of words, including words that do not occur in the training data, they are often used as a general way to improve accuracy in the form of extra word features (Turian et al., 2010). Two of the most popular methods to create such a mapping include: global matrix factorization and the local context window method. Pennington et al. (2014) combine both methods in the GloVe word embeddings. The available word vectors are derived from a 2014 Wikipedia<sup>4</sup> dump and the Gigaword 5 corpus<sup>5</sup>. Both sources together comprise 400,000 word types and there are four versions available that differ in the size of their dimensions: 50, 100, 200 and 300. GloVe word embeddings capture fine-grained semantic and syntactic regularities using a global log-bilinear regression model with a weighted least-squares objective. The training objective of GloVe is to learn word vectors such that their dot product equals the logarithm of the words’ probability of co-occurrence.

We incorporate our feature set using a similar method to the lookup lexicons. GloVe word embeddings are essentially a dictionary where each entry consists of a word type and their word vector. If a given lowercase token matches a GloVe lexicon entry then we extend the feature vector of that token with its corresponding word embeddings. Turian et al. (2010) mention that the weights in word embeddings are not necessarily in a bounded range. If the range of the word embeddings is too large, they will exert more influence than the remaining features. To prevent the word embeddings from exerting too much influence on the prediction when they consist of an unbounded range of real numbers we adopt Turian et al.’s (2010) method of scaling the word vectors. Assuming that all word embeddings are represented in a matrix  $E$ : Each row  $E_i$  contains the word embeddings of a token, each column  $E_j$  represents one dimension of the word embeddings and each cell contains a word embedding  $E_{ij}$ . We scale each word vector dimension by a scaling constant  $\sigma$  and the inverse of the standard deviation over

<sup>4</sup><http://dumps.wikimedia.org/enwiki/20140102/>

<sup>5</sup><https://catalog.ldc.upenn.edu/LDC2011T07>

the values across all words:

$$w_{new} = \frac{\sigma * E_{ij}}{stdev(E_j)} \quad (1)$$

## 4 Experiments

In the following section we present the data we used, then the tools and parameters and finally the results of our experiments.

### 4.1 Data

Our training and test data consists of the data made available for SemEval 2016 Task 10. The training data includes three harmonized data-sets: STREUSLE 2.1 (Schneider and Smith, 2015), Ritter and Lowlands Twitter dataset (Johannsen et al., 2014). The test set also consists of three sources: online reviews from the TrustPilot corpus (Hovy et al., 2015), tweets from the Tweebank corpus (Kong et al., 2014) and TED talk transcripts (Cettolo et al., 2012; Neubig et al., 2014). All datasets use the 17 Universal POS categories and the extended BIO scheme from Schneider and Smith, 2015. For feature development we used a shuffled held-out portion of the train set.

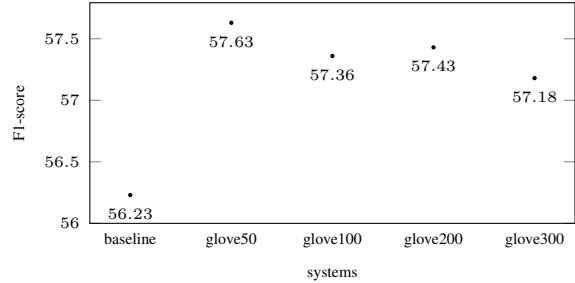

### 4.2 Experimental Setup

We conduct the experiments on the aforementioned DiMSUM data sets. We use the AMALGrAM 2.0 tagger as baseline system with the following parameters:<sup>6</sup> four training iterations, features that appeared less than five times were cutoff, a constraint for the decoding process that asserts that the “O” label is never followed by an “I”, including loss term and a cost penalty of 100 for errors against recall. Furthermore we use brown clusters and five MWE lexica mentioned in section 3.2. Additionally we create a new tagset that suits the DiMSUM tags. We only consider tags occurring in the DiMSUM training set, yielding  $|Y| = 170$  tags.

$$\underbrace{|\{BbOo\}|}_{4} \times \underbrace{(|N| + |V| + |\emptyset|)}_{26+15+1} + \underbrace{|\{Ii\}|}_{2} = 170$$

All evaluation scores where obtained using the evaluation script for SemEval 2016 Task 10.

<sup>6</sup>We have been orienting ourselves towards the parameters used in Schneider and Smith (2015).

**Figure 1:** Evaluation of the influence of high dimensional word embeddings on the performance of the baseline system using combined F1-scores.

### 4.3 YAGO Feature Experiments

The effects of the YAGO feature on AMALGrAM can be seen in Table 5. Compared to the baseline (BL) the WordNet hypernyms have almost no effect on MWE detection (+0.02) while improving SST (+0.64). The supersense rankings improve MWE detection (+0.49) as well as SST (+0.62). Combining the features further improves the detection for MWEs (+0.59) and SST (+1.13).

### 4.4 GloVe Feature Experiments

The first experiment involves the evaluation of different word embedding dimensions. Figure 1 shows a comparison between the baseline system (BL) which uses no word embeddings and our system adopting GloVe word embeddings with four dimension sizes: 50, 100, 200 and 300. This experiment uses word embeddings in their given real-valued form without scaling them. All systems using word embeddings show improved performance and are approximately one percent higher than the baseline. In this experiment the system performs best with 50 dimensional word embeddings, after which the performance shows a slight decrease with growing vector dimensionality.

The second experiment evaluates the influence of unscaled versus scaled word embeddings using the method of Turian et al. (2010) which we described in section 3.4. Table 2 compares the F1-scores of four systems: the first - *Glove50* - uses unscaled word embedding whereas the remaining three systems scale those word embeddings with varying  $\sigma$ -values (0.01, 0.1 and 1). According to Turian et al. (2010) their method works best with a  $\sigma$ -value that scales the standard derivation to 0.1. With our data

|                 | Glove50 | $\sigma=0.01$ | $\sigma=0.1$ | $\sigma=1$   |
|-----------------|---------|---------------|--------------|--------------|
| MWE             | 57.52   | <b>58.49</b>  | 57.71        | 58.38        |
| SST             | 57.65   | 57.14         | 57.04        | <b>57.98</b> |
| <b>combined</b> | 57.63   | 57.36         | 57.15        | <b>58.05</b> |

**Table 2:** Influence of unscaled (Glove50) versus scaled word embeddings for MWE, SST and both tags (combined) using F1-score. Last three columns use Turian et al.’s 2010 scaling method with varying  $\sigma$ -values.

|                 | -brown |       | +brown |              |
|-----------------|--------|-------|--------|--------------|
|                 | BL     | Best  | BL     | Best         |
|                 |        |       |        |              |
| MWE             | 58.13  | 57.69 | 58.10  | <b>58.38</b> |
| SST             | 56.28  | 57.43 | 55.87  | <b>57.98</b> |
| <b>combined</b> | 56.59  | 57.47 | 56.23  | <b>58.05</b> |

**Table 3:** Comparison of baseline (BL) and our most successful system (Best) with (+brown) and without (-brown) Brown cluster.

that value is  $\sigma = 0.1$ . However our results contradict Turian et al. (2010) as our experiment shows that  $\sigma = 0.01$  is more successful in predicting MWEs whereas  $\sigma = 1$  is more suitable for the detection of supersenses as well as both combined.

The third experiment evolves around the interaction between Brown clusters and word embeddings. As both methods have a similar aim - capturing the semantic representation of words - it is of interest to distinguish their influence on the system performance. To accomplish this we train the baseline system (BL) and our most successful system (Glove50,  $\sigma = 1$ ) with (+brown) and without using Brown clusters (-brown). Table 3 represents the resulting F1-scores. Our system profits from the Brown clusters as the F1-scores for all categories (MWE, SST and combined) improves.

#### 4.5 Final System Comparison

Finally we evaluate the combined impact of our features on the performance of the baseline system. Table 5 compares the baseline system plus YAGO, baseline plus GloVe and our combined system using both YAGO and GloVe features (final)<sup>7</sup> with var-

|                 | system | Acc          | P            | R            | F1           |
|-----------------|--------|--------------|--------------|--------------|--------------|
| MWE             | YAGO   | 91.70        | 70.43        | <b>50.31</b> | <b>58.69</b> |
|                 | GloVe  | <b>91.99</b> | <b>73.47</b> | 48.43        | 58.38        |
|                 | final  | 91.70        | 71.74        | 47.35        | 57.05        |
| SST             | YAGO   | 85.02        | 55.96        | 58.08        | 57.00        |
|                 | GloVe  | <b>85.34</b> | <b>56.82</b> | <b>59.20</b> | <b>57.98</b> |
|                 | final  | 85.15        | 56.52        | 59.09        | 57.78        |
| <b>combined</b> | YAGO   | 81.29        | 57.98        | 56.60        | 57.28        |
|                 | GloVe  | <b>81.81</b> | <b>58.97</b> | <b>57.15</b> | <b>58.05</b> |
|                 | final  | 81.57        | 58.49        | 56.86        | 57.66        |

**Table 4:** Accuracy (Acc), precision (P), recall (R) and F1-score (F1) for MWE detection, SST and both (combined) for the baseline system (BL) + YAGO, BL + GloVe and BL + YAGO + GloVe (final).

ious measurements. Our GloVe feature produces the overall best results except for the detection of MWEs due to a decrease in recall. In this case the YAGO feature improves all measures which leads to the highest performance. Although the combination of both features (final) results in an improvement of the baseline the performance mostly ranges in between the results for the individual GloVe and YAGO features.

## 5 Feature Analysis

To get a deeper understanding of the impact and benefit of our features we conduct the following analyzes. First we compare the coverage of our YAGO lookup with NLTK’s WordNet component and examine the accuracy of our ranking feature. Then we analyze the coverage of GloVe on the provided data set and give a detailed recall analysis for each tag.

### 5.1 YAGO coverage

For the coverage comparison we extract all supersense bearing nouns from the whole gold annotated DiMSUM data set. We query the extracted nouns and count the ones that are found exclusively with the lookup component of the YAGO feature and not by NLTK-WordNet. Figure 2 (see Appendix A) displays the results for each supersense that has at

<sup>7</sup>This is a revised version of our submitted system for SemEval 2016 where we used our YAGO combined and unscaled

GloVe100 features. The results of our submitted system were slightly better (combined F1-score 57.77%), but could not be reproduced after revising our system.

|                 | <b>BL</b> | <b>Hyp</b> | <b>Rank</b> | <b>H+R</b>   |
|-----------------|-----------|------------|-------------|--------------|
| <b>MWE</b>      | 58.10     | 58.12      | 58.59       | <b>58.69</b> |
| <b>SST</b>      | 55.87     | 56.61      | 56.49       | <b>57.00</b> |

**Table 5:** Evaluation of the YAGO feature with F1-score comparing baseline (BL), baseline + WordNet hypernym features (Hyp), baseline + ranking features (Rank) and baseline + both additional features combined (H+R).

least 100 associated nouns. Looking at the results we observe a decreased coverage of the WordNet lookup for nouns associated to supersenses that tend to have an increased proportion of named entities, e.g. “n.location”, “n.group” or “n.person”. For the YAGO lookup this correlation is inverted resulting in an increased amount of additionally found supersense bearing nouns for the previously described supersenses.

We also investigate the YAGO feature’s ranking component. First we extract a tf-idf index from the DiMSUM training data set. We use the index to generate a ranking for each expression that we are able to detect with our YAGO feature on the test data set. Figure 3 (see Appendix A) shows the relative distribution of gold supersenses for the first five ranking positions. In this evaluation, the correct supersense is present in the first two ranks for the majority of cases. This experiment also indicates how well the detection of supersense bearing nouns performs. E.g. out of 413 nouns in the DiMSUM test set that are marked with the “n.person” supersense, 146 were detected and received a rank.

## 5.2 GloVe errors

We conduct two experiments to assess our GloVe feature: The first experiment examines the number of tokens for both the train and test set for which there is a GloVe word vector. As described in section 3.4 we use lowercase tokens and match them to their corresponding GloVe word embeddings if possible. With this method we get a coverage of 97.35% for the train set and 94.32% for the test set. Which means that almost every word of the DiMSUM data set is represented by GloVe word embeddings.

To fully assess our GloVe feature we investigate the improvement and deterioration of each tag with

our second experiment. To accomplish this we compare the difference between the F1-score of our system and the F1-score of the baseline (F1-score discrepancy) for each tag. Since there are two types of tags - MWE and supersenses - we conduct an analysis for each type. We provide separate evaluations for tokens that have already been seen in the training set (seen) and tokens that have never been seen before (unseen). Firstly we examine the F1-score discrepancy for all supersenses. Figure 4 (see Appendix A) shows the result for all supersenses that occur more than 50 times in the test data set having a F1-score discrepancy that is higher than  $|0.5|$ . Most supersenses - whether they have been previously seen in the training set or not - improve with the use of the GloVe feature. An exception is “n.event” - a supersense whose F1-score decreases by -8.2% for seen tokens. The average F1-score discrepancy of all noun and verb supersense tags is +0.59; this further confirms our claim that the majority of the supersenses improve with the adoption of the GloVe feature. Lastly we examine the F1-score discrepancy for all MWE tags that occur more than 50 times in the test set. The results can be seen in Figure 5 (see Appendix A). The detection of “I” on seen tokens decreases by 13.2%, whereas the detection of “B” improves for unseen tokens by +8.2%. Overall the GloVe feature has a slightly positive influence on MWE detection.

## 6 Conclusion

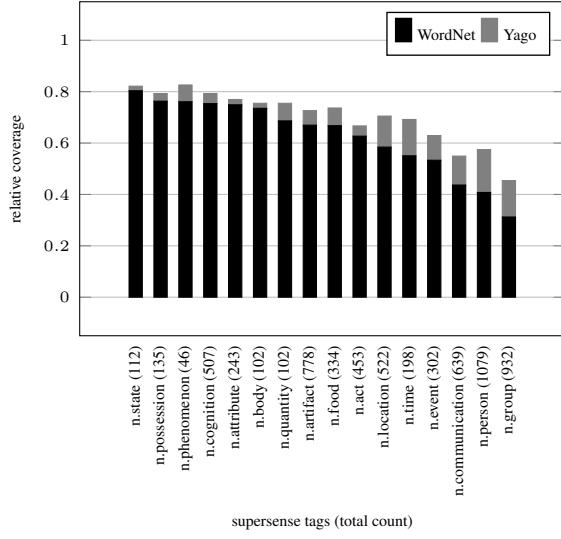

Both YAGO and GloVe are effective in improving the performance for SST and MWE detection. Our experiments show that the GloVe word embeddings provide information in addition to Brown clusters that help the system further distinguish between tags. Unfortunately the benefits of our features don’t add up but instead balance each other out. Learning the reason for this could be subject to future work. One could also replace the heuristics we employed for the detection of named entities in the text with more sophisticated named entity resolution techniques. Another possibility would be the comparison of the effect of different word embeddings on the performance. It might also be advantageous to further research the scaling of word embeddings.

## Abstract

This paper describes an experimental approach to Detection of Minimal Semantic Units and their Meaning (DiMSUM), explored within the framework of SemEval’16 Task 10. The approach is primarily based on a combination of word embeddings and parser-based features, and employs unidirectional incremental computation of compositional embeddings for multiword expressions.

## 1 Motivation

This paper proposes an approach to the segmentation of POS-tagged English sentences into minimal semantic units along with labelling of units with semantic classes (“supersenses”). Supersenses are “lightweight semantic annotation[s] of text originating in WordNet” (Schneider et al., 2012). Here, we investigate two major ideas, as follows.

First, inspired by Salehi et al. (2015) we hypothesise that word embeddings (WEMBs), e.g. from word2vec (Mikolov et al., 2013a), could be an extremely valuable resource of knowledge for guessing the sense of the word. WEMBs have been shown to represent distinguishable sense components learnt from large training corpora. Many papers have described experiments with word meaning extraction from word embeddings, and demonstrated that it’s possible to detect semantic relations between words based on them. Additionally, they may be used to simulate various types of relations between words with simple linear operations over word vectors, and for capturing morphological properties of words (Mikolov et al., 2013b; Vylomova et al., 2015).

However, more generally, they lack any coherent sense-to-value correspondence. According to this, it’s natural to attempt to use WEMBs as a source of word meaning information in predicting the senses of semantic units, as part of the larger task of simultaneously detecting minimal semantic units and assigning them meaning. It should be noted that the general term “multiword expression” (MWE) embraces expressions of different types (Baldwin and Kim, 2010). Some of them are meaning-based and the meaning may be preserved under substitution with synonyms, e.g.; other kinds, on the other hand, are semantically idiomatic word combinations, where we would expect WEMBs to have less utility. This first approach is thus an examination of the use of WEMBs in analysing semantic units of mixed semantic compositionality.

Our second hypothesis is that parser-based features will positively impact on the identification of MWEs. Our preliminary explorations showed that the syntactic structure of a text is closely related to the probability of an MWE occurring. For instance, in almost all cases an MWE is fully subsumed within a single clause; in the DiMSUM training set, e.g., there is just one sentence (out of 4800) where this condition is violated. Additionally, all of the components of an MWE tend to be directly connected within a dependency graph. As we observe strong correlation between the distance between two words in a parse tree and their likelihood of forming an MWE, we decided to employ parse trees as a source of features. It may be noted that we initially attempted to create a system where an MWE is treated as a special kind of clause: we modified

the syntactic tree using knowledge of MWE boundaries in the training corpus and then trained a special version of the parser aware of such modified trees. That special parser version was used to directly produce MWE-labeled clauses over an arbitrary text. Although such a direct approach didn't yield good results, we believe that directly incorporating MWE identification as part of the parsing process is a promising and fruitful direction for future work.

In our submission, we intentionally avoided the use of any pre-existing lexical resources, including multiword lexicons, to better focus our attention on WEMBS.

Our source code is available at:

<https://github.com/andreas-softwareengineer-pro/dimsum-semeval2016>.

## 2 Overview

An overall architecture of our system is shown in Figure 1. The neural network consists of three blocks: (1) an *incremental vector (recurrency)* calculator for a candidate MWE; (2) a two-layer perceptron for sense classification; and (3) a (somewhat wider) two-layer perceptron for MWE classification. An incremental vector produced by the first block is used as a source of feature vectors by each of the latter blocks.

The incremental vector calculator produces a vector  $v_n \in \mathbb{R}^{D_v}$  for a  $n$ -word semantic unit expression:

$$v_n = \tanh \left( \begin{array}{l} W_v(P_n) \times \text{wordvec}(w_n) + \\ W_h(P_n) \times \text{hash}(w_n) + \\ W_f \times \text{wordfeat}(w_n) + \\ W_c(P_n) \times \left\{ \begin{array}{ll} v_{n-1}, & n > 0 \\ \text{seed}, & n = 0 \end{array} \right. \end{array} \right)$$

where  $W_v \in \mathbb{R}^{D_v \times M}$ ,  $W_h \in \mathbb{R}^{D_h \times M}$ ,  $W_f \in \mathbb{R}^{D_f \times M}$  and  $W_c \in \mathbb{R}^{D_c \times M}$  are parameter matrices,  $D_v$ ,  $D_h$ ,  $D_f$  and  $D_c$  are their respective feature vector sizes,  $M$  is the incremental vector size,  $w_n$  and  $P_n$  are the  $n$ th word and its part of speech, respectively, *wordvec* is a word embedding lookup, *hash* is a hash function over characters of the word (used as a means of generating embeddings for unknown words and preserve the ability to distinguish

concrete words), and *wordfeat* produces a vector of various word-wise features (see Table 2), in the spirit of approaches like Drahomíra johanka Spouštová et al. (2009). When calculating  $v_1$  (for a single word), an initial *seed* vector of parameters learnt through backpropagation is used. The motivation behind using the  $n = 1$  stage for every MWE (rather than simply starting with  $n = 2$  and two word vectors) is based on an intention to avoid switching between word embeddings (that play the role of features) and internally calculated  $v_i$  that we expect to better capture the structure of the MWE based on the WEMBS (including following their dimension counts). Also, this technique makes the vector composition learning cycle more frequent w.r.t. the amount of training data, improving the learning rate and the final penalty. This evaluation schema is inspired by the work of Socher et al. (2011; 2010; 2014). It's actually a recursive neural network (RNN) but, in contrast to previously used techniques, the recursion is based on candidate MWEs rather than the whole content of the sentence.

The incremental vector is used as an input to two two-layer perceptrons: one for MWE classification and one for one-hot sense vector learning. Back propagation processing of these two also drives the training of the incremental vector calculator, as described above.

We calculate distance-based features based on positions of two adjacent words in an MWE. A *position* here may mean a position in a sentence, in a parse tree, or, say, inside or outside a quoted phrase. The distance feature vector is supplied as input to the MWE classifier. As an alternative, it may be supplied to the incremental vector calculator input (shown by the dotted line at Figure 1, although no significant difference in performance was observed when we did this).

## 3 Learning

As briefly mentioned above, our procedure considers  $n$ -word expressions incrementally, starting with single words.

### 3.1 MWE boundary

The system learns a single scalar output value of +1 for every extension from  $(n - 1)$ -word prefix to a  $n$ -

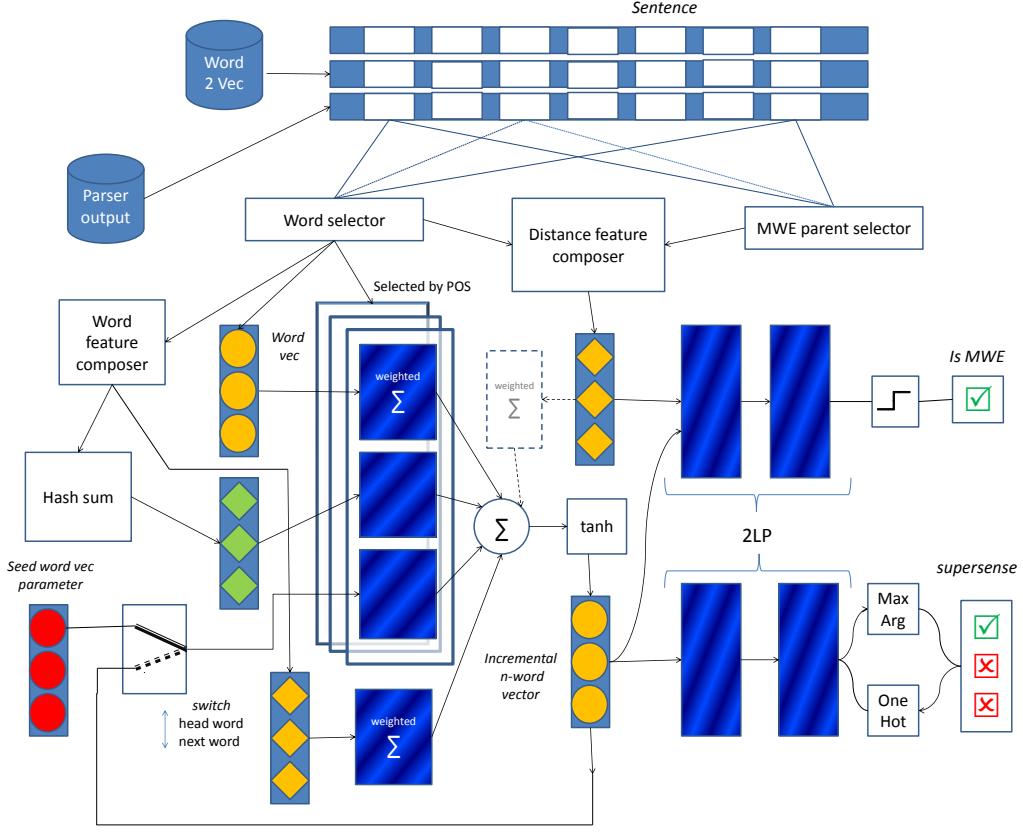

Figure 1: An outline of the system architecture

word MWE (either complete or incomplete), where  $n \geq 2$ . In such a way, every  $n$ -word expression finally yields  $n - 1$  incremental positive samples.

Also, for every word, regardless of whether it is a standalone word or a member of MWE, it learns a  $-1$  value (i.e. a negative sample) for its (unobserved) extension to an MWE with a random word. Such a random word is chosen of the  $L$  words ahead in the same sentence, not involved in the same MWE with the current word.<sup>1</sup>

During the learning process (and, correspond-

ingly, during the prediction), recursive computations of the incremental vector are solely fed by members of the same MWE, and are restarted for each semantic unit.

### 3.2 Senses

We learn a sense once per complete  $n$ -word expression, including  $n = 1$ . We have a distinct output per sense, including ‘unknown’ (42 in total in the DiMSUM data set). We factorise sense classification error by the number of senses in order to balance the backpropagation of two perceptrons to the incremental vector calculator.

## 4 Prediction

We use a greedy procedure for MWE prediction in a text. An *outer* loop iterates through all words of a sentence. It selects each word (not yet consumed by some previously predicted MWE) as the head

<sup>1</sup>We limit  $L$  to 9 words, and also limit the probability of every word selection to  $< 0.25$  (by randomly down-weighting the sample processing for  $L < 4$ ) in order to prevent possible bias to the distribution of inter-word offsets occurring while processing the last few words of a sentence. We solely pick the same sentence words as negative samples in order to make learning more focused on prediction environment patterns rather than noise, as we use a small training corpus, and at the same time to keep an approximate balance in count between negative and positive samples.

word of a possible new MWE and restarts the incremental vector computation. An *inner* loop iterates through (up to  $L$ ) remaining words in the sentence following the current head word. Each time, a probability for such a second word to be a continuation of the MWE is evaluated. Once a new MWE or an MWE extension is predicted, it consumes the right hand word and designates it to be the next word of the MWE; the incremental vector is updated respectively with the new MWE member. Such a procedure is able to generate a deep stack of nested MWEs with gaps, but we restrict the depth to be compliant to the DiMSUM data format.

## 5 Features

### 5.1 Word Embeddings

We utilised a publicly available pre-trained CBOW word2vec model, with 300-dimensional word vectors based on the Google News corpus. Out-of-vocabulary words are represented with zero-filled vectors.

We use the following search strategy when looking up a word in the word2vec dictionary (until the first successful lookup returns the final embedding):<sup>2</sup>.

1. strip off leading “#” and “@”
2. if the word is a number then replace by “NUM”
3. lowercase the word
4. (optionally) lemmatize
5. remove all non-alpha characters
6. return the word embedding associated with the word OR if no match, return a zero vector

### 5.2 Word Hash Sum

We produce a 64-dimensional +1/-1 hash sum vector for words where the embedding vector is unknown; a zero vector was supplied for words (somehow) found in the Google News WEMB database.

<sup>2</sup>We tried using light spelling correction to reduce the rate of unknown words (a simple substitution of one character and then selecting the most probable word according to its frequency ranking). However it didn’t seem to be effective, as the number of mispredicted words was greater than the number of correctly predicted ones, in particular due to the absence of a great number of frequent words (“stop-words”) in the Google News vectors DB. Thus, a more sophisticated system would be needed if one wants to correct typos.

| Feature   | Range                                    | Description  |
|-----------|--|--|
| Gap       | $\frac{n}{8}, n \in \mathbb{Z}_{\geq 0}$ | gap between word positions (divided by 8)  |
| ParDist   | $\{2; 0; -\frac{3}{2}\}$                 | hierarchical distance between words in a parse tree; three gradations for distances of 1,2, $\geq 3$ |
| ParParent | $\{-1, 1\}$                              | two words are head word and child word of the same clause, according to the parser output            |
| InterQt   | $\{-1, 1\}$                              | double-quotes anywhere between given words?  |

Table 1: Distance features

Only alphabetic characters were counted in the hash sum.

### 5.3 Word Distance features

Table 1 displays inter-word distance-based features.

We used a parser prediction file created for the source text in order to evaluate a hierarchical distance between two candidate words. The hierarchical distance here means the maximum of two counts of edges that connect two given words to the nearest clause they share. For instance, two sibling nodes have the hierarchical distance value of one. The same is also true of a phrase head word and its immediate dependent word (that case is indicated by a distinct feature). We employed TurboParser v.2.0.0 (Martins and Almeida, 2014) and trained it on a Penn TreeBank data collection (some conversion was needed to match with the part-of-speech tagset used in the DiMSUM task).

### 5.4 Heuristic word features

The full list of miscellaneous word features (concerning capitalization, punctuation characters, lookup success etc.) is presented in Table 2.

## 6 Results

The system configuration which was used as our official run for the SemEval 2016 task was parameterized as follows: wide layer 1 in MWE prediction perceptron = 1024 nodes; hash sum size = 16bit, calculated both for known and unknown word, using all characters in a word (alpha + non-alpha); a

| Feature               | Value range | Description  |
|-----------------------|-------------|--|
| Cap <sub>First</sub>  | {−1, 1}     | Word starts with a capital letter  |
| Cap <sub>Norm</sub>   | [0, 1]      | Word starts with a capital letter, a value normalized by dividing by the sentence word count   |
| Cap <sub>Ratio</sub>  | [0, 1]      | Ratio of uppercase letters in the word   |
| Has <sub>NAlpha</sub> | {−1, 1}     | Word has non-alpha characters  |
| Has <sub>Num</sub>    | {−1, 1}     | Word has any digit inside  |
| Has <sub>Prime</sub>  | {−1, 1}     | Word has an apostrophe   |
| Is <sub>At</sub>      | {−1, 1}     | Word starts with “@”   |
| Is <sub>Hash</sub>    | {−1, 1}     | Word starts with “#”   |
| Is <sub>Num</sub>     | {−1, 1}     | Word is num (integer, float or “NUM” keyword)  |
| Is <sub>Punct</sub>   | {−1, 1}     | Word contains punctuation character(s) (one or more of “!?.;,:[]()”)   |
| Is <sub>Unk</sub>     | {−1, 1}     | word2vec out-of-vocabulary word, including stop words  |
| Is <sub>Url</sub>     | {−1, 1}     | Word is “URL”  |
| Log <sub>Range</sub>  | [0, 12]     | Smoothed logarithm of the word’s frequency range found in the word2vec dictionary, $\log(0.1 \times \text{range} + 1)$ ; the more frequent the word, the lower the value |
| Quot <sub>Pre</sub>   | {−1, 1}     | A double-quote is located at the previous word position  |
| Quot <sub>Post</sub>  | {−1, 1}     | A double-quote is found at the next word position  |

Table 2: Word Features

mean vector of word embeddings over the sentence was included as extra feature; distance features are supplied to the composed vector evaluator (as shown with the dotted line in Figure 1); a confidence level of −0.15 was applied to the MWE perceptron when predicting a two-word MWE prefix (but not when expanding it to the third and next words, encouraging an MWE to start). The whole DiMSUM training

| Type        | Prec   | Recall | F1     |
|-------------|--------|--------|--------|
| Experiments |        |        |        |
| MWEs        | 0.4697 | 0.4655 | 46.76% |
| Supersenses | 0.5320 | 0.5138 | 52.27% |
| Combined    | 0.5194 | 0.5046 | 51.19% |
| Official    |        |        |        |
| MWE         | 0.6122 | 0.2807 | 38.49% |
| Supersenses | 0.5009 | 0.5326 | 51.62% |
| Combined    | 0.5114 | 0.4846 | 49.77% |
| Macro       |        |        | 49.94% |

Table 3: Results

set was used to train the system.

Table 3 displays the results, measured with the DiMSUM evaluation script.

Table 4 represents a brief ablation study with feature vector disabled. Word embeddings seem to be the critical source of supersense information, and they are also one of the important contributors to MWE recall. The incremental  $n$ -word vector is critical for MWE precision, and Distance features are of great importance both for precision and recall in MWE detection, but especially for the recall. Word hash and, surprisingly, heuristic word features are of much less significance than other feature vectors.

## 7 Findings & Conclusions

The system captures supersenses rather well (when we consider the large number of senses, small size of the training data, and ambiguity in the sense assignments). However, it frequently admits harsh mispredictions that are probably caused by the lack of global sense coherence in WEMBs (Qu et al., 2015). Also, it suffers from the lack of (other than MWE-related) context information in cases of ambiguity. Improving context awareness may be the most obvious next step. Unsurprisingly, the most frequent supersenses have the best recall, up to 80% for v.STATIVE. The mean recall value for senses is around 50–60%, and there are senses (like N.WEATHER) that are never correctly predicted. Exceptions are N.ATTRIBUTE, N.LOCATION, and V.CHANGE, where recall is below 30% despite them being reasonably frequent. Some of the most frequent mispredictions are the following: N.PERSON → N.GROUP; N.COMMUNICATION →

| Ablated<br>features | MWEs   |        |        | Supersenses |        |        | Combined |        |        |
|---------------------|--------|--------|--------|-------------|--------|--------|----------|--------|--------|
|                     | Prec   | Recall | F1     | Prec        | Recall | F1     | Prec     | Recall | F1     |
| –Recurrency         | 0.2125 | 0.4960 | 29.75% | 0.4638      | 0.3581 | 40.41% | 0.3591   | 0.3843 | 37.13% |

Table 4: Feature ablation results

N.ARTEFACT; N.ATTRIBUT → N.COGNITION;  
N.ACT → N.EVENT; and V.EMOTION → V.COGNITION.

MWE identification looks generally reasonable for all principal types of MWEs (even, surprisingly, ones of an idiomatic nature), but the overall accuracy is low.

**Hysteresis bias pattern.** The MWE classifier tends to be biased toward *not* joining two words into a MWE<sup>3</sup>; at the same time, once an MWE is predicted, it tends to be extended excessively to include a third and subsequent words, often selecting a non-relevant word with some gap.<sup>4</sup> This probably means that the proposed sampling schema is not balanced enough to work for small amounts of training data.

**Lookahead.** The method obviously lacks the ability to model context when predicting MWEs. In cases of expressions like *John , Mary & Company*, for example, our system will predict *John Mary Company* with all the punctuation missing. Some bidirectional, attentional (Bahdanau et al., 2014; Cohn et al., 2016) or lookahead-based approach is needed, as we may not have a reasonable isolated rule for whether *John* should be joined to the comma. A similar situation may also occur in punctuation-less contexts.

**Parsing.** The use of parsing results in markedly better precision and recall. Taking into account the strong correlation between parser-based features and MWE boundaries, further investigation of the parser-based approach is warranted.

<sup>3</sup>An example from the DiMSUM test data: *English speaking advisor* produces an MWE predicted to be *English advisor* (not including *speaking*)

<sup>4</sup>As a very rough compensation of such an effect, one may use two confidence levels, one (negative) at  $n = 2$ , another (positive) at  $n \geq 3$ .

**Multiword-to-Sense Collision.** A shared  $n$ -word incremental vector computation both for MWE and sense learning imposes a collision. It may be observed that for better MWE training, the distance features should be supplied to the computation input (as shown with the dotted line in Figure 1), but this will decreases the sense prediction score.

**Needs a deeper network.** The training dynamics observed in the experiments show that the neural networks (especially the one used for MWE prediction) need to be deeper (use more than two layers, as suggested in Sutskever et al. (2014)).

## Abstract

This paper presents the description of a system which detects complex words. It solely uses information regarding the presence of a word in a prepared vocabulary list. The system outperforms multiple more advanced systems and is ranked fourth for the shared task, with minimal loss to the best system. F-score optimization guaranteed the first place in this measurement. Different features are considered and evaluated. Maximal bounds are predicted. The rule “the simplest methods give the best results” is confirmed.

## 1 Introduction

The goal of Complex Word Identification (CWI) is to detect words in a text that are complex (not easy to understand) for some group of people. CWI is one of the tasks of SemEval-2016 (Paetzold and Specia, 2016).

CWI can be treated as the first step of Lexical Simplification (LS). LS was a task of SemEval-2012 (Specia et al., 2012). Complex words were identified using n-grams, the length of the word, and the number of syllables (Ligozat et al., 2012; De Belder et al., 2010; Biran et al., 2011). The resources exploited in this task include Wikipedia, WordNet, Google Web 1T corpus (Sinha, 2012; Paetzold and Specia, 2015). Additional annotation of input sentences was performed by: a part-of-speech tagger, and word sense disambiguation (Amoia and Romanelli, 2012; Jauhar and Specia, 2012).

A similar task is the prediction of the readability of a whole text. In comparison, in CWI, each word

has to be scored. The applied methods are summarized in (Dębowski et al., 2015).

This paper presents findings regarding the necessary data and the performed experiments. For the final submission, a simple system was chosen, which scored at fourth place.

## 2 Task Data Analysis

It is important to notice the difference between training and test data. Each sentence in the training set was annotated by 20 annotators. If at least one of them classified a word in a sentence as complex, it was marked as complex. The training data consists of 2237 classified words. On the other hand, each sentence in the test data (88221 classified words) was annotated by only one annotator.

Complex words represent 31.56% of the words in the training data. Fortunately, organizers published the unaggregated annotations – every word in a sentence has 20 annotations. In this scenario, only 4.55% instances are classified as complex.

A priori probability of the word being complex is important knowledge for the classification task.

What is more, the organizers shared the baseline results for test data (Table 1). It shows that complex words represent 4.7% of instances in the test data – similar to training.

## 3 Resources and Methods

Knowledge bases are essential to this task. Wikipedia is one of the most popular sources of text used in NLP. Using the cycloped.io (Smywiński-Pohl and Wróbel, 2014) framework the English and Simple English Wikipedia were preprocessed. The

**Table 1:** Scores for baseline systems on the test data. 1) All complex – all words are classified as complex, 2) All simple: all words are classified as simple, 3) Ogden’s lexicon: words present in Ogden’s Basic English vocabulary are classified as simple, others as complex. G-score is defined as a harmonic mean of accuracy and recall.

| System          | Accuracy | Recall | G-score |
|-----------------|----------|--------|---------|
| All complex     | 0.047    | 1.000  | 0.089   |
| All simple      | 0.953    | 0.000  | 0.000   |
| Ogden’s lexicon | 0.248    | 0.947  | 0.393   |

text extracted from articles allowed the calculation of term frequency (TF) and document frequency (DF). TF represents the total number of times a word appears in the corpora; DF is the number of documents in which the word occurred at least once.

It was required to apply the same tokenization of corpora as in the data from the organizers.

For every word which needed classification, many features were created:

- TF and DF for the word and its lemma use,
  - English Wikipedia,
  - Simple English Wikipedia,
  - corpora created from training and test sentences,
- length of sentence (number of words),
- length of word (number of characters),
- position of word in sentence,
- GloVe word embedding (Pennington et al., 2014).

For quick development, sklearn (Pedregosa et al., 2011) was used. Many supervised machine-learning algorithms were tested using cross-validation:

- decision trees with maximum depth from 1 to 6,
- linear classifier with stochastic gradient descent (SGD) training,
- k-nearest neighbors classifiers for k=3,5,10,20,
- random forest,
- extremely randomized trees,
- AdaBoost,
- GradientBoostingClassifier,
- LinearSVC.

**Table 2:** Ranking of features in terms of G-score. The last position presents the score for all features used in one model.

| Feature                        | G-score |
|--------------------------------|---------|
| DF of Simple English Wikipedia | 0.781   |
| lemma TF of                    |         |
| Simple English Wikipedia       | 0.781   |
| TF of Simple English Wikipedia | 0.780   |
| lemma TF of English Wikipedia  | 0.778   |
| TF of training corpus          | 0.774   |
| TF of English Wikipedia        | 0.767   |
| GloVe word embeddings          | 0.767   |
| TF of CHILDES Parental Corpus  | 0.738   |
| length of word                 | 0.618   |
| position of word in sentence   | 0.556   |
| length of sentence             | 0.505   |
| all features                   | 0.784   |

## 4 Evaluation

All experiments were conducted by employing cross-validation on raw vote data. Training data were aggregated – a word is labeled as complex if at least two annotators marked it accordingly.

### 4.1 Metrics

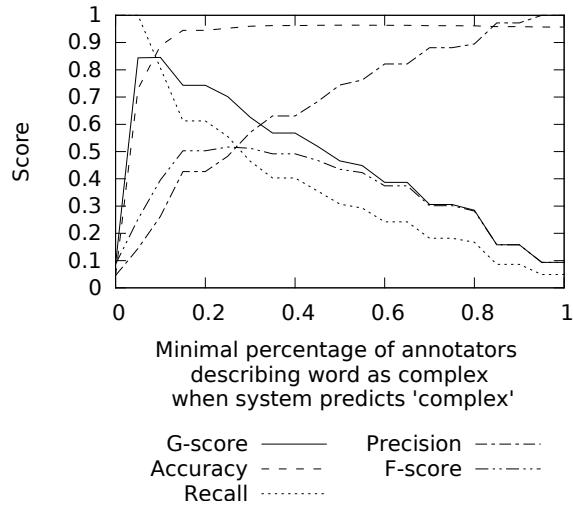

The results are scored using a harmonic mean of accuracy and recall (marked as G-score). In comparison to F-score (a harmonic mean of precision and recall), it is higher if more instances are predicted as complex.

### 4.2 Experiments

Tree-based classifiers achieved the best results (except for word embeddings). Table 2 presents the G-scores obtained by training a classifier with each of the features. Combining features gives only a slightly better score.

#### 4.2.1 Upper Bounds

Complex word identification is a subjective task. The understanding of a word depends on the knowledge of a particular person. Therefore, 100% G-score is impossible to achieve. Due to the fact that the training data was annotated by multiple annotators, it was possible to measure the inter-annotator agreement. Two theoretical systems were scored on the training data. Both systems have knowledge regarding the annotators’ assessment of the words in

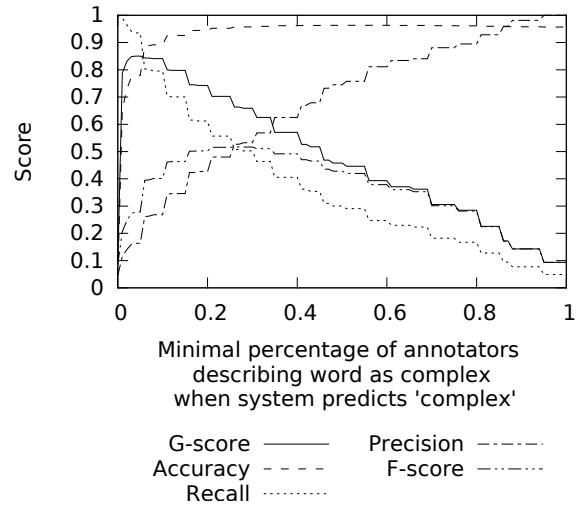

**Figure 1:** Results for the first theoretical system using classification with information about context.

sentences. The first one has information regarding the context (whole sentence) – for each sentence, it knows how many annotators recognized each word as complex. The second one knows how many times each word was assessed as complex (without context).

1. The problem can be treated as simple classification and not sequence labeling. For every word in every sentence, the system predicts words as complex if at least  $X$  people annotated it as complex. The maximum G-score is 84.54% for  $X=10\%$  and the F-score is 51.66% for  $X=25\%$ . This system has information regarding the word and the sentence. However, it is still not sequence classification – it has no information regarding the predictions of the other words in the sentence. Figure 1 presents results in a function of  $X$ .

2. Going further input data can be solely words, without the sentence, so that we can aggregate annotations for the same words, but in different sentences. The system describes a word as complex if at least  $X$  people annotated it as complex (this system has no information regarding the context of the sentence). The maximum G-score is 85.04% for  $X$  from 4% to 5%, and the F-score is 51.71% for  $X$  from 26% to 27%. This system has information only about the word. Figure 2 presents results in a function of  $X$ .

The results above show that a G-score of 86% can

**Figure 2:** Results for the second theoretical system using classification without information about context.

not be exceeded on this data.

#### 4.2.2 Final Submission

The experiments showed a minimally increased score for more advanced classifiers using more features in comparison to the simple one-rule algorithm with one feature. Simple models are usually more difficult to overfit. The complexity of this algorithm is  $\mathcal{O}(1)$  for every word using hashing.

The final submission uses DF of Simple English Wikipedia. The scores, as a function of threshold, are presented in Figure 3.

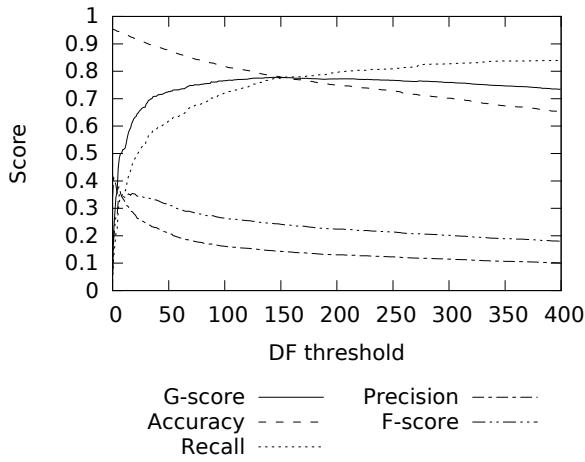

The main submission is optimized for G-score, and its threshold is 147. Words with a DF exceeding this threshold are considered simple, and others are considered complex. A set of simple words contains almost 11 thousand tokens (without sanitization). The size of the model is 78 kilobytes.

The second submission was optimized for F-score and the threshold was 18.

## 5 Results and Discussion

Table 3 shows the top 10 results of the systems on the test data in terms of G-score. The system placed fourth with two other systems.

The best system, SV000gg, ensembles 23 distinct systems using 69 morphological, lexical, semantic, collocation, and nominal features. The system is much more advanced than the one presented in this

**Figure 3:**

**Table 3:** Top 10 systems in terms of G-score. Additionally, the average scores of all systems and their standard deviations are provided.

| System               | Accuracy | Recall | G-score |
|----------------------|----------|--------|---------|
| SV000gg-Soft         | 0.779    | 0.769  | 0.774   |

| HMC-DecisionTree     | 0.846    | 0.698  | 0.765   |
| JUNLP-RandomForest   | 0.795    | 0.730  | 0.761   |
| MACSAAR-RFC          | 0.825    | 0.694  | 0.754   |
| TALN-SIM             | 0.847    | 0.673  | 0.750   |
| MACSAAR-NNC          | 0.804    | 0.660  | 0.725   |
| Average              | 0.737    | 0.591  | 0.620   |
| Standard deviation   | 0.130    | 0.202  | 0.123   |

**Table 4:** Top 3 systems in terms of F-score. Additionally, the average scores of all systems and their standard deviations are provided.

| System                | Precision | Recall | F-score |
|-----------------------|-----------|--------|---------|
| <b>PLUJAGH-SEWDFF</b> | 0.289     | 0.453  | 0.353   |
| LTG-System2           | 0.220     | 0.541  | 0.312   |
| LTG-System1           | 0.300     | 0.321  | 0.310   |
| Average               | 0.123     | 0.590  | 0.193   |
| Standard deviation    | 0.061     | 0.202  | 0.073   |

paper. Its result is higher by almost one percentage point.

The next system in the ranking, TALN-WEI, uses external resources, i.e. WordNet, simple/complex word lists, tools, i.e. part-of-speech tagger, and a dependency parser. A random forest classifier is then trained.

JUNLP-NaiveBayes employs word sense disambiguation and features extracted from an ontology. Also, a random forest classifier is used. Additional word lists are developed, i.e. scientific, geographical, and non-English.

Surprisingly, UWB-ALL is almost the same as the one presented in this article (the English version of Wikipedia is used, not Simple English).

The presented system took first place in terms of F-score. The higher score is probably due to this submission being optimized for F-score with no other teams doing this.

Beating 85% G-score is not possible without more information. It is possible that having the possibility to model every person's knowledge would improve the results. However, this approach needs historic data annotated by a specified user and the predictions would be only relevant for this user.

# USAAR at SemEval-2016 Task 11: Complex Word Identification with Sense Entropy and Sentence Perplexity

José Manuel Martínez Martínez and Liling Tan

Universität des Saarlandes  
Campus, Saarbrücken, Germany  
j.martinez@mx.uni-saarland.de  
liling.tan@uni-saarland.de

## Abstract

This paper describes an information-theoretic approach to complex word identification using a classifier based on an entropy based measure based on word senses and sentence-level perplexity features. We describe the motivation behind these features based on information density and demonstrate that they perform modestly well in the complex word identification task in SemEval-2016. We also discuss the possible improvements that can be made to future work by exploring the subjectivity of word complexity and more robust evaluation metrics for the complex word identification task.

## 1 Introduction

Complex Word Identification (CWI) is the task of automatically identifying difficult words in a sentence.

It is an important subtask prior to the textual/lexical simplification task that pertains to the substitution of abstruse words with lucid variants which can be apprehended by a wider gamut of readers (Siddharthan, 2006; Specia et al., 2012; Shardlow, 2013).

The aim of the CWI task is to annotate the difficult words as shown in the underlined examples in the previous paragraph, such that a lexical simplification system can produce the following sentence:

It is an important subtask before the textual/lexical simplification task that

concerns the replacement of difficult words with simpler variants which can be understood by a wider range of readers.

Lexical simplification is a specific case of lexical substitution where the complex words in a sentence are replaced with simpler words.

Historically, lexical substitution was conceived as a means to examine the issue of the appropriateness of a fixed word sense inventory in the word sense disambiguation task the “sense” of a polysemous word is correctly identified given a context sentence (Kilgarriff, 1997; Palmer, 2000; Hanks, 2000; Ide and Wilks, 2007; McCarthy and Navigli, 2009). By allowing fluidity in the “sense” inventory and by quantifying how much the systems were able to generate good substitutes, these lexical substitutes would have built a word sense cluster of words that may not be covered by a set of pre-defined words in a sense inventory, e.g. Princeton WordNet (Miller, 1995) and Open Multilingual WordNet (Bond and Paik, 2012).

## 2 Entropy and Perplexity

Entropy is an information-theoretical measure of the degree of indeterminacy of a random variable<sup>1</sup>. In simpler words, entropy measures how unpredictable an event is likely to occur (Shannon, 1951).

For the case of complex word , we can also assume that the degree of word ambiguity contributes to its level of unpredictability which determines its complexity. We define the degree of word ambiguity as the number of possible senses a word can have,

<sup>1</sup><https://www.encyclopediaofmath.org/index.php/Entropy>

more specially the number of synsets of a lemma of the target word as recorded in the Princeton WordNet. Formally, we define the *sense entropy* of a word,  $H(word)$ , as such:

$$H(word) = - \sum_{k=1}^n p(sense_k) \log p(sense_k) \quad (1)$$

where  $n$  is the number of possible sense of a word and  $p(sense_k)$  is the probability of sense given the context sentence where the word occurs. We assume a uniform distribution across all senses of a word, thus we assign  $1/n$  to the  $p(sense_k)$  variable.

Perplexity is inverse measure of entropy that measures how predictable an event is likely to occur. Intuitively, if a complex word appears in a sentence, the sentence would become less common and less predictable, yielding a higher sentence perplexity score. Mathematically, we define the *sentence perplexity*,  $2^{H(sentence)}$  as follows:

$$2^{H(sentence)} = 2^{-\sum_{i=1}^N p(word_i) \log p(word_i)} \quad (2)$$

where  $N$  is the number of words in the sentence and  $p(word_i)$  is the unigram probability of the word generated from a modified Kneser-Ney language model (Chen and Goodman, 1999).

### 3 Experimental Setup

The dataset for the CWI task in SemEval-2016 is annotated at word level with binary labels; 1 for complex and 0 for non-complex.

|             | <b>Train</b> | <b>Test</b> |
|-------------|--------------|-------------|
| # Sentences | 200          | 8,929       |
| # Labels    | 2,237        | 88,221      |
| # Lemma     | 1,903        | 20,016      |
| # Synsets   | 1,617        | 12,989      |
| % WN Cover  | 84.97        | 64.89       |
| % Complex   | 31.86        | 4.68        |

**Table 1:** CWI Task Dataset for SemEval-2016.

Table 1 presents the corpus statistics of the dataset provided for the CWI Task. The organizers have decided to emulate the limited human language capacity with a small training set and a large testing set that reflects the relatively larger proportion of text that a human will encounter in reality. However, we

do note the stark difference between the percentage of complex words in the training and test data; it skews towards words being annotated with the non-complex labels.

To compute the sense entropy, we annotated the dataset with lemmas using the PyWSD lemmatizer (Tan, 2014) and reference the lemmas to the Princeton WordNet. The training and testing set comprise 2,237 and 88,221 words respectively. Of the annotated words, the training and testing set has 1,903 and 20,016 unique lemmas and the WordNet covers 84.97% and 64.89% of these lemmas respectively. When a lemma is not covered by WordNet, we assign an entropy of 0 that indicates that the lemma's complexity is easily predictable and the classifier would assign the majority label to the word.

To compute the sentence perplexity as presented in the previous section, we use the English Wikipedia section of the SeedLing corpus (Emerson et al., 2014) and the news articles from the DSL Corpus Collection (Tan et al., 2014) to train the language model using the KenLM tool (Heafield et al., 2013). On average, there are 11 annotated words per sentence and every word in the same sentence shares the same sentence perplexity.

Using both the sense entropy and sentence perplexity as features, we train a boosted tree binary classifier (Friedman, 2002) using the Graphlab Create<sup>2</sup> machine learning toolkit to identify the word complexity.

Interestingly, when we use the raw number of senses instead of sense entropy as a feature on various machine learning classifiers, the number of senses were uninformative and the classifiers either labels all words as complex or all words as non-complex.

### 4 Results

We submitted 2 systems to the CWI task in SemEval-2016 (Paetzold and Specia, 2016), one using only the sense entropy (*sentropy*) and another that includes the sentence perplexity feature (*entropelxity*).

The complex word classification would be evaluated based on classic (i) accuracy, (ii) precision, (iii) recall, (iv) F-score. In ad-

<sup>2</sup><https://dato.com/products/create/>

dition to the harmonic F-score between the precision and recall, the organizers reported the harmonic mean between the accuracy and recall, dubbed G-score<sup>3</sup>.

Since the accuracy score computes the percentage of true positive labels globally, it might be more indicative to read the accuracy scores given the highly skewed dataset (<5% of the test set is labelled as complex).

Table 2 presents the comparative results between our systems, 4 systems that ranked top in F-score and G-score and 2 baseline systems that uses threshold frequencies that best separate complex from simple words learned from the English and Simple English Wikipedias.

PLUJAGH-SEWDFF uses frequency thresholding techniques, they consider any word that occurs less than 147 times in the simple English Wikipedia to be complex. LTG-System2 uses a decision tree classifier trained using similar threshold features. SV000gg uses a soft and hard voting ensemble to combine 23 different systems that includes threshold-based and lexicon-based techniques and machine learning classifiers based on 69 distinct morphological, lexical, semantic, collocational and nominal features.

Compared to the top systems, our system has performed modestly and our Sentropy system outperforms the thresholding baselines. We note that our accuracy and precision scores are relatively competitive as compared to the top systems but our recall is distinctly lower which affects the F- and G-scores. Possibly, we could improve the system by using a word sense disambiguation tool that provide the sense probabilities instead of assuming uniform probabilities across all senses, especially when word senses are often dictated by the most common sense of the word given the context sentence.

Intuitively, we can expect the Entropology system with sentence-level perplexity to underperform in this particular test set because the variance of the perplexity measures are low since all words within the same sentence attain the same sentence perplexity. For a dataset where there are more training sentences, the feature could perform better.

<sup>3</sup>This should not be confused with the G-Measure that is used to measure cluster similarities (Fowlkes and Mallows, 1983).

## 5 Discussion

### 5.1 Subjectivity of Word Complexity

From the example in the introduction, we see the subjectivity of word complexity and how it may vary from speaker to speaker. Arguably *substitution* and *replacement* could have been of equal word complexity depending on the speaker’s level of English proficiency. Although the word *variant* could easily be considered simple for a native French/German speaker learning English where the equivalence *Variante* exists in his/her native language, it might have been considered a complex word for other second English language speaker.

The annotations from the CWI task training set were collected from 20 annotators over a set of 200 sentences. A word is labelled complex if any one of the annotator deems it to be complex, while the testing set was annotated by 1 annotator.

To explore the reader-based subjectivity in word complexity identification, we suggest that future work on CWI explores reader-specific annotations and models user-specific annotations. In this respect, readers’ meta-data such as their native and non-native languages, country of residence, etc. could potentially be more telling in predicting their English proficiency and identifying complex word catered to specific readers or groups of readers.

### 5.2 Evaluation Metrics

Complex Word Identification is a novel task and possibly the standard F-score and accuracy measures might not be reflective of the task difficulty or the system efficiency. Given the binary nature of the classification task, we suggest the use of Matthews correlation coefficient (Matthews, 1975) that measures the correlation coefficient between the observed and predicted binary labels, which can be viewed as a variant of the chi-square coefficient<sup>4</sup>.

It measures the discordant relations between the true and false positives and negatives and avoids the need to optimize the systems based on either accuracy or precision but a healthy fusion of both. The coefficient value ranges from -1 to +1 where +1, 0

## 6 Related Work

Although the lexical simplification/substitution task is well-studied, the complex word identification task has mostly been discussed as an anterior subtask.

Devlin and Tait (1998) implemented a lexical substitution system that *considers all words as complex words* and generated the simpler variant of the words by referencing the most frequent synonym of the word from the WordNet synsets and SUBTLEX corpus (Brysbaert and New, 2009).

Another method to identify complex words is to use the Zipfian nature of language by *thresholding frequencies and classify words that occurs below a certain threshold as complex*. Zeng et al. (2005) and Elhadad (2006) applied the thresholding method to the medical domain to identify technical terms that non-experts would find it difficult to read, the complex terms and varying frequencies correlate with the word difficulty scores elicited from questionnaires (Zeng-Treitler et al., 2008). Similarly, (Zampieri and Tan, 2014) used  $n$ -gram based frequency threshold to identify complex words that has caused second language Chinese learners to make errors in their essays.

Other than the heuristics described above, previous studies had also used **supervised machine learning algorithms** and data annotated with binary labels for each words in the training corpus. Malmasi et al. (2016) use Zipfian word ranks and character  $n$ -grams features to train a random forest, an SVM and a nearest neighbour classifier to predict word complexity.

Shardlow (2013) compared various techniques to

identify complex words, viz. (i) treating every word as complex, (ii) thresholding frequency using the mean of the thresholds discovered through the highest accuracies achieved across cross-validations folds of the training and (iii) an SVM classifier using word-level and character-level (orthographic and phonemic) frequencies and the number of synsets of each words.

While the ‘*everything is complex*’ technique achieved the highest recall, the SVM classifier scored the best precision<sup>5</sup>. The coefficients in his SVM classifier presented the sense feature as the weakest while the frequency features indicated higher correlations with the binary label distribution<sup>6</sup>. In comparison, our sense entropy system is based solely on the number of senses per word reported modest results in the CWI task.

## 7 Conclusion

In this paper, we presented our systems submitted to the complex word identification task in SemEval-2016. We introduced the notion of sense entropy that measures the unpredictability of a word based on its number of senses and used it as a feature to identify complex word . The implementation of our system is released as an open source tool available on <https://github.com/alvations/entropexity>.

<sup>5</sup>The SVM outputs were significantly different from the other two techniques.

<sup>6</sup>Although coefficient values indicates a feature ‘strength’ anecdotally and the coefficients does not necessarily explain the true effect on the label decision because each coefficient is influenced by other variables.

## Abstract

This paper describes our submission to the Complex Word Identification (CWI) task in SemEval-2016. We test an experimental approach to blindly use neural nets to solve the CWI task that we know little/nothing about. By structuring the input as a series of sequences and the output as a binary that indicates 1 to denote complex words and 0 otherwise, we introduce a novel approach to complex word identification using Recurrent Neural Nets (RNN). We also show that it is possible to simply ensemble several RNN classifiers when we are unsure of the optimal hyper-parameters or the best performing models using eXtreme gradient boosted trees classifiers. Our systems submitted to the CWI task achieved the highest accuracy and F-score among the systems that uses neural networks.

## 1 Introduction

The *Deep Learning Tsunami* has hit the Natural Language Processing (NLP) and Computational Linguistics field (Manning, 2016). Deep neural nets has shown to be the ultimate hammer in various NLP shared tasks, systems trained on neural nets often emerge as the top systems and/or beat state-of-the-art performance (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014; Levy et al., 2014; Shazeer et al., 2016; Gupta et al., 2015; Jean et al., 2015; Kreutzer et al., 2015; Sultan et al., 2014; Sultan et al., 2015)

In the concluding remarks of the Google’s Deep Learning course on Udacity<sup>1</sup>, Vincent Vanhoucke

said, “*What’s really cool about those [neural net application] examples is that you don’t have to know much about the problem you’re trying to solve*”. Armed with basic knowledge of deep learning and neural nets and almost zero familiarity of the problem, we attempt to treat the Complex Word Identification (CWI) task as a binary classification task using Long Short-Term Memory (LSTM) Recurrent Neural Nets (RNN) with Gated Recurrent Units (GRU).

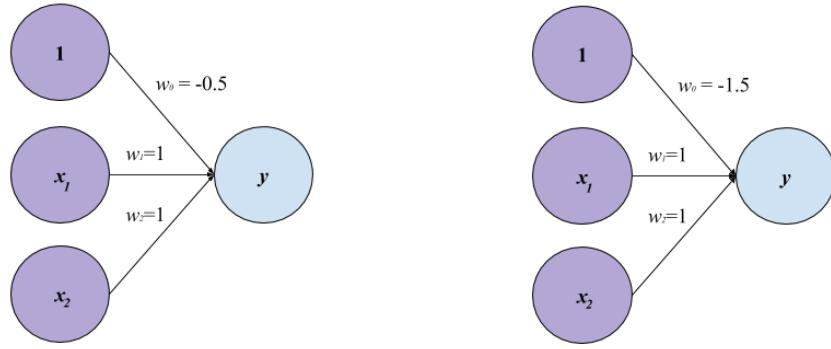

## 2 Neural Network and Deep Learning

Neural Networks are powerful at modelling various modalities, e.g. signals, text, images, videos. As the name suggests, neural network is inspired by the brain’s synaptic transmission mechanism that transmits signalling molecules (aka neurotransmitters) to different signal receptors (aka neurons) throughout our body. Metaphorically, we can emulate a neuron as a computational unit and consider the neurotransmitters as real number inputs and outputs that pass from a neuron to another. Each input to a neuron comes with a associated weight and the neuron will process the different inputs (often by summing them) and passing it to a non-linear function which will provide an output value.

For instance, we can think of a neuron as a typical AND/OR logic gate. Given two binary inputs  $x_1$  and  $x_2$  and a *bias* unit with input 1 and a varying weights, we pass it to a neuron that sums the product of the weights and input and passes the sum to a non-linear function that outputs a boolean  $y$  value of 0 if the sum is below 0 and 1 if the sum is above 0.

From the left graph and table in Figure 1, we see

Figure 2: Emulate an XOR Gate with Feed-forward Network

that the neuron emulates an OR logic gate where it outputs 1 when either of the input is a positive input and outputs 0 when both inputs are 0s. Similarly, right graph and table in Figure 1 presents a neural depiction of a AND logic gate.

If we consider the 2nd row in the left table of Figure 1, the *bias* with the value of 1 and inputs  $x_1 = 0$  and  $x_1 = 1$  are fed into neuro to produce the  $y$  output. Within the neuron, it first sums the inputs and the associated weights up (i.e.  $w_0 * \text{bias} + w_1 * x_1 + w_2 * x_2$ ). Then using a non-linear thresholding function, the neuron outputs  $y = 1$  since the sum is larger than 0. Thus the neuron fulfils the function of an OR that accepts a 1 and 0 input bit to produce a positive bit.

The problem gets more complicated when we want to use neurons to emulate an exclusive OR XOR logic gate, to get a positive binary output, only one of the inputs can be positive and XOR returns a negative output when there are more than one or less than one positive input(s).

We can split the XOR problem into small logical expressions:

$$\text{XOR} = [x_1 \text{ AND NOT } x_2] \text{ OR } [\text{NOT } x_1 \text{ AND } x_2]$$

As shown in Figure 2, we can emulate an XOR gate by stacking two layers of neurons. On the first layer, we solve for

- (i)  $z_1$  to represent  $[x_1 \text{ AND NOT } x_2]$  with weights -0.5, 1 and -1 attached to the bias,  $x_1$  and  $x_2$
- (ii)  $z_2$  to represent  $[\text{NOT } x_1 \text{ AND } x_2]$  with weights -0.5, -1 and 1 attached to the bias,  $x_1$  and  $x_2$ .

At the second layer, we apply the same weights we use for the OR gates and feed  $z_1$  and  $z_2$  as the input to produce the XOR outputs. Interestingly, if we look at the first layer, we notice that the  $z_1$  and  $z_2$  will never both be 1s. Often the network architecture we use to solve the XOR example is referred to as a *feed-forward multi-layered network*.

The logic gates examples motivate the simple use of single neurons and the effect of stacking layers of neurons to produce the desired outcome<sup>2</sup>. Hence the notion, “*Deep Learning*”.

<sup>2</sup>The logic gates examples are taken from Emily Fox and Carlos Guestrin machine learning course on Coursera, <https://www.coursera.org/learn/ml-foundations>

In all the logic gate examples we have manually assigned the weights that are associated with the neurons and it perfectly predicts the desired XOR outputs. In practice, these weights has to be trained using pairs of input bits and their respective outputs.

The rest of the paper will not go through the neural network architecture used in our submission in the same level of detail as this section. Goldberg (2015) and Cho (2015) provides a great read on using deep learning and neural networks for NLP tasks and the formal mathematical descriptions of how to train the networks.

### 3 Recurrent Neural Net

A Recurrent Neural Net (RNN) is an architecture of deep neural network that chains up neurons in a sequential manner. The Elman Network is the simplest formulation of RNN; it allow arbitrarily sized structured inputs to be represented by a fixed-size vector observing the structured properties of the input (Elman, 1990).

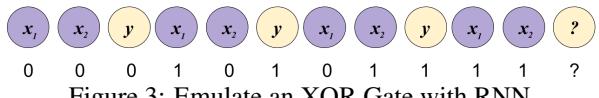

Figure 3: Emulate an XOR Gate with RNN

Returning to the XOR problem, instead of using a feed-forward multi-layered network, we can change the problem into a sequential one. Figure 3 shows how the inputs can be chained in a sequential manner in candence,  $x_1, x_1, y, x_1, x_1, y, \dots$  (*input input output, input input output, ...*). And at the end of the sequence, the network can predict the output of the last set of inputs without an output.

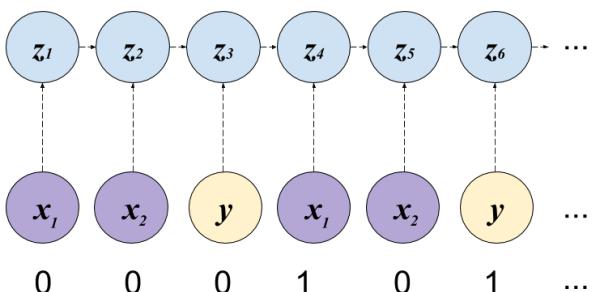

Figure 4: Training an RNN to solve XOR

Figure 4 presents a naive method to chain the inputs  $x_i$ , outputs  $y$  and hidden units  $z_i$  to train an RNN and the dotted lines presents trainable weights.

Despite its simplicity, RNN produces competitive results for sequence tagging (Xu et al., 2015) and language modelling (Mikolov et al., 2010). However, it is hard to train effectively due to the vanishing gradient problem; the gradients in the later steps of the sequence quickly diminishes during back-propagation (Rumelhart et al., 1988) and they don't reach the earlier inputs.

To solve the vanishing gradients problem, Hochreiter and Schmidhuber (1997) introduced the Long Short-Term Memory (LSTM). The intuition is to introduce a “memory cell” to preserve the gradients; at every input state, a gate is used to control how much of the new input should be kept in the memory cell how much it should forget. Cho et al. (2014) proposed a similar “memory” device, Gated Recurrent Unit (GRU), to control that add extra weight matrices to learn what long-distance relationships to remember or forget.

## 4 Complex Word Identification

Complex Word Identification (CWI) is task of identifying difficult words in a text automatically. Usually, it is structured as a subtask prior to lexical simplification where a difficult words from a text is substituted to simpler ones (Specia et al., 2012; Shardlow, 2013). The inputs of the task is a target word and the context sentence in which it occurs. For example, given the underlined word and the context sentence,

*The short words math or maths are often used for arithmetic , geometry or basic algebra by young student and their schools.*

The desired output for the inputs would either be a 1 to indicate that the target word is complex and 0 if the target word is not.

### 4.1 Complex Word Identification with RNN

Neural network has opened a Pandora box where engineers can stack the network in different architectures to train their desired models for almost any NLP task. The sequential nature of language production fits the recurrent structure of the RNN and engineers can easily redesign any NLP task into a sequence prediction task.

Knowing little about the task, we lemmatize and lowercase the sentence<sup>3</sup> and restructure the CWI inputs as a sequence where the target word is separated by a placeholder symbol  $< s >$  followed by the context sentence, e.g.

*arithmetic < s > the short word math or math are often use for arithmetic , geometry or basic algebra by young student and their school .*

Then we fit all the training instances into an RNN network with GRU to output the binary labels. However, we are unsure of the optimal hyper-parameters for the model, so we trained 180 models with varying *embedding sizes* (10, 20, 50, 100, 200, 1000), *GRU sizes* (10, 20, 50, 100, 200, 1000) and *no. of epoch* (1, 3, 5, 7, 10).

We select the top model with the lowest labelling error on the training labels as our Baseline submission. Since we do not know the variance between the training and evaluation data, we select outputs from the top 5 models with the lowest training error and train an eXtreme Boosted Trees regressor (Friedman, 2001; Chen and Guestrin, 2016) to produce a single output label.

The open-source implementation of our system can be found on <https://github.com/alvations/stubbornNess>. It is based on the Passage RNN<sup>4</sup> and XGBoost<sup>5</sup> Ensemble libraries.

## 5 Results

Table 1 presents the results of the best systems and the neural network systems from the CWI task in SemEval-2016 (Paetzold and Specia, 2016). We have submitted our systems under the team name, *Sensible*.

The CWI task was evaluated based on classic accuracy, precision recall and F-score metric. Additionally, the organizers decided to account for the harmonic mean between the accuracy and recall and they called it the G-Score.

The top teams used a variety of heuristics and classificatoin based techniques. PLUJAGH-SEWDFF uses frequency thresholding where they

Table 1: Results of Best (Upper) and Neural Network Systems (Lower) in the SemEval-2016 CWI Task

consider any word that occurs less than 147 times in the simple English Wikipedia to be complex. Similarly, LTG-System2 uses threshold features to train a decision tree classifier. SV000gg combines 23 different systems uses soft and hard voting ensemble, their pre-ensembled systems includes threshold- and lexicon-based heuristics and machine learning classifiers trained on 69 distinct linguistic features.

CoastalCPH’s NeuralNet system extracted an array of features (including parts-of-speech, frequencies, character perplexity and embeddings) and they train a deep neural network with 2 hidden layers. AmritaCEN’s w2vecSim trained an SVM classifier using Word2Vec embeddings and the similarity between the target word, in addition, they used character and token based features to train the classifier. Their w2vecSimPossystem added a POS feature to train the classifier.

Among the neural network systems, our baseline system achieved the highest F- and G-score. We are also the only team that restructured the target word and sentence to train recurrent neural net to predict the output label. One possible reason for the poor performance of our systems is due to the training data size of the task. The training data contains 2,237 labelled instances while the test data contains 88,221 instances. Given more data, we believe that our system can scale towards accuracies comparative to the top systems.

Although our ensemble system performed poorly in the harmonic scores, we see that it achieves reasonably high accuracy close to the top systems. Our ensemble system was penalized due to the low recall and rate. Provided that we have more training data, the recall should proportionally increase and

improve our ensemble system.

## 6 Conclusion

In this paper, we motivated the use of deep learning and neural nets in NLP applications and introduced basic notions of feed-forward and recurrent neural nets through the XOR example. And as expected, we can easily build a relatively competitive system with little understanding of the task by restructuring the inputs as a sequence to train an RNN classifier.

We have introduced a novel approach using RNN to solve the complex word identification task and showed that we can easily ensemble several RNN classifiers if we are unsure of the optimal hyper-parameters or the best performing models using extreme gradient boosted trees classifiers.

# SV000gg at SemEval-2016 Task 11: Heavy Gauge Complex Word Identification with System Voting

**Gustavo Henrique Paetzold and Lucia Specia**

Department of Computer Science

University of Sheffield, UK

{ghpaetzold1, l.special}@sheffield.ac.uk

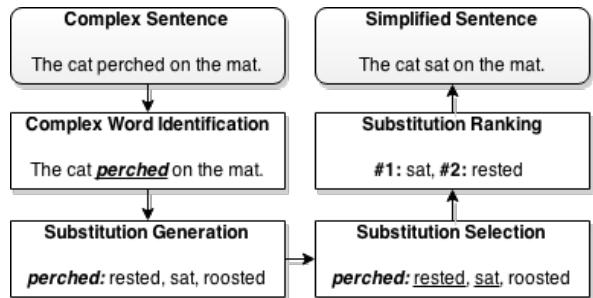

## Abstract

We introduce the SV000gg systems: two Ensemble Methods for the Complex Word Identification task of SemEval 2016. While the SV000gg-Hard system exploits basic Hard Voting, the SV000gg-Soft system employs Performance-Oriented Soft Voting, which weights votes according to the voter's performance rather than its prediction confidence, allowing for completely heterogeneous systems to be combined. Our performance comparison shows that our voting techniques outperform traditional Soft Voting, as well as other systems submitted to the shared task, ranking first and second overall.

## 1 Introduction

In Complex Word Identification (CWI), the goal is to find which words in a given text may challenge the members of a given target audience. It is part of the usual Lexical Simplification pipeline, which is illustrated in Figure 1. As shown by the results obtained by (Paetzold and Specia, 2013) and (Shardlow, 2014), ignoring the step of Complex Word Identification in Lexical Simplification can lead simplifiers to neglect challenging words, as well as to replace simple words with inappropriate alternatives.

Various strategies have been devised to address CWI and most of them are very simple in nature. For example, to identify complex words, the lexical simplifier for the medical domain in (El-hadad and Sutaria, 2007) uses a Lexicon-Based approach that exploits the UMLS (Bodenreider, 2004) database: if a medical expression is among the technical terms registered in UMLS, then it is complex.

**Figure 1:** Lexical Simplification pipeline

The complexity identifier for the lexical simplifier in (Keskisärkkä, 2012), for Swedish, uses a threshold over word frequencies to distinguish complex from simple words. Recently, however, more sophisticated approaches have been used. (Shardlow, 2013) presents a CWI benchmarking that compares the performance of a Threshold-Based strategy, a Support Vector Machine (SVM) model trained over various features, and a “simplify everything” baseline.

(Shardlow, 2013)'s SVM model has shown promising results, but CWI approaches do not tend to explore Machine Learning techniques and, in particular, their combination. As an effort to fill this gap, in this paper we describe our contributions to the Complex Word Identification task of SemEval 2016. We introduce two systems, SV000gg-Hard and SV000gg-Soft, both of which use straightforward Ensemble Methods to combine different predictions for CWI. These come from a variety of models, ranging from simple Lexicon-Based approaches to more elaborate Machine Learning classifiers.

## 2 Dataset and Evaluation

In the CWI task of SemEval 2016, participants were asked to submit predictions on the complexity of words based on the needs of non-native English speakers. The setup of the task is as follows: given a target word in a sentence, predict whether or not a non-native English speaker would be able to understand it. For training, a **joint** and a **decomposed** dataset were provided. Both datasets consist in 2,237 instances containing a sentence, a target word, its position in the sentence, and complexity label(s). The **decomposed** dataset contains 20 binary complexity labels, provided by 20 annotators, while the **joint** dataset contains only one label: 1 if at least one of the 20 annotators did not understand it (complex), and 0 otherwise (simple). Participants were allowed to train their systems over either, both or none of the datasets, as well as use any external resources.

The test set contains 88,221 instances and follows the same format of the joint dataset, but was generated using only one word complexity label. The difference between the training and test sets is that while each instance in the training set was annotated by 20 people, each instance in the test set was annotated by only one person. The goal with this setup was that of replicating a realistic scenario in Text Simplification, where systems must predict the individual preferences of a target audience based on the overall needs of a population sample.

For evaluation, common metrics – Accuracy, Precision, Recall and F-score – are used, along with a new metric designed specifically for CWI: the **G-score**. The G-score consists of the harmonic mean between Accuracy and Recall, and aims at capturing the performance of a CWI approach to be used within a Lexical Simplification system. The reasoning behind the metric is that an ideal CWI system should avoid both false negatives and false positives, which is measured through Accuracy, and at the same time capture as many complex words as possible, which is measured through Recall. High values on these two metrics would prevent a lexical simplifier from making unnecessary and possibly erroneous word replacements and from neglecting words which should be simplified.

## 3 System Overview

Our strategy explores the idea behind the popular saying “*two heads are better than one*” for the CWI problem. We believe that combining the “opinion” of various distinct approaches to a given task can yield better results than any of the individual approaches. This idea is not new for classification tasks like ours, and have been thoroughly explored in several ways. Strategies that combine multiple Machine Learning classifiers are often referred to as Ensemble Methods. Such methods range from very simple solutions, such as Hard Voting, in which labels are determined based on how many times they were predicted by the classifiers, to very elaborate approaches, such as Random Forests (Breiman, 2001) and Gradient Boosting (Friedman, 2001).

The strategy we employ consists of a variant of Soft Voting, in which the class of a given instance is determined as in Equation 1.

$$c_f = \arg \max_c \sum_{s \in S} T(s, c) \quad (1)$$

In traditional Soft Voting,  $c_f$  is the selected class,  $c$  is one of the possible classes in a classification problem,  $S$  the collection of systems considered, and  $T$  a confidence estimate, i.e. a function that expresses how confident system  $s$  is that  $c$  is the correct class. Its goal is to increment Hard Voting by incorporating the systems’ classification confidence in the decision process, hopefully making for a more reliable way of exploiting their strengths and weaknesses.

Although sensible in principle, Soft Voting might not be able to effectively combine systems if they do not have a reasonably uniform way of determining the confidence on their predictions. The presence of over-optimistic or over-pessimistic systems may skew the results severely, and hence make the resulting classifier have worse performance than that of the best system among those considered in the voting. Another clear limitation of traditional Soft Voting is that it cannot include systems which simply cannot estimate the confidence level of their prediction. Lexicon-Based CWI approaches such as the ones of (Elhadad and Ph, 2006) and (Elhadad and Sutaria, 2007), for example, predict that a word is simple if it is present in a certain vocabulary. These

approaches tend to be very effective in certain contexts, but can only produce binary confidence estimates: if the word is in the vocabulary, then it is 100% sure the word is simple, if not, it is 100% sure the word is complex.

In order to address these limitations, we exploit Performance-Oriented Soft Voting (Georgiou and Mavroforakis, 2013). Instead of using the systems’ summed confidence to predict a label, it uses their performance score over a certain validation dataset. Formally, we decompose function  $T$  from Equation 1 into the two functions illustrated in Equation 2.

$$c_f = \arg \max_c \sum_{s \in S} P(s, d) * D(s, c) \quad (2)$$

In Equation 2,  $P$  represents the score of system  $s$  over a certain dataset  $d$  given a certain performance metric, such as Precision, Recall, F1, Accuracy, etc. Function  $D$ , on the other hand, outputs value 1 if system  $s$  has predicted  $c$  for the classification problem in question, and 0 otherwise.

This setup works under the assumption that the systems’ performance under a validation dataset is a reliable surrogate for confidence predictions, and allows for any type of systems to be combined, whether or not they are homogeneous in their way of predicting classes.

In what follows, we described the features and settings used in the creation of our two CWI systems: SV000gg-Hard and SV000gg-Soft. While SV000gg-Hard uses basic Hard Voting, SV000gg-Soft uses Performance-Oriented Soft Voting. Since both of them combine a series of sub-systems, to avoid confusion, we henceforth refer to these sub-systems as “voters”.

### 3.1 Features

Our voters use a total of 69 features. They can be divided in four categories:

- **Binary:** If a target word is part of a certain vocabulary, then it receives label 1, otherwise, 0. We extract vocabularies from Simple Wikipedia (Kauchak, 2013), Ogden’s Basic English (Ogden, 1968) and SubIMDB (Paetzold, 2015).

- **Lexical:** Includes word length, number of syllables, number of senses, synonyms, hyponyms and hyponyms in WordNet (Fellbaum, 1998), and language model probability in Wikipedia (Kauchak and Barzilay, 2006), Simple Wikipedia and SubIMDB.
- **Collocational:** Language model probabilities of all n-gram combinations with windows  $w < 3$  to the left and right of the target complex word in Wikipedia, SUBTLEX (Brysbaert and New, 2009), Simple Wikipedia and SubIMDB.
- **Nominal:** Includes the word itself, its POS tag, both word and POS tag n-gram combinations with windows  $w < 3$  to the left and right, and the word’s language model backoff behavior (Uhrik and Ward, 1997) according to a 5-gram language model trained over Simple Wikipedia with SRILM (Stolcke and others, 2002).

In order for language model probabilities to be calculated, we train a 5-gram language model for each of the aforementioned corpora using SRILM (Stolcke and others, 2002). Nominal features were obtained with the help of LEXenstein (Paetzold and Specia, 2015).

### 3.2 Voters

We train a total of 21 voters which we have grouped in three categories:

- **Lexicon-Based (LB):** If a word is present in a given vocabulary of simple words, then it is simple, otherwise, it is complex. We train one Lexicon-Based voter for each binary feature described in the previous Section.
- **Threshold-Based (TB):** Given a certain feature, learns the threshold  $t$  which best separates complex and simple words. In order to learn  $t$ , it first calculates the feature value for all instances in the training data and obtains its minimum and maximum. It then divides the interval into 10,000 equally sized parts, and performs a brute force search over all 10,000 values to find the one which yields the highest G-score over the training data. We train one Threshold-Based voter for each lexical feature described in the previous Section.

| System                           | Accuracy | Precision | Recall | F-score      | G-score      |
|----------------------------------|----------|-----------|--------|--------------|--------------|
| All Complex                      | 0.047    | 0.047     | 1.000  | 0.089        | 0.089        |
| All Simple                       | 0.953    | 0.000     | 0.000  | 0.000        | 0.000        |

**Table 1:** Performance scores. Separated by double horizontal lines are three system groups: our voters, other systems submitted to the SemEval task, and our Ensemble solutions.

- **Machine-Learning-Assisted (ML):** Learn a binary classification model from the training data using a Machine Learning algorithm. We build models using the following seven algorithms in the scikit-learn toolkit (Pedregosa et al., 2011):

1. Support Vector Machines
2. Passive Aggressive Learning
3. Stochastic Gradient Descent
4. Decision Trees
5. Ada Boosting
6. Gradient Boosting
7. Random Forests

Additionally, we use Keras<sup>1</sup> to otrain a Multi-Layer Perceptron voter. Its architecture, including number and size of hidden-layers, was decided through 5-fold cross-validation over the training set. The aforementioned models use as input all binary, lexical and collocational features. Finally, we also train a Conditional Random Field model using CRFSuite (Okazaki, 2007). It uses as input all nominal features described in the previous Section. The hyper-parameters of all Machine Learning-assisted voters are determined through 5-fold cross-validation over the G-score.

We select the number of the top G-score systems to be considered through 5-fold cross-validation over the joint dataset. For completion, we also include a traditional Soft Voting system that combines Machine Learning approaches only, given that the others do not have well-established ways of calculating prediction probability estimates.

## 4 Results

Table 1 illustrates the performance scores of all individual voters, along with the 25 best performing systems in the CWI task, a standard Soft Voting approach, and our two SV000gg systems. Despite their simplicity, our system voting strategies are the two most effective CWI solutions submitted to SemEval 2016, having both obtained considerably higher G-scores than traditional Soft Voting. These results

show the importance of finding clever ways to combine distinct strategies for a task, since, by not considering Lexicon and Threshold-Based voters, the traditional soft voter suffered a considerable loss in G-score.

The results of the individual voters reveal that Decision Trees and Ensemble Methods achieve noticeably higher performance than the Multi-Layer Perceptron, which have been used as state-of-the-art solutions to various tasks. Another surprise comes with the scores of Threshold-Based voters, which offer competitive performance in comparison to Machine Learning techniques. The performance of our Conditional Random Field voter suggest that nominal features are not as reliable as numeric features in predicting word complexity.

The effectiveness of Ensemble Methods is further highlighted by the scores of ours' and others' solutions for the SemEval task: precisely 50% of the top 10 systems use some type of Ensemble.

## 5 Conclusions

We have presented our contributions to the Complex Word Identification task of SemEval 2016: the SV000gg systems, which exploit two types of system Ensemble voting schemes. Along with the typical Hard Voting, we employ Performance-Oriented Soft Voting, which diverges from traditional Soft Voting by weighting votes not by their prediction confidence, but rather by overall system performance.

Our performance comparison shows how effective our voting strategies can be: they top the rankings in the SemEval task, outperforming even elaborate Ensemble strategies. We hope that our approach will serve as a reliable alternative to other problems in Natural Language Processing and beyond.

In the future, we also intend to explore the use of Gaussian Processes and Multi-Task Learning for Complex Word Identification.

## Abstract

SemEval 2016 task 11 involved determining whether words in a sentence were complex or simple for a cohort of people with English as a second language. Training data consisted of 200 annotated sentences, representing the combined judgements of 20 human annotators, such that if any annotator of the group labelled a word as complex, then it was considered to be complex. Testing was based on single annotator judgements. Our system used a random forest classifier with a variety of features, the most important of which were term frequency statistics garnered from four large corpora, and style lexicons built on two large corpora. Minor features in the final system include the presence or absence of words in various readability word lists; many other features we tried were not successful. Our ranking amongst submitted systems did not reflect the strength of our system, due to submitting a far from optimal weighting between complex and simple, but we show that when a more appropriate weighting is used, our system ranks amongst the best submitted systems.

## 1 Introduction

Most work related to readability measurement (Chall and Dale, 1995) focuses on text-level assessment, but it is clear that being able to determine the difficulty of individual words is important to both that task as well as related ones such as lexical text simplification (Shardlow, 2014). Although some words can be considered conceptually difficult — that is, a level of intellectual sophistication is required to grasp its meaning — for language learners,

it is more common for words to be considered difficult (or complex) simply because a reader has had little or no exposure to them. This exposure may depend on many different external factors related to the person’s background, some of which may generalize across other similar readers, while others may be entirely idiosyncratic to the reader in question. For example, those who study academic English, or operate in an academic environment, have a different vocabulary exposure to those who specialize in hospitality English. Therefore, there is value in not only trying to predict some prior difficulty of a word, but also trying to generalize across readers in a similar cohort. Task 11 of the 2016 SemEval competition (Complex Word Identification) is aimed at addressing this challenge.

This paper describes our system for the task. We commenced with previous work in word readability scoring (Brooke et al., 2012) and stylistic lexicon creation (Brooke and Hirst, 2013; Brooke and Hirst, 2014). For features, we drew on a diverse set of corpus-based and human-derived metrics, and built a random forest-based classifier. While a mistake related to the proper distribution of complex versus simple words prevented us from scoring amongst the top teams in either of the evaluations metrics used in this task, we show that by appropriate class weighting with the same classifier and features, we can obtain results on either metric that are competitive or better than the best teams.

## 2 Background

The motivation for SemEval 2016 Task 11 was the need to automatically identify complex

words (Shardlow, 2013) for the task of automated text simplification (Shardlow, 2014). However, the modelling of word complexity and text complexity has a long history, much of it using the term *readability*, and intended for finding reading material of an appropriate level of difficulty for children and language learners (Chall and Dale, 1995). The measurement of word readability, or lexical complexity, is a fundamental component for a range of techniques and their applications beyond automated text simplification: text readability measurement is used as a basis for automatically recommending reading to language learners (Collins-Thompson and Callan, 2004a); lexical complexity measurement can also allow the automatic glossing of reading material presented electronically (Walmsley, 2011), or the display of text comprising a mixture of two languages (Uitdenbogerd, 2014).

Early work on readability resulted in a large number of measures being developed, typically based on tests given to school-aged native speakers of English (Klare, 1974). The majority of these measures had two recognizable components: grammatical difficulty and word difficulty. The word difficulty component of the measures had the following varieties: inclusion in a list of generally known words, such as the Dale-Chall measure (Chall and Dale, 1995); word length in letters, such as the Automated Readability Index (Senter and Smith, 1967) and Coleman-Liau formulae (Coleman and Liau, 1975); word length in syllables, such as the Flesch and Kincaid formulae (Kincaid et al., 1975); the proportion of words exceeding a word length threshold in characters, such as Lix; and proportion of words exceeding a length threshold in syllables, such as the SMOG formula (Klare, 1974). Criticism of these early readability measures included their inability to capture conceptual difficulty (Gordon, 1980), leading the field to be abandoned to some extent until the current millennium, in which corpus-based techniques, language models, and classifiers became popular, and large-scale corpora became readily available (Collins-Thompson and Callan, 2004b; François, 2009).

For second language learners, it has been observed that higher frequency of exposure increases the chance that a word is known, leading to a typical vocabulary knowledge profile in which the per-

centage of known words per 1000 in a ranked list by frequency, monotonically decreases (Meara, 1992). When language learning is optimized based on word frequency, as is often recommended by researchers of language acquisition (Sinclair and Renouf, 1988), the effect may even be exaggerated.

### 3 Data

The training data released for this task included about 200 sentences, in which each word token that was not a proper noun was annotated as either complex or simple. A word was considered complex if any one annotator from a set of 20 annotators marked it as such. We found many sentences being tagged entirely or almost entirely as complex, for no obvious reason; for training, we excluded any sentence where the number of complex words was greater than or equal to the number of tagged words minus 2, leading to 29 sentences being removed. We also excluded from training any appearances of a set of 140 closed-class function words, which we always classified as simple; both test and training data have words from our list that were tagged as complex, but these appear to be mostly errors, and in general we didn't want our classifier focusing on classifying extremely common words.

After applying these two filters, the total number of tokens tagged complex in the training set was 427, and the total number of tokens tagged simple was 1234, or roughly a 3 to 1 ratio of simple to complex. By contrast, the test set, which was the result of annotation by individual annotators of about 9000 sentences, had a ratio of simple to complex of almost 18 to 1 (after the common words are removed), which is an extreme difference in class distribution; though we expected to see this effect, when we prepared our system we had no good way of estimating its magnitude. Late in the competition, the organizers released individual annotations which allowed for a more accurate estimate of the expected class distribution, but we became aware of that only after the competition was over, and our work here is based on optimizing using the initial class distribution.

### 4 Lists of Features

We divide our feature lists into three categories: major features, minor features, and unused features.

Major features are those which we believe are essential to the good performance of the model; minor features were helpful in the version of the classifier we used here, based on 20-fold cross-validation in the training set, but the effect was fairly modest; and unused features were not found to be helpful, but we include them for completeness to give a full sense of everything we tried. There are too many features (and too many combinations) to offer up individual numerical analysis of what worked and what didn't. Our features were selected by optimizing G-score (see Section 6) with a 20-fold cross-validation of the training set.

## 4.1 Major Features

**Term frequency statistics** We collected term frequency statistics from four large corpora: the British National Corpus (“BNC”: Burnard (2000)), the Gigaword corpus (Graff and Cieri, 2003), the International Conference on Web and Social Media (ICWSM) blog corpus (Burton et al., 2009), and Project Gutenberg (read using the GutenTag tool (Brooke et al., 2015)). We consciously chose corpora that had significant variety with respect to their genre, with the intent of allowing the classifier to focus in on particular kinds of words that certain groups might have trouble with. Note that we typically used the count for the specific word type, but where it didn't exist in the corpus we substituted the lemma count, rather than giving a count of zero. All of the corpora were of benefit to the final model.

**Six style lexicons** For the ICWSM and the Project Gutenberg corpora, we built lexicons for six lexical styles using the co-occurrence information in these corpora. The six styles are: literary, abstract, objective, colloquial, concrete, and subjective; each style for each corpus is an individual feature. We used the seed set for the six styles from Brooke et al. (2013), and the co-occurrence profile ranking approach from Brooke and Hirst (2014). We chose these two corpora because they are extremely large, varied in content, and we have used and evaluated them in other work; highly constrained language like the newswire text in the Gigaword corpus is unlikely to be of much use for building stylistic lexicons in this fashion.

## 4.2 Minor Features

**Dale-Chall List** The presence or absence of the word in the Dale-Chall list, a list of 3000 common words used in the Dale-Chall readability metric (Chall and Dale, 1995).

**Academic Word List** The ranking of the word on the 570-word Academic Word List, which divides academic language into 10 frequency categories (Coxhead, 2000).

**Beginner List** A list of 4636 beginner words, including words from the Dolch list (Dolch, 1936), previously used as a training/test set in earlier lexical readability work (Brooke et al., 2012).

**Is Lemma** A boolean feature indicating whether a word is its lemma or not. For instance *run* is a lemma but *ran* is not.

## 4.3 Unused Features

**Document Frequency** We tested document frequency as a complement or alternative to term frequency for the various corpora.

**Average Sentence Length** The average sentence length of the documents the word appears in, for the 4 corpora used for term frequency. It was a useful feature in our earlier work on lexical readability (Brooke et al., 2012), and is an excellent readability feature generally (Uitdenbogerd, 2005).

**Word Length** The length of the word, in characters, was useful in early iterations but not in the final model.

**Average Word Length** The average word length in the documents that the word appears in, for the 4 corpora, is another feature from Brooke et al. (2012).

**Formality lexicon** The formality lexicon built from the ICWSM corpus in Brooke and Hirst (2014). We believe the information in it overlaps considerably with the 6-style lexicon.

**Readability rank** The readability rank of words as given by the model from Brooke et al. (2012).

**Complexity lexicon** Using the words from the training set, we attempted to build a complexity dictionary using the method of Brooke and Hirst (2014). The results were not competitive when the six-style lexicon was included.

**Latinate affixes** A boolean feature which indicates the presence or absence of a Latinate affix, which can indicate increased formality (Brooke et al., 2010).

**Number of Senses** The number of senses of the lemma of the word in WordNet (Fellbaum, 1998).

**Hyphen fix** For hyphenated words, derive all other statistics using the first word in the hyphenation, instead of the whole word.

**Bigram style lexicon** The features we use do not distinguish between the word type in different contexts, so we cannot distinguish between word senses. We saw examples of this in the data, such as the word *tried* in the legal sense in *was tried for murder*. We made an initial attempt at integrating this information by building a bigram style lexicon, using the same method as the regular method, averaging the styles of the two possible contexts, and either replacing the word style or including it as a different feature. However, performance was worse.

**Is Cognate** While not actually implemented, we considered the possibility of using cognates, which might allow us to discount otherwise complex words which are easy for L2 speakers coming from European language backgrounds because there is a very similar word in other languages (Uitdenbogerd, 2005). However, the results of our early investigation suggested that cognates were not appearing with greater frequency among the simple words than expected, and that therefore the language background of the participants was probably not uniformly European.

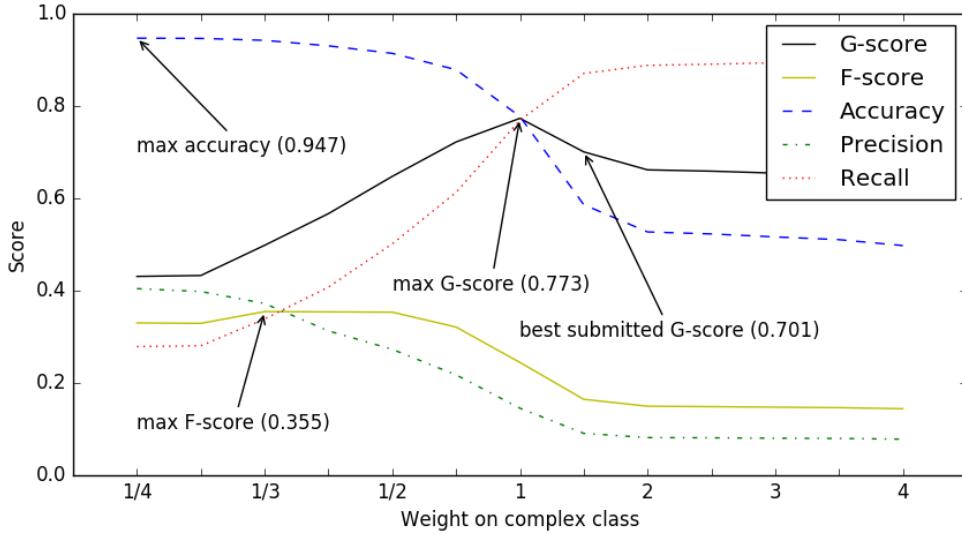

## 5 Classifier

Though rarely competitive on large feature sets, a decision-tree-based classifier has several advantages, being considered by some as the only true off-the-shelf classifier (Hastie et al., 2008), in part because it does not require the feature scaling that

is typical in linear classification models, and naturally mixes boolean, ordinal and continuous features without having to convert one to the other. If the number of examples and features is low enough, Random Forests — an ensemble classifier that builds multiple decision trees using subsets of the examples and features and then combining the individual votes — is a powerful classifier with all the advantages of the basic decision tree (except interpretability). On the basis of 20-fold cross-validation over the training set, we found that it was the best classifier among a wide range of options (including all the other ensemble classifiers) that we tested in Sci-kit learn (Pedregosa et al., 2011). We tuned the parameters with an initial feature set, carried out feature selection, and then tuned the parameters again, with very little further effect. The only two parameters that were different to the default were the number of estimators (50); and the maximum depth (3). We also tested with different class weights to improve our performance with regard to G-score, which is discussed in the next section. Having class weights penalizes errors for a particular class more, which effectively forces the classifier to guess that class more often, shifting the class distribution.

## 6 Evaluation Metrics

The evaluation for this task includes 3 basic metrics (precision, recall, and accuracy) and two combined metrics based on them (F-score and G-score). For precision and recall, the positive class is COMPLEX, and this is the basis for calculating F-score. G-score, the primary evaluation metric for this competition, is the harmonic mean of precision and accuracy, putting extra emphasis on recall for the COMPLEX class beyond that which is built into the accuracy score. Relevant to this task, the effect of G-score is opposite to the class imbalance problem mentioned earlier: when training on a set where the positive class is over-represented, the resulting classifier will do better on G-score than F-score because it will tend to overestimate the instances of the positive class, improving recall.

**Figure 1:** Scores for various metrics for different weightings of the COMPLEX class

## 7 Results

Figure 1 shows the performance of our system for the various metrics across different weightings of the COMPLEX class. With regard to G-score and F-score, our best submitted system is far from optimal, since we overestimated the effect of G-score, and underestimated the influence of the class imbalance between the training and test sets; we incorrectly put too much weight on the COMPLEX class, which resulted in a G-score of 0.701 (12th ranked) for the 1.5 weighting of COMPLEX, and 0.647 (19th ranked) for the 3.0 weighting of COMPLEX. However, across all possible weightings, our best G-score (0.773), which is our system without any weighting at all, is tied with the second best G-score in the competition (the best score was 0.774). If we put more weight on simple words, we reach the maximum F-score of 0.355 when the ratio is (roughly) 3 to 1 in favor of simple words; this F-score is better than any other reported F-score (the best F-score of a submitted system is 0.353), though we note that teams might have been more focused on optimizing G-score, since it was the primary metric. Accuracy is maximized simply by minimizing the number of COMPLEX guesses, and in fact guessing only SIMPLE will net an accuracy of 0.953, which is impossible for our system to beat.

Table 1 shows the results of a small feature ab-

| Features           | G-score | F-score |
|--------------------|---------|---------|
| All Features       | 0.773   | 0.355   |
| No term frequency  | 0.550   | 0.001   |
| No 6-style lexicon | 0.748   | 0.349   |
| No minor features  | 0.772   | 0.347   |

**Table 1:** Feature ablation

lution study using the best system with regard to each the two combined metrics (no weighting for G-score, 1/3 weighting for F-score); results were erratic for less than optimal values. Term frequency information is clearly the most important source of information for deciding complexity, but we also see improvements due to the stylistic lexicons built using co-occurrence information, and the minor features. The effects are not consistent with respect to degree across the two metrics, likely because different feature sets result in substantially different class distributions, which in turn have very different effects on G-score and F-score.

## 8 Discussion

Our results using the unweighted model put us among the best teams in the competition, though in fact there are 6 other teams with G-scores within 0.01 of each other, and what we know about the effects of weighting should make us cautious about coming to any strong conclusion about which of

these systems (or other systems, for that matter) are better. From our perspective, it is unfortunate for us that the organizers created a situation where the class distribution in the test set was very unclear. As it happens, the use of G-score almost exactly counters the effect of the class imbalance (in fact, it seems as if G-score may have been selected exactly for this purpose), such that a classifier built on the training data with an eye to F-score will do well with regard to G-score over the testing data (though not the training data), but it didn't seem obvious to us that this would be the case. More generally, we wonder whether some kind of ROC metric might not be more appropriate for this task. In our opinion, the quality of a model of complexity is orthogonal to producing a class distribution which optimizes a particular metric, and collapsing the two just creates confusion and might lead us to overlook otherwise good approaches.

Most of our performance seems to be due to term frequency and word co-occurrence information from a set of four large corpora. Although using multiple corpora was helpful, we actually rather doubt that our model is learning much that is particular to the group of people involved; more likely it is learning a more general model of word difficulty. Choosing the correct proficiency level is primarily a matter of choosing the best class distribution (via weighting); if one has individual annotations of the target population (which we didn't use, but were eventually made available), this is relatively straightforward. What would have been more interesting is if the task had involved multiple groups with very distinct characteristics (for example, two very different L1 language backgrounds, or L1 children versus L2 adults), so that a good model would have had to truly adapt to the specific characteristics of different groups to be successful. It would also be interesting to see if we could build models that can adapt to individuals, predicting words that a reader would or wouldn't know based on a small sample of words tagged by them only. Such a setup might bring us closer to the goals that motivate the task.

# CLaC at SemEval-2016 Task 11: Exploring linguistic and psycho-linguistic Features for Complex Word Identification

Elnaz Davoodi and Leila Kosseim

Concordia University

Department of Computer Science and Software Engineering

Montréal, Québec, Canada H3G 2W1

{e\_davoo, kosseim}@encs.concordia.ca

## Abstract

This paper describes the system deployed by the CLaC-EDLK team to the *SemEval 2016, Complex Word Identification task*. The goal of the task is to identify if a given word in a given context is *simple* or *complex*. Our system relies on linguistic features and cognitive complexity. We used several supervised models, however the Random Forest model outperformed the others. Overall our best configuration achieved a G-score of 68.8% in the task, ranking our system 21 out of 45.

## 1 Introduction

Text simplification involves reducing the complexity of a text in order to make it more accessible to a larger audience or to a specific audience such as children, second language learners, the elderly, etc.

Research efforts on text simplification have mostly focused on either lexical (Devlin and Tait, 1998; Carroll et al., 1998; Biran et al., 2011) or syntactic simplification (Chandrasekar and Srinivas, 1997; Siddharthan, 2006; Kauchak, 2013). Lexical simplification involves replacing specific words in order to reduce lexical complexity, while still conveying the same information. Lexical simplification is still a challenging task as identifying and simplifying complex words in a given context is not straightforward. Complex word identification is the first step towards lexical simplification.

For the challenge, we experimented with a number of features that we suspected would be correlated with a word's complexity level and selected five that were the most discriminating on the given training

data set. Using a Random Forest classifier, we built two models that we deployed to the Sem-Eval 2016 Complex Word Identification Task. These models achieved better than average ranking compared to the other participating systems. We believe that the approach proposed in this paper can link linguistic features and cognitive complexity together in order to improve lexical simplification.

## 2 Complex Word Identification Task Setup

The SemEval 2016 Complex Word Identification Task required participating systems to automatically classify words as *simple* or *complex* in a given context. For training, participants were given 2247 instances. Each instance consisted of a target word  $W$ , its offset in the sentence and a class label (0 if  $W$  was considered *simple* in the sentence, or 1 if  $W$  was *complex* in the sentence). For example, given the training instance 1 below, the target word *happened* is classified as simple; however in training instance 2, the same word is classified as complex.

**Training instance 1:** There are several stories about Mozart 's final illness and death , and it is not easy to be sure what happened . happened 21 0

**Training instance 2:** Although anoxic events have not happened for millions of years , the geological record shows that they happened many times in the past . happened 5 1

Given the above, the task was to identify if a word is *complex* or *simple* in a test set of 88,221 instances.

## 3 Methodology

We experimented with various supervised models for this binary classification task; however Random

Forest outperformed the others. We also experimented with various features and retained the five features described below.

### 3.1 Feature Set

In our final complex word identification system, we used as features: the frequency of the target word in the Web1T Google N-gram Corpus, its Part of Speech (POS) tag, the number of synonyms it has in WordNet, the inverse of its length and a psycholinguistic feature indicating its “abstract” level. These features were selected based on their discriminating power on the training data.

#### 3.1.1 Frequency in the Web1T Google N-gram Corpus

The Google N-gram corpus (Michel et al., 2011) is a collection of English one- to five-grams with their frequencies from different sources and from different years. This corpus contains approximately 1 trillion words from the Web. In order to focus on the more recent usage of the words and reduce the size of the corpus, we considered the frequency of the target words in sources which were indexed after year 2000. This way, we reduced the influence of frequent but obsolete words. We used this feature based on the assumption that simpler words are more frequently used.

#### 3.1.2 Part of Speech Tag

We suspected that a word’s POS tag may influence its complexity level. As a word may be tagged with different parts-of-speech, we suspected that a particular usage may be more complex than another depending on how common that usage is. For example, the word *highlight* may be used as a noun or, less frequently, as a verb. Hence, *highlight* as noun may be more likely to be considered *simple* and *highlight* as verb may be more likely to be considered *complex*. As a feature, we used the POS tags of target words given in the training and test data sets. The words in each sentence are tagged using Stanford POS tagger (Toutanova et al., 2003).

#### 3.1.3 Number of Synonyms in WordNet

Another linguistic feature that we suspected may be correlated with the complexity of a word is the number of synonyms it has. Based on our statistical analysis of the training set, complex words have

fewer synonyms than simpler words. For instance, the probability that a complex word has less than 4 synonyms is 33.65% on the training set; while this number is 24.10% for simple words. This can be explained by the fact that complex words tend to denote specific entities or concepts and therefore tend to have less synonyms. Thus, we considered the number of synonyms of the target word as one of our features.

#### 3.1.4 Inverse of Word Length

Based on the work of traditional text complexity measures such as the Flesch index (Kincaid et al., 1975), we took into account the length of a word as a feature to determine its simplicity level.

#### 3.1.5 Psycholinguistic Feature

We suspected that the more abstract a word, the more complex it will be perceived. To investigate the correlation between the degree of abstractness of a word and its complexity, we used the MRC psycholinguistic database (Wilson, 1988). This electronic resource contains the score of 26 psycholinguistic features for 150,834 words. One such feature indicates the level of abstraction associated with the entity or concept denoted by the word. This concreteness feature is available for 8,228 words and is indicated by an integer value ranging from 100 (very abstract) to 700 (very concrete). For this psycholinguistic feature, if the target word had a concreteness value in the MRC, we used its value as a feature. However, using this feature has a drawback since it does not cover all the words. For now, we deal with this problem by considering the value of out-of-database words as 0.

### 3.2 Feature Selection

In order to evaluate the effectiveness of these five features, we used two feature selection methods: (1) information gain (a filter-based method) and (2) subset selection (a wrapper method). Table 1 shows the features ranked using information gain. For example, WordNet synonyms are the most discriminating features; whereas word length is the least.

On the other hand, using the subset selection method, the best subset of features was determined to be the frequency in the Web1T Google N-gram Corpus + the number of synonyms in WordNet +

| Feature                                 | Information Gain |
|---|------------------|
| Number of Synonyms in WordNet           | 0.048            |
| Psycholinguistic Feature                | 0.024            |
| Part of Speech Tag                      | 0.015            |
| Frequency in Web1T Google N-gram Corpus | 0.007            |
| Inverse of Word Length                  | 0.006            |

Table 1: Information gain of each feature.

| Learning Model      | Precision | Recall | F-Measure | Class            |
|---------------------|-----------|--------|-----------|------------------|
| Naïve Bayes         | 0.680     | 0.978  | 0.803     | 0 (Simple)       |
|                     | 0.267     | 0.017  | 0.032     | 1 (Complex)      |
|                     | 0.548     | 0.672  | 0.557     | Weighted Average |
| Neural Network      | 0.707     | 0.913  | 0.797     | 0 (Simple)       |
|                     | 0.509     | 0.193  | 0.280     | 1 (Complex)      |
|                     | 0.644     | 0.684  | 0.632     | Weighted Average |
| Decision Tree (J48) | 0.715     | 0.919  | 0.804     | 0 (Simple)       |
|                     | 0.551     | 0.212  | 0.306     | 1 (Complex)      |
|                     | 0.662     | 0.694  | 0.645     | Weighted Average |
| Random Forest       | 0.738     | 0.815  | 0.775     | 0 (Simple)       |
|                     | 0.491     | 0.383  | 0.430     | 1 (Complex)      |
|                     | 0.660     | 0.677  | 0.667     | Weighted Average |

Table 2: Performance of various learning models evaluated using 10-fold cross-validation on the training set.

the psycholinguistic feature. It is interesting to note that both methods identify the psycholinguistic feature and the number of synonyms in WordNet as two of the most discriminating features; and word length as less useful.

## 4 Results and Discussion

We experimented with various learning models trained on the features described above. As a baseline, we used a Naïve Bayes classifier. Table 2 shows the weighted average precision, recall and F-measure on the training set evaluated using 10 fold cross-validation. As can be seen in Table 2, all learning models perform significantly better in classifying simple words rather than complex words. Based on the weighted average of the learning models, we submitted two Random Forest models: CLaC-EDLK-RF\_0.6 and CLaC-EDLK-RF\_0.5. The only difference between these submissions is the threshold for class assignment. In the first submission, we used the threshold of 0.5, and in the second we used 0.6. Our official ranking at the shared task ranked our CLaC-EDLK-RF\_0.6 as 21<sup>st</sup> and CLaC-EDLK-RF\_0.5 as 24<sup>th</sup> out of 45 sys-

tems using the G-score. However, based on the F-score, CLaC-EDLK-RF\_0.5 ranked 26<sup>th</sup> and CLaC-EDLK-RF\_0.6 ranked 30<sup>th</sup>.

## 5 Future Work

For future work, we plan to investigate the use of other linguistic and psycholinguistic features. Because the MRC database contained a concreteness score for only 8,228 words, we plan to combine more psycholinguistic features from the same database. In addition, it would be interesting to investigate the influence of context on the readers' understanding of a target word. To do this, we could examine a window-based approach to consider the surrounding words which may affect the complexity of a word.

## Acknowledgement

The authors would like to thank the anonymous reviewers for their feedback on the paper. This work was financially supported by NSERC.

{niloymukherjee93, brajagopal.cse, dipankar.dipnil2005}@gmail.com  
sivaji\_cse\_ju@yahoo.com

## Abstract

The complex word identification task refers to the process of identifying difficult words in a sentence from the perspective of readers belonging to a specific target audience. This task has immense importance in the field of lexical simplification. Lexical simplification helps in improving the readability of texts consisting of challenging words. As a participant of the SemEval-2016: Task 11 shared task, we developed two systems using various lexical and semantic features to identify complex words, one using Naïve Bayes and another based on Random Forest Classifiers. The Naïve Bayes classifier based system achieves the maximum G-score of 76.7% after incorporating rule based post-processing techniques.

## 1 Introduction

Extensive research has been performed in the field of lexical simplification (Specia et al., 2012; Rello et al., 2013; Paetzold, 2015). Lexical simplification refers to identifying complex words and replacing them with lexically simple substitutes (Specia et al., 2012). The English lexical simplification task<sup>1</sup> was organized in the year 2012, in which the complex words were provided by the organizers.

The complex word (CW) identification is the first step towards the lexical simplification task. Understanding words which are not frequently used in any language is very difficult for non-native speakers. It may be challenging for a reader to interpret a particular word because it might be absent in his vocabulary. Also it may so happen that he knows the

word but cannot comprehend it as he fails to capture the context it is used in. Generally, it is observed that the frequent use of complex words decreases the readability of the document. Thus, the complex word identification (CWI) task aims to classify those challenging words in a sentence with respect to a particular target audience.

For example, in the following sentence, the words in *italics* are complex words. These words are related to biology and are rarely used in our daily life. e.g. “The first *amniotes*, such as *Casineria*, resembled small lizards and evolved from *amphibian reptiliomorphs* about 340 million years ago.”

Some research has been performed in CWI task in comparison to the lexical simplification (Shardlow, 2013; Paetzold, 2015). The important features which have been used previously in the CWI task are frequency thresholding and lexical matching etc. (Shardlow, 2013).

Some motivations of the CWI task are to understand the defining characteristics of the words which are challenging for non-native speakers to interpret. Another is assessing an individual’s vocabulary limitations from the group he is a part of.

We have participated in the SemEval 2016-Task 11: Complex Word Identification<sup>2</sup> (Paetzold and Specia, 2016). The main goal of this task is to identify the complex words from English sentences. We identified highly correlated features and performed the classification using Naïve Bayes and Random Forest classifiers. After the classification, we used post-processing techniques with deterministic features to improve the F-Score of our system.

<sup>1</sup><https://www.cs.york.ac.uk/semeval-2012/task1.html>

<sup>2</sup><http://alt.qcri.org/semeval2016/task11/>

## 2 Dataset Description

Participants were provided with training and test datasets by the organizers of CWI task. A subset of words of a sentence are tagged as complex or non-complex. The training and test datasets comprise of 2,237 and 88,221 instances respectively. The numbers of complex and noncomplex words are 706 and 1531 for the training dataset, whereas the number of complex and noncomplex words are 4,131 and 84,090 in the test dataset.

The training dataset was collected through a survey, in which 400 annotators were presented with 200 sentences. They were asked to select the words which they did not understand in terms of the meaning. Each of the words in the training dataset have been annotated by 20 distinct annotators. Even if one of the 20 annotators judged the word to be complex it has been tagged as complex. The test set has annotations made over 9,000 sentences by only one annotator (Paetzold and Specia, 2016).

## 3 Features

### 3.1 Data Pre-processing

The Stanford Parser<sup>3</sup> was used to get the lemma of the tagged words in the training dataset. Further, the lemmas of these words have been used to identify various features. The R (version 3.1.0)<sup>4</sup> software is used to collect various statistics and identifying the features which have high correlation with the complex or noncomplex class.

### 3.2 Part-of-Speech (POS)

We used POS tags of the words as a feature. The frequencies of corresponding POS tags of complex and noncomplex words are given in Table 1.

### 3.3 Hypernym and Hyponym

The main idea of the present approach is to find out the position of the words in the tree constructed by the WordNet.<sup>5</sup> Our hypothesis is that generic words being easier to understand are present at the top of the WordNet tree. Alternately specialized words which are difficult to understand are at the bottom of

| POS    | Complex | Noncomplex |
|--------|---------|------------|
| NN     | 263     | 413        |
| NNS    | 101     | 198        |
| JJ     | 93      | 247        |
| VBN    | 46      | 99         |
| RB     | 45      | 103        |
| VBD    | 40      | 101        |
| Others | 116     | 358        |

Table 1: POS tagging statistics

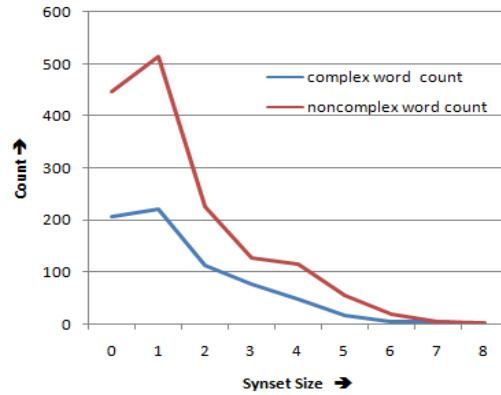

Figure 1: Statistics of synset size

the tree. We used the number of hypernym and hyponym as features. For example, the word ‘car’ has no hypernym and is tagged as noncomplex, whereas the word ‘resemble’ has eight hypernyms and therefore is tagged as complex. We observed that 762 out of 1531 (around 50%) noncomplex words have no hypernyms in the training dataset.

### 3.4 Synset Size

The synset size is one of the important features which has been used to identify CWs in previous related work (Shardlow, 2013). We observed that the words with larger synset sizes have several senses and are generally ambiguous in nature. These words may be confusing for the readers and are considered complex. For example, approximately 73% of the words having synset size greater than equal to five were marked as complex in the training dataset. It can be observed from Figure 1 that the probability of a word being noncomplex is high when the synset size of that word is low.

<sup>3</sup><http://stanfordnlp.github.io/CoreNLP/>

<sup>4</sup><https://www.r-project.org/>

<sup>5</sup><https://rednoise.org/rita/reference/RiWordNet.html>

### 3.5 Named Entity (NE)

Generally, NEs are understood by the non-native speakers. They are aware of currencies or nationalities, e.g. Dollars or British. We found 54 out of 78 (approximately 70%) NEs are noncomplex in the training data. We used the 7 class model of Stanford NER<sup>6</sup> to identify the NEs in the tagged words of the training and test dataset. We used NEs as a feature and for the post-processing as well.

### 3.6 Stopwords

We observed that determiners like a/an/the or conjunctions like or/and/but have a low probability of being complex. Thus, we used stopwords as a feature.

### 3.7 Syllable count

The words with a high number of syllables are difficult to pronounce and onerous to read too. The syllable count was calculated by the number of consonants present between contiguous chunks of vowels. We used syllable count as a feature to identify the CWs.

### 3.8 Most frequently used English words

We collected a list of most frequently used words in English language from the web.<sup>7</sup> Two lists were prepared, one containing top 2,000 words and the other containing top 5,000 words. We observed that the words present in the list of ‘most frequently used words’ have a lower chance of being complex.

### 3.9 Index of words

The index of each tagged word in a sentence is used as a feature.

**Negative features:** The length of the word was not used as a feature because a lot of noncomplex words in the training dataset were hyphenated and hence had higher length. The hyphenated words which are individually understandable should be considered as noncomplex.

## 4 System Framework

The Naïve Bayes and Random Forest classifiers were implemented using the Weka tool.<sup>8</sup>

### 4.1 Evaluation

The performance of the systems was calculated using Accuracy, Precision, Recall, F-Score, and G-Score (Paetzold and Specia, 2016). The accuracy is calculated as:

$$\text{Accuracy} = (\text{correctly classified instances}) / (\text{total instances}).$$

The G-Score metric has been used to rank the systems. The G-score is the harmonic mean of Accuracy and Recall (Paetzold and Specia, 2016).

### 4.2 Post-Processing

**Crawler:** The specialized words of any particular subject are not generally understood by readers and are found to be complex. Thus, we prepared word lists of three specific topics (Biology, Geography, and Physics).

A web crawler was developed to collect specialized words from the glossaries of Biology,<sup>9</sup> Geography,<sup>10</sup> and Physics.<sup>11</sup> A total of 1327, 1689, and 273 number of words were collected for Biology, Geography and Physics, respectively. We observed that there are 48 CWs in the training dataset belong to the above glossaries. Thus, a word is tagged as complex, if it is found in any three of these glossaries.

**Dictionary Module:** We observed that the words not present in the English dictionary are tagged as complex. A python dictionary module *pyenchant*<sup>12</sup> (both US and UK) was used to identify the non-English words. If a word was not found in either of them, then it was tagged as complex.

**Most frequently used English words:** If a word is not found in the 5,000 word list, then it was tagged as complex.

**Named Entity as noncomplex:** The NEs which are identified as CWs by our system are re-annotated as noncomplex words. We also tagged positional words (such as 2nd/3rd/4th) as noncomplex.

### 4.3 Results

We performed the 10-fold cross validation on the training dataset using the Random Forests classifier and achieved a F-Score of 0.53. Again, we applied the post-processing on the results obtained by the above system and observed an improvement of 0.04 in the F-Score. Thus, we presented all the results on the test dataset after implementing the post-processing techniques.

The Naïve Bayes and Random Forest classifiers based systems achieved the maximum accuracies of 0.767 and 0.795 respectively. However, the precision of both the systems are quite low (0.139 and 0.151). One of the main reasons is that the number of CWs in test dataset are quite low as compared to CWs in the training dataset (4.69% and 31.6% for test and training dataset, respectively). This happened because 20 annotators have annotated the training dataset and a word is tagged as complex if any one of the annotator annotated so. Whereas, a word in the test dataset is annotated by only one annotator.

The maximum recalls achieved by Naïve Bayes and Random Forest based systems are 0.767 and 0.73 respectively. Both the systems achieved almost similar recalls and accuracies because all the features used are biased towards complex words. The maximum F-Score achieved for the Naïve Bayes based system is 0.236 and that for Random Forest based system is 0.25. The detailed statistics of the system performances are given in Table 2. The confusion matrix for the above systems are given in Table 3.

The team **SV000gg** has achieved the first and second positions with G-scores of 0.774 and 0.773, respectively. The team **TALN** which came third with the maximum G-Score of 0.772 has used Random Forest classifier. They included the number of annotators who marked a particular word complex as a feature.

Our Naïve Bayes and Random Forest based systems achieved fourth and seventh position with the maximum G-scores of 0.767 and 0.761 respectively. There are two other systems namely **UWB** and **PLUJAGH** who have also achieved the fourth position. The team **UWB** uses Maximum Entropy classifiers and uses document frequencies of words in

|           | <b>Acc.</b> | <b>Prec.</b> | <b>Rec.</b> | <b>F-Score</b> | <b>G-Score</b> |
|-----------|-------------|--------------|-------------|----------------|----------------|
| <b>NB</b> | 0.767       | 0.139        | 0.767       | 0.236          | <b>0.767</b>   |
| <b>RF</b> | 0.795       | 0.151        | 0.730       | 0.250          | 0.761          |

**Table 2:** System performance (NB: Naïve Bayes, RF: Random Forest, Acc.: Accuracy, Prec.: Precision, Rec.: Recall)

| <b>Predicted</b> |          |           |          |           |          |
|------------------|----------|-----------|----------|-----------|----------|
|                  |          | <b>NB</b> |          | <b>RF</b> |          |
|                  |          | <b>0</b>  | <b>1</b> | <b>0</b>  | <b>1</b> |

|                  | <b>1</b> | 964       | 3167     | 1115      | 3016     |

**Table 3:** Confusion Matrix for systems

Wikipedia as the only feature. They obtain higher accuracy of 0.803, but have the same G-Score as our system. The team **PLUJAGH** achieved the same G-Score as our system, but they achieved the higher accuracy of 0.795. Their system learns the threshold of word frequencies in Wikipedia that maximizes the F-score over the joint dataset. Another system of the team **PLUJAGH** achieved the maximum F-Score of 0.353, but got quite low G-Score of 0.608 and obtained 22nd position.

## 5 Conclusion and Future Work

In this paper, we have presented two systems for identifying the complex words in English. We believe that this problem will become increasingly important for lexical simplification. Our Naïve Bayes based system obtained the fourth position with the maximum G-score of 0.767.

In the training dataset, various stopwords within complex phrases were tagged as complex, because the annotator could not understand the context of that phrase. Thus, capturing complex phrase in a sentence is an interesting task and it would require context and n-gram level features. Apart from this, the feature set can be extended to build a model to identify the persons suffering from dyslexia.

## Abstract

This paper describes team *MAZA* entries for the 2016 SemEval Task 11: Complex Word Identification (CWI). The task is a binary classification task in which systems are trained to predict whether a word in a sentence is considered to be complex or not. We developed our two systems for this task based on classifier stacking using decision stumps and decision trees. Our best system, using contextual features, frequency information, and word and sentence length, achieved 91.2% accuracy and 30.8% F-Score. The system ranked 4<sup>th</sup> among the 38 entries in the CWI task in terms of F-Score.

## 1 Introduction

Lexical simplification is a popular task in natural language processing and it was the topic of a successful SemEval task in 2012 (Specia et al., 2012). It consists of applying computational methods to substitute words or short phrases for simpler ones to improve text readability and comprehension aimed at a given target population (e.g. children, language learners, people with reading impairment, etc.). Lexical simplification is considered to be the sub-task of text simplification that deals with the lexicon while other sub-tasks address, for example, complex syntactic structures (Siddharthan, 2014).

To perform lexical simplification efficiently, computational methods should be first applied to identify which words in a text pose more difficulty to readers and they therefore good candidates for substitution (Shardlow, 2013). This task is called complex word

identification (CWI) and it is the topic of the 2016 SemEval Task 11 with the same name.

The CWI shared task is modeled as a binary text classification task. Participants are provided with training data containing sentences and a label for each word in them containing a value of either 1 (for complex words) or 0 (for simple words). The label was attributed according to the judgment of human annotators that were required to indicate which words in the sentences could not be easily understood. Below, an example can be found of a sentence from the training set. Complex words are marked in bold.

- (1) The name ‘kangaroo mouse’ refers to the species’ **extraordinary** jumping ability, as well as its habit of **bipedal locomotion**.

In the example presented above, the CWI systems should label *extraordinary*, *bipedal* and *locomotion* as complex words.<sup>1</sup> To accomplish this task, the *MAZA* team applied a decision stump meta-classifier and a wide set of features that we will describe here.

## 2 Data

Organizers of the SemEval CWI task provided a training and test set comprising English sentences with each word annotated with a complex or simple label. According to the CWI task website<sup>2</sup>: ‘400 annotators were presented with several sentences and asked to select which words they did not understand

<sup>1</sup>Note that participants are free to consider *bipedal locomotion* as single words or as a multiword expression.

<sup>2</sup><http://alt.qcri.org/semeval2016/task11/>

their meaning'. There was no scale or gradation, all words should be assigned as simple or complex.

The training set was composed of 2,237 sentences. It contains judgments made by 20 annotators over a set of 200 sentences. A word is considered to be complex if at least one of the 20 annotators assigned them as complex. Subsequently a test set with the same format was released containing 88,221 sentences. According to the organizers, the test set contains by judgments made over 9,000 sentences by a single annotator.

The proportion of training vs. test instances of 1:40 should also be noted as it represents an additional challenge to participants. This data split is different from other similar text classification shared tasks which provide much more training than test instances (at least 10:1) (Tetreault et al., 2013; Zampieri et al., 2015). Given the amount of training data, participating teams should employ efficient algorithms able to perform generalizations on a much larger test set.<sup>3</sup>

### 3 Features

We experimented with two types of features in our submissions. Each of these two classes, as described below, contains several features which we combine using a meta-classifier.

#### 3.1 Frequency and Length Features

These are features based on the occurrence of the target word in a given reference corpus and its length. The idea is inspired by the Zipfian frequency distribution of words that indicate that the most frequent words in any language tend to be shorter (e.g. in English some of the most frequent words are: *it, the, an, and*). If we consider that frequent words are also likely to be short, our assumption is that complex words are likely to be, on average, both less frequent and longer than simple ones (Zipf, 1949). This assumption is also related to text readability and it has been tested in an experiment with dyslexic readers concluding that frequent words tend to improve readability while shorter words help text comprehension (Rello et al., 2013).

The reference corpus we used was the English

section of the DSL corpus collection (DSLCC) (Tan et al., 2014). This corpus seems to be an appropriate choice for our task as it was designed for language variety discrimination. For this reason, it contains English texts from both England and the United States. This ensures a desired variability in terms of spelling and word combination between the two most representative English varieties.

The frequency and length features we use are:

- **Word Probability:** The probability of the word occurring in the reference corpus.
- **Word Length:** The number of characters in the word. Our aforementioned intuition is that longer words tend to be both less frequent and more complicated to readers (Zipf, 1935; Zipf, 1949).
- **Sentence Length:** The number of characters in the sentence to which the target word belongs.

#### 3.2 Context Features

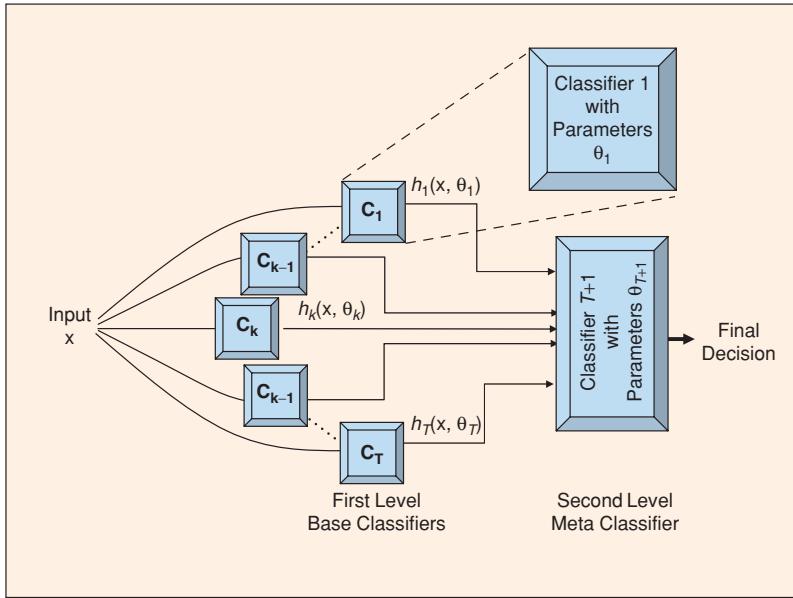

This set of features is based on estimating the likelihood of the target word within its context in a sentence. For a given target word  $w_i$ , we calculate six different types of probability, as described here.

The probabilities were extracted using the Microsoft Web N-gram service<sup>4</sup> which is based on web-scale data.

- **Conditional Probabilities:** We estimate the conditional probability of  $w_i$ , given its preceding context. Two probabilities are calculated: the probability of  $w_i$  given the previous word and the probability of  $w_i$  given the previous two words.
- **Joint Probabilities** Additionally, we also extract the joint probability of  $w_0$  and its surrounding words. We derived such joint probabilities for  $\{w_{i-2}, w_{i-1}, w_i\}$ ,  $\{w_{i-1}, w_i\}$ ,  $\{w_i, w_{i+1}\}$  and  $\{w_i, w_{i+1}, w_{i+2}\}$ .

<sup>3</sup>As noted by Zampieri and Tan (2014) in the Chinese Error Correction Shared Task (Yu et al., 2014)

<sup>4</sup><http://research.microsoft.com/en-us/collaboration/focus/cs/web-ngram.aspx>

**Figure 1:** An illustration of a meta-classifier architecture. Image reproduced from Polikar (2006).

## 4 Experimental Setup

We employed a meta-classifier for our entry, also referred to as classifier stacking. A meta-classifier architecture is generally composed of an ensemble of base classifiers that each make predictions for all of the input data. Their individual predictions, along with the gold labels are used to train a second-level meta-classifier that learns to predict the final decision for an input, given the decisions of the individual classifiers.

This setup is illustrated in Figure 1. This meta-classifier attempts to learn from the collective knowledge represented by the ensemble of local classifiers. The first step in such a setup is to create the set of base classifiers that form the first layer of the architecture. We describe this process below.

### 4.1 Ensemble Construction

Our ensemble was created using a set of decision stump classifiers. A decision stump is a decision tree trained using only a single feature (Iba and Langley, 1992); it is usually considered a weak learner.

We used the features listed in Section 3 to create an ensemble of 9 classifiers. Each classifier predicts every input and assigns a probability output to each of the two possible labels.

Classifiers ensembles have proved to an efficient

and robust alternative in other text classification tasks such as language identification (Malmasi and Dras, 2015a) and grammatical error detection (Xiang et al., 2015). This motivated us to try this approach in the CWI SemEval task.

### 4.2 Meta-classifier

For our meta-classifier, we adopted a decision tree with bootstrap aggregating (bagging). The inputs to each decision tree are the two probability outputs from each decision stump in our ensemble, along with the original gold label. 200 bagged decision trees were created using this input. The final label was selected through a plurality voting process over the entire set of bagged decision trees.

### 4.3 Systems

Using the methods described so far, we created two different systems for the shared task. They are summarized next:

- **MAZA A:** Our first system used only the frequency and length features described in Section 3.1.
- **MAZA B:** The second system we created combined the frequency and length features used in *MAZA A* with the addition of the contextual features we described in Section 3.2.

| Rank | Team    | System                  | Accuracy | Precision | Recall | F-score | G-score |
|------|---------|-------------------------|----------|-----------|--------|---------|---------|
| 1    | PLUJAGH | SEWDFF                  | 0.922    | 0.289     | 0.453  | 0.353   | 0.608   |
| 2    | LTG     | System2                 | 0.889    | 0.220     | 0.541  | 0.312   | 0.672   |
| 3    | LTG     | System1                 | 0.933    | 0.300     | 0.321  | 0.310   | 0.478   |
| 4    | MAZA    | B                       | 0.912    | 0.243     | 0.420  | 0.308   | 0.575   |
| 5    | HMC     | DecisionTree25          | 0.846    | 0.189     | 0.698  | 0.298   | 0.765   |

| 20   | BHASHA  | SVM                     | 0.844    | 0.119     | 0.363  | 0.179   | 0.508   |

**Table 1:** The top 20 systems submitted to the shared task, ranked by their F-score.

We expected the system *B* to perform better, but we were interested in quantifying the impact of the contextual features on the test set results by the comparing the two systems.

## 5 Results

We present in Table 1 the best 20 out of 38 systems ranked by their F-score. We present the results obtained in terms of Accuracy, Recall, Precision, F-Score, and G-Score.<sup>5</sup> The complete results and more information about the evaluation can be found in the CWI shared task report paper (Paetzold and Specia, 2015).

As expected, our second system, *MAZA B* that incorporated contextual features along with frequency and length features performed better, ranking in 4<sup>th</sup> place overall. Our first system, *MAZA A* obtained performance more than 11 percentage points worse than the *B* system, coming in 18<sup>th</sup> place.

Our results show that the contextual features we applied in the *MAZA B* submission are very informative for this task. This suggests that the complexity of a word is strongly tied to the context in which it

is being used and it cannot be solely determined by how frequent or how long the word is.

## 6 Conclusion

In this paper we described our systems for SemEval 2016 Task 11: Complex Word Identification (CWI). Our best system, *MAZA B* was ranked 4<sup>th</sup> in terms of F-Score among 38 entries in the shared task. We consider the results we obtained to be very positive given the amount of teams participating in the task.

We applied a meta-classifier approach where each target word is classified by several base classifiers, and another classifier learns to predict the final label using the outputs of those classifiers. Our system’s competitive performance in task suggests that this is a promising approach for this task.

Future work could look at how additional language resources could be used for this task. Analyzing the language produced by learners could provide insight into the limitations of learners’ vocabulary. Learner corpora, widely used in the task of Native Language Identification (Malmasi and Dras, 2014; Malmasi and Dras, 2015b) could be useful here.

<sup>5</sup>According to the organizers, the G-score is the harmonic mean between Accuracy and Recall.

## Acknowledgments

We would like to thank the SemEval CWI organizers, Gustavo Paetzold and Lucia Specia, for organizing this event. We also thank the anonymous reviewers for their constructive comments.

## Abstract

We present the description of the LTG entry in the SemEval-2016 Complex Word Identification (CWI) task, which aimed to develop systems for identifying complex words in English sentences. Our entry focused on the use of contextual language model features and the application of ensemble classification methods. Both of our systems achieved good performance, ranking in 2<sup>nd</sup> and 3<sup>rd</sup> place overall in terms of F-Score.

## 1 Introduction

Complex Word Identification (CWI) is the task of identifying complex words in texts using computational methods (Shardlow, 2013). The task is usually carried out as part of lexical and text simplification systems. Shardlow (2014) considers CWI as the first processing step in lexical simplification pipelines. Complex or difficult words should first be identified so they can be later substituted by simpler ones to improve text readability.

CWI has gained more importance in the last decade as lexical and text simplification systems have been developed or tailored for a number of purposes. They have been applied to make texts more accessible to language learners (Petersen and Ostendorf, 2007); other researchers have explored text simplification strategies targeted at populations with low literacy skills (Aluísio et al., 2008). Finally, another relevant application of text simplification are people with dyslexia (Rello et al., 2013).

The SemEval 2016 Task 11: Complex Word Identification (CWI) provides an interesting opportunity

to evaluate methods and approaches for this task. The organizers proposed a binary text classification task in which participants were required label words in English sentences as either complex (1) or simple (0). The task organizers provided participants with a training set containing sentences annotated with this information, followed by an unlabeled test set for evaluation. The assessment of whether words in a sentence are complex or simple was performed by human annotators required to label the data.<sup>1</sup>

## 2 Data

Based on the information available at the shared task’s website<sup>2</sup>: “400 annotators were presented with several sentences and asked to select which words they did not understand their meaning.”

The CWI task dataset was divided as follows:

- **Training set:** 2,237 judgments by 20 annotators over 200 sentences. A word is considered complex if at least one of the 20 annotators assigned it as so.
- **Test set:** 88,221 judgments made over 9,000 sentences (1 annotator per sentence).

<sup>1</sup>Here the term *complex* is used as a synonym for difficult. Unlike the Morphology term *complex* (antonym of *simplex*) that defines compound words or words composed of multiple morphs (Adams, 2001).

<sup>2</sup><http://alt.qcri.org/semeval2016/task11/>

### 3 Methodology

The primary focus of our team’s entry was the use of judgements from different annotators to create training data. We looked at how adjusting the threshold for inter-annotator agreement would affect the results and whether the combination of data created using different threshold values could improve performance.

Initially, the training data released by the organizers was labeled in a way that a word was marked as complex if any annotator judged it so. During the course of the shared task the organizers released additional information about the training data, chiefly the individual judgements of the 20 annotators that were used to derive the final labels for each word.

We attempted to use this data in our system. During development we noted that by increasing this threshold to two, the performance of our system under cross-validation improved by a small amount. Accordingly, we pursued this direction as the main focus of our experiments.

#### 3.1 Classifiers

We utilize a decision tree classifier, which we found to perform better than Support Vector Machine (SVM) and Naïve Bayes classifiers for this data.

#### 3.2 Features

Our core set of features are based on estimating  $n$ -gram probabilities using web-scale language models. More specifically, this data was sourced from the Microsoft Web N-Gram Service<sup>3</sup>, although we should note that this service has been deprecated and replaced since the shared task.<sup>4</sup> These language models are trained on web-scale corpora collected by Microsoft’s Bing search engine from crawling English web pages.

Given a target word  $w_t$ , we extract several probability estimates to use as classification features. These estimates, which we describe below, use the target word as well its preceding and following words, as shown in Figure 1.

<sup>3</sup><http://weblm.research.microsoft.com/>

<sup>4</sup>It has been replaced by Microsoft’s Project Oxford: <https://www.projectoxford.ai/weblm>

#### 3.2.1 Word Probability

This is an estimate of how likely the target word is to occur in the language model:

$$P(w_t)$$

Rarer words would be assigned lower values and thus this feature can help quantify word frequency for the classifier.

#### 3.2.2 Conditional Probability

We calculate the bigram probability of  $w_t$ :

$$P(w_t | w_{t-1})$$

Similarly, we estimate the trigram probability:

$$P(w_t | w_{t-1}, w_{t-2})$$

These values estimate the likelihood of the target word occurring given the previous one or two words. They can help quantify if the word is being used in a common or less frequent context.

#### 3.2.3 Joint Probability

We also use the following joint probability estimates of the target word and its surrounding words:

$$\begin{aligned} & P(w_{t-1}, w_{t-2}, w_t) \\ & P(w_{t-1}, w_t) \\ & P(w_{t-1}, w_t, w_{t+1}) \\ & P(w_t, w_{t+1}) \\ & P(w_t, w_{t+1}, w_{t+2}) \end{aligned}$$

The intuition underlying the use of all of these  $n$ -gram language model features is that the understanding of certain words depends on the context they appear in. A large number of English words are polysemous and their classification, without taking into account the specific sense being used, could lead to misclassifications. This can occur in scenarios where a learner knows the most frequently used sense of a polysemous word, but is confronted with a different sense that they have not encountered before. Additionally, even if a known word is used in an unusual context, it could be a cause of confusion for learners.

This cavity is formed by the mantle **skirt** , a double fold of mantle which [...]

|           |           |              |           |           |
|-----------|-----------|--------------|-----------|-----------|
| the       | mantle    | <b>skirt</b> | a         | double    |
| $w_{t-2}$ | $w_{t-1}$ | $w_t$        | $w_{t+1}$ | $w_{t+2}$ |

**Figure 1:** An example of the context extracted for a target word, which is “skirt” in this example.

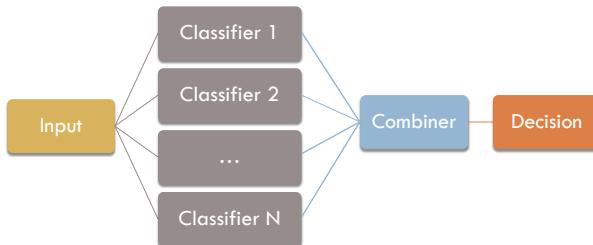

### 3.2.4 Word Length

Guided by the intuition that the most frequent words in a language are usually shorter, we use the length of a word as a classification feature.

## 4 Ensemble Classifiers

Classifier ensembles are a way of combining different classifiers or experts with the goal of improving accuracy through enhanced decision making. They have been applied to a wide range of real-world problems and shown to achieve better results compared to single-classifier methods (Oza and Tumer, 2008). Through aggregating the outputs of multiple classifiers in some way, their outputs are generally considered to be more robust. Ensemble methods continue to receive increasing attention from researchers and remain a focus of much machine learning research (Woźniak et al., 2014; Kuncheva and Rodríguez, 2014).

Such ensemble-based systems often use a parallel architecture, as illustrated in Figure 2, where the classifiers are run independently and their outputs are aggregated using a fusion method. For example, *Bagging* (bootstrap aggregating) is a commonly used method for ensemble generation (Breiman, 1996) that can create multiple base classifiers.

**Figure 2:** An example of parallel classifier ensemble architecture where  $N$  independent classifiers provide predictions which are then fused using an ensemble combination method.

It works by creating multiple bootstrap training sets from the original training data and a separate classifier is trained from each one of these sets. The generated classifiers are said to be diverse because each training set is created by sampling with replacement and contains a random subset of the original data.

Other, more sophisticated, ensemble methods that rely on meta-learning may employ a stacked architecture where the output from a first set of classifiers is fed into a second level meta-classifier and so on.

The first part of creating an ensemble is generating the individual classifiers. Various methods for creating these ensemble elements have been proposed. These involve using different algorithms, parameters or feature types; applying different preprocessing or feature scaling methods and varying (e.g. distorting or resampling) the training data.

## 5 Systems

In this section we describe the two systems we created and entered in the shared task.

### 5.1 System 1

Our first system was based on decision tree classifier trained on data where the minimum threshold for inter-annotator agreement was set to 3. Given that the testing data was only annotated by a single rater, we did not want to pick a value that was too high, even though this could improve cross-validation performance on the training data.

Additionally, we converted this setup to an ensemble by creating 100 randomized decision tree classifiers by using bagging, which we described earlier. The decisions of these learners were fused via plurality voting to yield the final label for an instance.

| Rank | Team    | System                  | Accuracy | Precision | Recall | F-score | G-score |
|------|---------|-------------------------|----------|-----------|--------|---------|---------|
| 1    | PLUJAGH | SEWDFF                  | 0.922    | 0.289     | 0.453  | 0.353   | 0.608   |
| 2    | LTG     | System2                 | 0.889    | 0.220     | 0.541  | 0.312   | 0.672   |
| 3    | LTG     | System1                 | 0.933    | 0.300     | 0.321  | 0.310   | 0.478   |
| 4    | MAZA    | B                       | 0.912    | 0.243     | 0.420  | 0.308   | 0.575   |
| 5    | HMC     | DecisionTree25          | 0.846    | 0.189     | 0.698  | 0.298   | 0.765   |
| 6    | TALN    | RandomForest_SIM.output | 0.847    | 0.186     | 0.673  | 0.292   | 0.750   |
| 7    | HMC     | RegressionTree05        | 0.838    | 0.182     | 0.705  | 0.290   | 0.766   |
| 8    | MACSAAR | RFC                     | 0.825    | 0.168     | 0.694  | 0.270   | 0.754   |
| 9    | TALN    | RandomForest_WEI.output | 0.812    | 0.164     | 0.736  | 0.268   | 0.772   |
| 10   | UWB     | All                     | 0.803    | 0.157     | 0.734  | 0.258   | 0.767   |

**Table 1:** The top 10 systems in task, ranked by their F-score.

## 5.2 System 2

For our second system we extended the threshold-based approach to an ensemble of decision trees trained on different data.

We created four individual classifiers, each trained with a different minimum threshold<sup>5</sup> ranging between 1–4. The outputs of these classifiers, a binary prediction, were then combined using a plurality voting combiner. It should also be noted that having an even number of base classifiers also introduces the possibility of ties occurring.

## 6 Results

The top 10 task submissions, ranked by the F-score, are shown in Table 1 with our systems highlighted. Both of our systems achieved very competitive results, ranking in second and third place overall.

Our second system, an ensemble of classifiers trained on distinct data derived using different levels of inter-rater agreement, performed slightly better than the first system. This could be interpreted as this evidence the second approach is slightly better, and we hypothesize that combining annotations from different combinations of annotators may help the classifier learn reliable models of the phenomenon, since individual annotations (as well as the original combined annotation) were noisy. However, determining this requires further experiments. This is due to the fact that with four classifiers in the ensemble, voting resulted in a tie for some 6% of the testing data. These ties were broken arbitrarily, introducing an element of stochasticity to our results.

In hindsight this does not appear to have been the

most intuitive or robust way of dealing with such ties since the distribution of classes is not balanced. In fact, this distribution is highly skewed, as we discuss in the next section.

## 6.1 Conclusion

We developed two ensemble-based systems for this task, both of which achieved competitive results in the final rankings. Our results indicate that the use of contextual features, as well as language models, are promising for this task.

Analysis of the gold standard labels release after the task shows that only 4.7% of the 88k samples belonged to the positive class. This is a very highly skewed distribution that can make it hard to train effective classifiers. It also means that accuracy cannot be used as the sole evaluation metric here; a balanced measure of precision and recall like the F-score is required. Alternatively, the balanced accuracy measure (Brodersen et al., 2010) could also be used. Such a high data imbalance can result in training classifiers that are biased towards the majority class. This bias can be more problematic if the distribution of classes is different in the test set. Accordingly, future work in this area could look at the use of methods for dealing with unbalanced datasets (He and Garcia, 2009). The application of such methods, in conjunction with ensembles, could potentially result in greater performance.

Future work could attempt to integrate additional language resources for this task. Analyzing the text produced by learners could provide insight into the limitations of learner vocabulary. Learner corpora, widely used in the task of Native Language Identification (Malmasi and Dras, 2014; Malmasi and Dras, 2015) could be useful here.

<sup>5</sup>Setting the threshold to 1 is equivalent to using the original training data.

## Acknowledgments

We would like to thank the CWI task organizers for managing the organization of this event. We also thank the anonymous reviewers for their insightful comments.

## Abstract

This paper presents the *MacSaar* system developed to identify complex words in English texts. *MacSaar* participated in the SemEval 2016 task 11: Complex Word Identification submitting two runs. The system is based on the assumption that complex words are likely to be less frequent and on average longer than words considered to be simple. We report results of 82.5% accuracy and 27% F-Score using a Random Forest Classifier. The best *MacSaar* submission was ranked 8<sup>th</sup> in terms of F-Measure among 45 entries.

## 1 Introduction

Complex Word Identification (CWI) is the task of automatically identifying complex words in texts. It is considered a sub-task carried out in most lexical simplification pipelines (Paetzold and Specia, 2015). In this step, complex words, which are likely to be difficult words for readers and language learners, are identified so they can be substituted for simpler ones (Specia et al., 2012; Shardlow, 2013). Lexical simplification methods are usually integrated into text simplification systems developed for a particular target population (e.g. people with reading impairment or dyslexia, language learners, etc.) (Siddharthan, 2014).

Given a sentence, a CWI system is trained to identify words which are considered by readers to be complex. To give an example, let us consider the following sentence extracted from the SemEval CWI task training set:

- (1) Leo took an oath of purgation concerning the charges brought against him , and his opponents were exiled.

Taking Example 1 into account, the task of the CWI system is to assign as complex the four underlined words, namely: *oath*, *purgation*, *charges*, and *exiled*. But what makes these words complex and not, for example, *opponents* or *took*?

In the lexical simplification literature, the term *complex* is a synonym for difficult or complicated. For practical purposes, we consider as complex words those that were assigned by a pool of human annotators, provided by the organizers of the CWI task, as difficult to be understood due to several factors that we will discuss in this paper. This is a readability notion that is not necessarily related to intrinsic linguistic phenomena (e.g. word formation).<sup>1</sup>

### 1.1 Motivation

*MacSaar* participated in the CWI SemEval task interested in two aspects of complex words. The first one is related to communication principles, or in other words, what makes words complex or simple to readers. One of our assumptions is that complex words tend to be less frequent in general language corpora than simple words. The second aspect is language learning. Lexical and text simplification methods are very important to produce simpler texts

<sup>1</sup>It is important to note that the definition of *complex* used here is different from that used in Morphology, where complex words are defined as compound words or words composed of multiple morphs as opposed to *simplex* words which are words with no affixes and not part of compounds (e.g. *happy* is a simplex word and *unhappiness* is a complex one) (Adams, 2001).

targeted at language learners which facilitate reading comprehension.

In communication theory, the *cooperative principle* states that interlocutors cooperate and mutually accept one another to be understood in a particular way to optimize each interaction (Grice, 1975). Interactions should take what Grice describes as the four maxims into account: *quality*, *quantity*, *relevance*, and *manner*.

We relate the *maxim of manner* to the usage of simple words that a learner will hear more frequently than complex words. Therefore, it should be possible to determine whether a word is complex or simple by observing Zipfian frequency distributions computed from suitable text corpora (Zipf, 1949). Another aspect to consider is the length of the words. Words that are more frequent tend to be shorter as noted by Zipf: ‘*the magnitude of words tends, on the whole, to stand in an inverse (not necessarily proportionate) relationship to the number of occurrences*’ (Zipf, 1935). That said, our approach takes both frequency and word length into account to determine whether a word is complex or not.

Finally, another aspect that we take into account is the difficulty in vocabulary acquisition that is related to the spelling of complex words (Xu et al., 2011; Dahlmeier et al., 2013). Educational applications that are tailored towards non-native speakers use character-level  $n$ -grams to identify possible spelling errors that language learner make. Thus making character combinations another interesting aspect to be consider in this task.

## 2 Related Work

CWI is a sub-task included in many lexical and text simplification systems. Lexical simplification, as the name suggests, focuses only on the substitution of complex words for simpler words in texts whereas text simplification comprises also the modification of syntactic structures to improve readability. Most text simplification systems also contain a lexical simplification module or component which often relies on the accurate identification of complex words for subsequent substitution. The three tasks are therefore inseparable.

Both lexical and text simplification approaches have been widely investigated. They have been

applied to different languages, examples include: Basque (Aranzabe et al., 2012), Italian (Barlacchi and Tonelli, 2013), Portuguese (Aluísio et al., 2008), Spanish (Bott et al., 2012), and the SemEval lexical simplification task for English (Specia et al., 2012).

To the best of our knowledge, very few methods have focused solely on complex word identification prior to the CWI shared task. An exception is the work by Shardlow (2013) which compared different techniques to identify complex words.

## 3 Methods

### 3.1 Task and Data

The SemEval 2016 Task 11, Complex Word Identification (CWI) is a binary text classification task at the word level. Systems are trained to attribute a label of either 1 (for complex words) or 0 (for simple words) to each word in a given sentence. There are no borderline cases or gradation, all words are either complex of simple.

A tokenized data set containing English sentences annotated with the complex or simple label for each word was provided. The training set contained 2,237 sentences, and the test set contained 88,221 sentences. The shared task website<sup>2</sup> states that: ‘the data was collected through a survey, in which 400 annotators were presented with several sentences and asked to select which words they did not understand their meaning’. There was no information of whether annotators were English native speakers.

The proportion of training vs. test instances makes the task more challenging than other similar shared tasks which provide much more training than test instances (Tetreault et al., 2013; Zampieri et al., 2015), a common practice in text classification tasks.<sup>3</sup>

### 3.2 Approach

Given the motivation described in Section 1.1, we approach the CWI task using word frequency and character-level  $n$ -gram features.<sup>4</sup> To emulate a language learner exposure to English, we use newspa-

<sup>2</sup><http://alt.qcri.org/semeval2016/task11/>

<sup>3</sup>The Chinese grammatical error diagnosis (CGED) shared task (Yu et al., 2014) is an exception. See the discussion in Zampieri and Tan (2014).

<sup>4</sup>Our implementation is open source and it can be found on: <https://github.com/alvations/MacSaar-CWI>

pers text from the English subsection of the DSL Corpus Collection (Tan et al., 2014) to compute the word frequencies and  $n$ -gram probability used to train our classifier.

The features used are explained in detail in the following sections and summarized in Table 1.

| Type                    | Feature   |
|-------------------------|---|
| Zipfian                 | Zipfian Frequency (ZipfFreq)<br>True Frequency (TrueFreq)   |
| Orthographic Difficulty | Word Length (no. of chars)<br>Word-level Trigrams Density<br>Sentence Length (no. of words)<br>Sentence-level Trigram Density |

Table 1: Features used in *MacSaar*

### 3.2.1 Zipfian Features

We model the language learners perspicuity by using insights from Zipfian properties of human language. Zipf (1949) predicts that the frequency of an element from a population of  $n$  elements,  $\text{ZipfFreq}$ , is defined as follows:

$$\text{ZipfFreq}(\text{word}) = \frac{1}{k^s H_{n,s}} = \frac{1}{k_{\text{word}}} \quad (1)$$

where  $k$  is the rank of the word sorted by most frequent first,  $s$  is the exponent characterizing the distribution,  $n$  is the vocabulary and size  $H_{n,s}$  is the generalized harmonic number i.e. the sum of the reciprocals of the size of vocabulary. In the simplest case, where we assume that the harmonic number and exponent to be 1, we compute  $\text{ZipfFreq}$  by taking the inverse of the the rank of a word.<sup>5</sup>

The Zipfian frequency is a hypothetical estimate of the nature of word frequency in natural language. To account for the true frequency of the word, we calculate the non-smoothed probabilities of the count of a word divided by the number of tokens in the corpus. Formally:

$$\text{TrueFreq}(\text{word}) = \frac{\text{count}(\text{word})}{N} \quad (2)$$

where  $N$  is the number of (non-unique) words in the corpus.

<sup>5</sup>In the actual implementation of our submission, we have taken the percentile of the word rank, i.e. the product of the rank of the word and the inverse of number of words in the vocabulary,  $|n|$ . Empirically, they have the same effect in a classification since  $|n|$  is a constant.

### 3.2.2 Character-based Features

To measure orthographic difficulty, we model word complexity by computing its (i) word length and (ii) sum probability of the character trigrams (normalized by the sum of all possible trigrams within the word). Intuitively, we could skip the normalization of the  $n$ -grams since we can assume that longer words are more complex. But we have the word length feature to account for the length of words, so the normalization of the  $n$ -grams probabilities would account for density of the  $n$ -gram probabilities independent of the length of the word.

Additionally, we computed (iii) sentence length and (iv) sum probability of the character trigrams of the sentence to account for contextual orthographic complexity with respect to the word-level spelling complexity. These sentence-level features are similar to those used in Native Language Identification (Gebre et al., 2013; Malmasi and Dras, 2015; Malmasi et al., 2015b).

As a meta-feature that captures both word and sentential level spelling complexity, we use the proportion of word to sentence orthographic difficulty by taking the ratio of the aforementioned features (ii) and (iv).

### 3.2.3 Classifiers

We trained 3 different classifiers using the features described in Table 1: a (i) Random Forest Classifier (RFC), (ii) Nearest Neighbor Classifier<sup>6</sup> (NNC) and (iii) Support Vector Machine<sup>7</sup> (SVM).

Nearest neighbor classifiers usually work well when the distribution between the training set data points are dense and similar to (or representative) of test set. Since there is a limitation of two official submissions, we only submitted the output generated by RFC and SVM.<sup>8</sup>

## 4 Results

The shared task organizers reported 45 submissions to the CWI task (including baseline systems). An overview of the task containing the complete scores

<sup>6</sup>RFC and NNC trained using Graphlab Create <https://dato.com/products/create/> with default parameters (without tuning)

<sup>7</sup>SVM trained using Scikit-Learn (Pedregosa et al., 2011)

<sup>8</sup>SVM has been shown to perform well for large text classification tasks (Malmasi and Dras, 2014; Malmasi et al., 2015a).

| Rank | Team           | System           | Accuracy     | Precision    | Recall       | F-score      | G-score      |
|------|----------------|------------------|--------------|--------------|--------------|--------------|--------------|
| 1    | PLUJAGH        | SEWDFF           | <b>0.922</b> | 0.289        | 0.453        | <b>0.353</b> | 0.608        |

**Table 2:** The top 15 out of 45 systems in the shared task, ranked by their F-score.

obtained by all participants is available in the shared task report (Paetzold and Specia, 2016).

In Table 2 we include the top 15 submissions ranked by F-Score. We report results in terms of Accuracy, Precision, Recall, F-score, and G-score. The best scores for each metric are presented in bold.<sup>9</sup> Our best performing system (RFC) achieved 82.5% accuracy and 27% F-Score. Our second system (SVM), scored 2.1 percentage points accuracy and 3.0 percentage points less than the one using RFC.<sup>10</sup> Our best submission was ranked 8<sup>th</sup> in the CWI task in terms of both F-Score and G-Score.

We observed that some systems were trained to obtain good Recall and G-Score, for example the system ranked 13<sup>th</sup> by team SV000gg, while others obtained high Accuracy, for example the systems by teams LTG (System1), PLUJAGH, and MAZA which obtained accuracy scores higher than 90%. No system delivered a balanced combination of both scores which confirms the difficulty of this task.

Finally, as to the performance of the NNC system, we tested the NNC model on the gold data and this system achieved 75.9% accuracy and 11% F-score. As expected, it did not perform well because of the split between training and test set.

<sup>9</sup>G-score is the harmonic mean between Accuracy & Recall.

<sup>10</sup>In the official CWI task scores (Paetzold and Specia, 2016), our second system is referred to as NNC even though it used an SVM. This occurred because we substituted the output of the NNC for the SVM but were unable to change the entry’s name.

## 5 Conclusion and Future Work

The two *MacSaar* submissions were ranked on the top half of the table, among the top 15 out of 45 entries, in the SemEval-2016 Task 11: Complex Word Identification (CWI). Our best system using a Random Forest Classifier was ranked 8<sup>th</sup> in terms of both F-score and G-Score. This indicates that the performance we obtained can be comparable to other state-of-the-art systems for this task.

More than a good performance, we showed that the use of Zipfian features are a good source of information for this task. The frequency of occurrence and word length in complex and simple words are two interesting variables to be investigated in future work. By looking at the relationship between word frequencies and word length Piantadosi et al. (2011) states that word lengths are optimized for efficient communication and that ‘information content is a considerably more important predictor of word length than frequency’. In our approach we did not take information content into account and we would like to investigate this in the future.

Another interesting, and to a certain extent surprising, outcome is that the SVM classifier did not outperform RFC using the same set of features. Due to its architecture, SVM is well-known for performing well in binary classification tasks and we would like to look analyse the most informative features and to perform error analysis to investigate the reasons for SVM’s poor performance in this task.

## Acknowledgments

We would like to thank Gustavo Paetzold and Lucia Specia for organizing the CWI shared task. We also thank the anonymous reviewers and Shervin Malmasi for their feedback.

## **Abstract**

This paper describes aggregated learning models for Complex Word Identification (CWI) task in SemEval 2016. The work focused on selecting the features that determine complexity of words and used different combinations of support vector machine (SVM) and decision tree (DT) techniques for classification. These classifiers were pipelined with pre-processing and post-processing blocks which helped improving accuracy of systems, though had little impact on recall. Four systems were evaluated on the test set; SVM and DT systems by team Bhasha achieved G score of 0.529 and 0.508 respectively and SVM&DT and SVMPP systems by team Garuda achieved G scores of 0.360 and 0.546 respectively.

## **1 Introduction**

CWI constitutes the first stage in lexical simplification (LS) pipeline (Specia et al., 2012). Performance of any LS system highly relies on accurate identification of complex words. (Shardlow, 2014) categorized errors in LS into six types and two of them (type 2A and 2B) are reflections of recall and precision of CWI system. The author concluded that type 2B errors occur with highest frequency, nearly 0.54, followed by type 2A (0.11). Also only 0.1 of simplifications were free from error. Thus, designing a robust CWI system impacts LS task the most.

CWI has long been researched and used in LS systems. (Paetzold, 2015) named some of the approaches used inclusive to LS task, like lexicon

based approaches, frequency thresholding based approaches, word length thresholding and user driven approaches. Trained classifiers have also been proposed in literature like, (Shardlow, 2013) used SVM as classifier on feature sets comprising of frequency, length, synonym counts etc.

This work is extension to the method proposed by (Shardlow, 2013). The proposed systems are built on broader set of features and multiple classifiers have been used individually or in aggregation to know trade-off between precision and recall. These systems are trained solely on the training data released by task organizers and no external resource has been used, except the WordNet (Miller, 1995; Fellbaum, 1998).

The rest of paper is organized as follows, section 2 describes the feature sets used. Section 3 describes the approaches used and submitted systems performance w.r.t other participants. Finally, section 4 presents the conclusions and outlines some directions of future work.

## **2 Feature Sets**

Selection of relevant feature is key to better performance of a machine learning model. While in some tasks, feature extraction is an obvious process, in tasks like CWI its hard to determine features aptness. So, in this work all the feature sets whose inclusion improves any of recall, precision or accuracy were used. These features have been described below.

## 2.1 Characters n-grams Frequency

These features are based on an assumption that character sequences that are frequently used should be easier to be recognized compared to rarely used sequences. For instance, if it is required to choose between Quixotic and Idealistic, idealistic would be easier to remember. Probably, because ideal, deal, idea are very commonly observed sequences, while quix is a rarely used character sequence in English dictionary. Given infinite possible character sequences, this work limited the sequences to 300 most frequently used uni, bi and tri-grams of characters.

## 2.2 Word's Features

In most of the LS tasks, word frequency thresholding has been used to determine its complexity (Brysbaert and New, 2009). In our systems, we have also included frequencies of words at positions [-2, -1, 1, 2] relative to the word, which is accounted only to observed higher accuracy.

We have also used Parts-of-Speech tag of target word and the words at position [-2, -1, 1, 2] relative to it as features. Brown corpus (Francis and Kucera, 1979) tagged with pos-tags used in the Penn treebank (Marcus et al., 1993) project was used to calculate trigram and emission probabilities for words and their parts of speech. Using Viterbi algorithm (Jurafsky and Martin, 2000) and probabilities calculated above, training and test sentences were tagged. Inclusion of pos-tags as features are again accounted to higher accuracy observed on validation set. The pos-tags are quantized as their occurrence frequency in combined training and testing datasets, table 1 contains the values.

Other word level features used are- word length (Keskisärkkä, 2012), words position, ratio of vowels and consonants, words stem length and frequency of stemmed words.

## 2.3 WordNet

The objective of LS is to find an alternative to complex word which is supposedly more common to target user. The words which have simpler synonyms available are more likely to be recognized as complex. For instance, succumb is likely to be complex provided yield is used more frequently. To intro-

| Pos-tags  | Values   | Pos-tags  | Values   |
|-----------|----------|-----------|----------|
| { PRP\$ } | 0.000645 | { WP }    | 0.000227 |
| { VBG }   | 0.039401 | { VBZ }   | 0.001063 |
| { VBD }   | 0.005699 | { DT }    | 0.001253 |
| { VBN }   | 0.047874 | { NN }    | 0.537558 |
| { VBP }   | 0.000189 | { FW }    | 0.000113 |
| { WDT }   | 0.000152 | { TO }    | 0.000008 |
| { JJ }    | 0.075610 | { PRP }   | 0.000873 |
| { RB }    | 0.024962 | { Other } | 0.0      |

**Table 1:** Pos-tags and the corresponding numerical values used in Classifiers

duce this into our system, we used WordNet to find synonyms of word and used word frequency relative to its SynSets as an input feature. Like in case of succumb, yield, succumb and yield have frequency counts of 4 and 0 respectively. So the input feature will be 0 [0 / (0+4)] for succumb and 1 [4 / (0+4)] for yield.

## 3 Proposed Systems

We are proposing three stage pipelined systems for CWI task, comprising of pre-processing, classification by one or ensemble of trained models, and post-processing stages. These stages are described below.

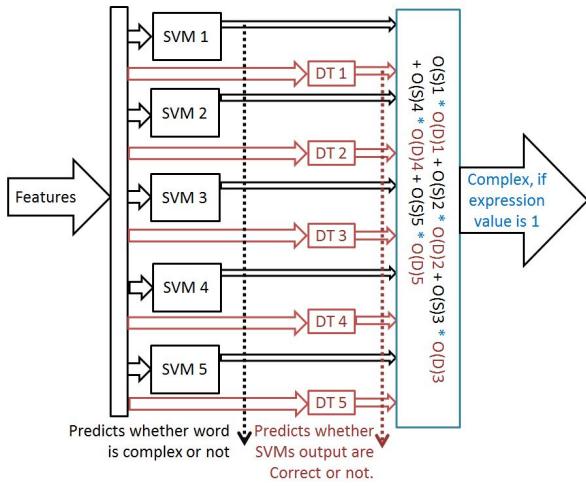

### 3.1 Pre-processing

This stage comprises of four preliminary checks that directly classify words based on rules.

1. All the named entities are classified as non-complex.
2. The words which dont belong to English are classified as complex. We have used words available in various corpora provided by nltk package and English word list (Lawler, 1999) for this.
3. Words with length less than 2 are classified as non-complex.
4. Words with pos-tags CD, DT and TO as per UPenn tag-sets are classified as non-complex.

### 3.2 Trained Classifiers

This stage consists of a trained classifier based on features described in section 2. We submitted four systems with classifiers trained using different classification algorithms. Systems submitted

**Figure 1:** HSVM&DT Architecture for CWI.

by team Bhasha were based on support vector machines (SVM) and decision tree (DT). We used standard classifiers available in scikit-learn package (Pedregosa et al., 2011). Systems submitted by Garuda team were based on hybrid of classifiers. They are described below.

**HSVM&DT:** This is a hybrid model, inspired by bagging ensembles, comprising of multiple SVMs and DT for classifying words. We have used 5 SVMs with different training parameters (gamma, kernel and C values) and 5 different DT classifiers. SVMs perform classification of words as complex or non-complex, while DTs classify the predictions of SVM as correct or incorrect. Figure 1 explains the architecture.

A pair of SVM and DT model works together to classify the words. For each pair, training data is divided into two sets; first set is used to train the SVM and on second set, trained SVM is used to predict the output. In second set, if predicted output of SVM is same as the actual word label, we define target output as 1 for DT classifier and other wise 0. With this new target output and input features same as SVM, DT model is trained. Five such pairs were trained, each trained on randomly sampled training data. Random sampling allows learning more generalized. This algorithm is described in figure 2. One clear distinction of this aggregated model from conventional bagging is in terms of combining methodology. Output of only those SVM classifiers are used for which corresponding DT predicts 1.

**SVMPP:** This model is built on CWI\_training\_allannotations data. Twenty separate SVMs were trained on each annotation available in training data. It was designed with a belief that this system would achieve higher recall, though precision may be substantially low. In training data, a word was defined as complex, if any of the annotation was complex. However in our design, we have calculated coefficients for all 20 classifiers that define the contribution of each SVM classifier in final output. Also, output label for this model was modified as  $\{-1, 1\}$  instead of  $\{0, 1\}$ . Detailed algorithm is described in figure 3.

#### HSVM&DT Algorithm

**Given:** Training Data S

for  $i = 1$  to 5:

Divide data in two sets  $S_\lambda, S_\mu$  in ratio 3:2

Train an SVM Classifier on  $S_\lambda$

Predict class of  $X_\mu \in S_\mu$  by trained SVM:  $Y'_\mu$

Generate training data for DT classifier:

if  $Y'_\mu == Y_\mu$ :

$Y_{\mu,DT} = 1$

else:

$Y_{\mu,DT} = 0$

Train DT Classifier with  $X_\mu, Y_{\mu,DT} \in S_\mu$

**Output Hypothesis:**  $0 \iff \sum O_{S[i]} * O_{D[i]} = 0$   
1, otherwise.

**Figure 2:** HSVM&DT Algorithm.

#### SVMPP Algorithm

**Given:** Training Data  $S_i$ ,  $i=1..20$  #20 annotators

**Output Pre-processing:**  $Y' = -1$ , if  $Y=0$   
 $Y' = 1$ , if  $Y=1$

for  $i = 1$  to 20:

Train SVM Classifier  $SVC_i$ , on  $S_i$ .

Calculate  $\lambda_i$  &  $\mu_i$  coefficients for classifier:

$$\lambda_i = T.P. / (T.P. + F.P.) \quad \mu_i = T.N. / (T.N. + F.N.)$$

T.P.  $\rightarrow$  True Positive F.P.  $\rightarrow$  False Positive

T.N.  $\rightarrow$  True Negative F.N.  $\rightarrow$  False Negative

**Output Hypothesis:**

$$0 \iff \sum f * O_{SVC_i} < 0;$$

1, otherwise.

where,  $f = \lambda_i$ , when  $O_{SVC_i} == 1$

$f = \mu_i$ , when  $O_{SVC_i} == -1$

**Figure 3:** SVMPP Algorithm.

As described in Figure 3, each SVM classifier has two associated coefficients  $\{\lambda, \mu\}$ .  $\lambda$  defines the precision of classifier in predicting non-complex words and  $\mu$  defines precision for identifying complex words.

### 3.3 Post-Processing

This stage comprises of final check to remove highly probable miss-classifications.

1. Character bigrams (402 character bigrams were present in training set) which were not observed in training data but is present in test data and has occurrence frequency less than 0.00005 are classified as complex (Ex: zt, kz etc.).
2. Words with occurrence frequency above 0.001 and labelled as non-complex (if label available) in training data but vice versa by trained model, are classified non-complex.

### 3.4 Performance Comparison

Table 2 compares the performance of our systems with respect to performance statistics of all submitted systems, including baselines. From the analysis, it can be easily concluded that none of our systems are very effective in deciding complexity of words. Three of our systems- SVMPP, DT and SVM could reach around average performances and were ranked 31, 38 and 41 based on G-Score among 52 systems. The performances of SVM and SVMPP are almost comparable to other SVM based submitted systems and SVM seems to be less effective for CWI. But our DT system failed in achieving performance scores comparable to other DT and RFC based systems.

System HSVM&DT performed even worse than individual SVM and DT classifiers and was ranked 48 among all the systems. To determine the reasons, we analyzed the system's performance on only two features- word's frequency and word's length and plotted the decision boundaries. And it was observed that the system failed to achieve its objective of using multiple classifiers to predict the complexity of word and then deciding a classifier that has highest confidence on its prediction. The main reason for its failure was that all SVMs had almost overlapping decision boundaries. And the error in DTs prediction further worsened the prediction.

| Systems         | Precision | Recall | Fscore | Gscore |
|-----------------|-----------|--------|--------|--------|
| maximum         | 0.299     | 1      | 0.353  | 0.774  |
| sv000gg         | 0.147     | 0.769  | 0.246  | 0.774  |
| plujagh         | 0.289     | 0.453  | 0.353  | 0.608  |
| average         | 0.114     | 0.606  | 0.173  | 0.560  |
| s.d. $[\sigma]$ | 0.065     | 0.252  | 0.081  | 0.194  |
| svmpp           | 0.099     | 0.415  | 0.160  | 0.546  |
| dt              | 0.118     | 0.387  | 0.181  | 0.529  |
| svm             | 0.119     | 0.363  | 0.179  | 0.508  |
| hsvm&dt         | 0.112     | 0.226  | 0.149  | 0.360  |
| minimum         | 0.0       | 0.0    | 0.0    | 0.0    |

**Table 2:** Systems Performance Measures

HSVM&DT, however, can be a very effective classifier for any task if we can manage to generate non-overlapping decision boundaries for all SVMs or any other constituent classifier. The performance of this system, though, is open for examination and needs to be explored further.

## 4 Conclusion

We tried several combinations of SVM and DT classifiers, but they could only achieve average of G-scores of all the submitted systems. As concluded by (Paetzold and Specia, 2016) in the CWI task description paper, DT and RFC perform better than most of the submitted systems. Also, the authors concluded that frequency measure possesses the highest confidence in deciding complexity of words. In our later study, we tried reducing the number of features and it was found that by merely including word-frequency, pos-tags, word-length and WordNet features, and training a DT model on same training set, system was able to achieve better G score on the test set. So, average performance of our systems can be mainly accounted to improper selection of features for the task. Inclusion of too many features shadowed the impact of frequency feature. In our future study, we plan to work on finding a suitable feature selection method for CWI and then work on classifier. Also as discussed before, failure of HSVM&DT model in this task is mainly accounted to lack of diversity in classifiers. We will continue our work on an ensemble classifier based on the principle of this model.

## Abstract

This paper presents the participation of the TALN team in the Complex Word Identification Task of SemEval-2016 (Task 11). The purpose of the task was to determine if a word in a given sentence can be judged as complex or not by a certain target audience. To experiment with word complexity identification approaches, Task organizers provided a training set of 2,237 words judged as complex or not by 20 human evaluators, together with the sentence in which each word occurs. In our contribution we modelled each word to evaluate as a numeric vector populated with a set of lexical, semantic and contextual features that may help assess the complexity of a word. We trained a Random Forest classifier to automatically decide if each word is complex or not. We submitted two runs in which we respectively considered unweighted and weighted instances of complex words to train our classifier, where the weight of each instance is proportional to the number of evaluators that judged the word as complex. Our system scored as the third best performing one.

## 1 Introduction

Approaches to automatically identify if a target audience will perceive a certain word as complex or not constitute a core component in several language-related areas of research, including *Lexical Simplification* (Bott et al., 2012) and *Readability Assessment* (Collins-Thompson, 2014).

The Complex Word Identification Task of SemEval-2016 proposes a shared framework for

evaluating complex word identification systems. Task participants were provided with a set of sentences where, for each sentence, one or more words have been rated as complex or not by 20 human evaluators. An example sentence from this dataset is:

*If the growth rate is known , the maximum lichen size will give a minimum age for when this rock was deposited.*

In this sentence, the words 'lichen' and 'deposited' were classified as complex by at least one out of the 20 evaluators, unlike e.g. 'growth', which did not receive this label by any of them.

In our participation in Task 11, we cast the identification of complex words as a binary classification problem in which each word is evaluated as complex or not, given the sentence in which it occurs. We modelled each word by a set of lexical, semantic and contextual features and evaluated distinct binary classification algorithms. Our approach to Task 11 obtained good performance: our team ranked as the second best performing one and one of the two systems we proposed scored as the third best performing system according to the G-score official evaluation metric (harmonic mean between Accuracy and Recall).

In Section 2 we provide an overview of relevant research related to Complex Word Identification. Section 3 and 4 respectively introduce the Task 11 dataset and present the text analysis tools and resources we exploited to characterize complex words. In Section 5 we describe the word features we used to build our complex word classifier. In Section 6 we present and discuss the performance of our Task 11 system. Finally, in Section 7 we formulate our

conclusions and outline future venues of research.

## 2 Related work

The identification of complex words constitutes a key aspect of *Lexical Simplification* (Bott et al., 2012). It can be defined as the problem of replacing difficult words by their simpler synonyms taking into account the specific context in which each word is used. Several techniques have been applied so far to identify complex words. In the context of the PSET Project (Devlin and Tait, 1998), the first lexical simplification system for English was developed, aimed at people with aphasia. It relies on a word difficulty assessment based on psycholinguistic evidence (Quinlan, 1992) in order to decide whether to simplify a word. Recent work exploited the availability of comparable corpora of original documents (e.g. English Wikipedia) and their 'simplified' versions (e.g. Simple English Wikipedia pages) to induce measures which can be used to compare and rank 'quasi-synonymic' word pairs (Yatskar et al., 2010). (Shardlow, 2013) compares three techniques to identify complex words in English: a psycholinguistic approach (Devlin and Tait, 1998), frequency thresholding (i.e. words with low frequency are considered complex), and a machine learning algorithm trained only on word features (frequency, syllable count, ambiguity, etc.). In this work, a corpus of complex words is created based on edit histories from the Simple Wikipedia. The authors conclude that the three tested methods perform similarly in terms of F-measure. (Saggion et al., 2016) use the combined evidence of word frequency and word length to assess the word complexity of a list of synonyms so as to select the simpler one in an Spanish lexical simplification system. (Rello et al., 2013) argue that word frequency and length are two important factors affecting readability and understanding for people with dyslexia.

Besides lexical simplification, the identification of complex words constitutes a core component of *readability assessment* (Collins-Thompson, 2014), the problem of quantifying the readability of a given text. The presence of complex words usually penalizes readability. Lists of easy words (Dale and Chall, 1948), word characteristics (Kincaid et al., 1975; Gunning, 1952; Mc Laughlin, 1969), or word use in

context (e.g. language models) (Si and Callan, 2001) are all techniques or resources which have been used to support the assessment of text readability: these approaches could also be adapted to evaluate word complexity.

## 3 Dataset

The organizers of SemEval-2016 Task 11 released a *training dataset* composed of 2,236 words together with the sentence in which each word occurs. For each word, the binary complexity judgements of 20 human evaluators were provided (complex word or not complex word). Similarly, Task 11 *testing dataset* consisted of 88,221 words together with the sentence in which each word occurs. In this case, for each word, the binary complexity judgement of only one human annotator was collected.

## 4 Resources and Tools

In order to identify complex words, we characterize each word by means of a set of lexical, semantic and contextual features. To this purpose, we analyze both the word and the sentence in which it occurs by means of the language resources and text analysis tools described in what follows.

### 4.1 Language Resources

Information about the frequency of use is important to assess word complexity. Therefore, in our complex word identification approach we exploit the word frequency data of two large corpora: (i) a 2014 English Wikipedia Dump and (ii) the British National Corpus (Leech and Rayson, 2014). We also use WordNet (Miller, 1995) to model semantic word features by relying on word senses and synset relations (e.g. hypernymy). Moreover, we use the Dale & Chall list of 3,000 simple words (Dale and Chall, 1948) in order to incorporate the text readability dimension, as this list contains words which 4th grade students considered understandable.

### 4.2 Text Analysis Tools

We analyze the sentences in which a word to evaluate occurs by means of the Mate dependency parser (Bohnet, 2010). As a result, we obtain a lemmatized and Part-Of-Speech (POS) tagged version

of the sentence, along with its syntactic dependencies. Both POS tags and dependency information are used to compute several features as described in the following Section.

We also processed each sentence by the UKB graph-based Word Sense Disambiguation algorithm (Agirre and Soroa, 2009). Specifically, we benefited from the UKB implementation integrated in the Freeling workbench (Padró and Stanilovsky, 2012). In this way, we may disambiguate single or multiword expressions against WordNet 3.0.

## 5 Method

In order to evaluate the complexity of a word, we modelled each word as a feature vector. Then, we used such word representation to enable the training and evaluation of distinct binary classification algorithms tailored to determine whether a word is complex or not. To this end, we relied on the Weka machine learning framework (Witten and Frank, 2000). We evaluated the performance of four classification algorithms: Support Vector Machine (with linear kernel), Naïve Bayes, Logistic Regression and Random Forest. For each algorithm, we experimented the effectiveness of the following two training approaches:

- *Simple*: in which complex and non complex word training instances have the same relevance (weight);
- *Weighted*: in which we weighted each non complex word with weight 1 and each complex word with a weight ranging from 1 to 20 with respect to the number of human annotators (over 20) that evaluated the word as complex.

In the remainder of this Section we describe the set of word features we used, and motivate their relevance with respect to the characterization of complex words. When presenting word features, we group subsets of related features in the same subsection (Shallow features, Dependency Tree features, etc.). It is important to note that some of the word features presented are computed by considering, besides the target word, also context words in a  $[-3, 3]$  window, where position 0 refers to the target word. If the context word at a specific position cannot be

determined, the value of the related feature is set to *undefined*.

### 5.1 Shallow Features

We exploited the following set of shallow word features:

- **Word length** (CharNumber): the length of the target word (number of characters).
- **Position of the word** (WordPosition): the position of the target word in the sentence. The value of this feature is normalized in the interval  $[0, 1]$  by dividing the the position of the target word in the sentence by the length of the same sentence (number of words). The position of the first word of a sentence is 0.
- **Words in sentence** (NumSentenceWords): the number of tokens in the sentence.

### 5.2 Dependency Tree Features

The following set of features is derived by processing the dependency tree of the sentences that include the word to evaluate:

- **Word depth in the dependency tree** (DepthInTree\_position - 7 features): we considered the depth in the dependency tree of the target word (*position* equal to 0), the three previous words and the three following words.
- **Parent word length** (ParentCharNumber): the length (number of characters) of the parent of the current (target) word in the dependency tree.

### 5.3 Corpus-based Features

Word frequency data derived from the British National Corpus and the 2014 English Wikipedia was used to compute the following set of features:

- **British National Corpus frequency** (BNCFrequency\_position - 7 features): we considered the BNC frequency<sup>1</sup> of the target word lemma (*position* equal to 0), the three previous word lemmas and the three following word lemmas.

---

<sup>1</sup>[http://ucrel.lancs.ac.uk/bncfreq/lists/1\\_1\\_all\\_fullalpha.txt.Z](http://ucrel.lancs.ac.uk/bncfreq/lists/1_1_all_fullalpha.txt.Z)

- **English Wikipedia frequency** (ENwikiFrequency\_position - 7 features): we considered the 2014 English Wikipedia frequency of the target word (*position* equal to 0), the three previous words and the three following words. Word frequencies were computed over a tokenized and lower-cased version of the English Wikipedia.
- **Simple word list** (Dale\_Chall): a binary feature to point out the presence of the target word in the Dale & Chall list.

#### 5.4 WordNet features

We used WordNet 3.0 to compute the following features. Given a target word, we refer as *target-word-synsets* the set of synsets that have the same POS of the target word and include the target word among their lexicalizations (all the senses of the target word). Note that this set of features is computed without relying on Word Sense Disambiguation.

- **Number of Synsets** (WNSynsetN): the number of synsets in *target-word-synsets* (i.e. number of senses of the target word).
- **Number of Senses** (WNSenseN): the sum of the number of word senses (i.e. the number of lexicalizations) of each *target-word-synset*.
- **Depth in the hypernym tree** (WNDepth): the average depth in the WordNet hypernym hierarchy among all the *target-word-synsets*.
- **Number of Lemmas** (WNLemma): the average number of synset lexicalizations among all the *target-word-synsets*.
- **Gloss length** (WNGloss): the average length of synset Glosses among all the *target-word-synsets*, in terms of number of tokens.
- **Number of relations** (WNRelation): the average number of semantic relations among all the *target-word-synsets*.
- **Number of Distinct POSs** (WNDistinctPOS): the number of distinct POS represented by at least one *target-word-synset*.

- **Part of Speech** (WN\_POS - 4 features): for each WordNet POS (*POS* equal to Noun, Verb, Adjective and Adverb) we counted the number of synsets with that POS among the *target-word-synsets*, thus generating four features.

#### 5.5 WordNet and corpus frequency features

The following set of features was computed by combining WordNet data, the word frequencies of the British National Corpus (BNC) and the results of the UKB WordNet-based Word Sense Disambiguation algorithm applied to the sentences where complex words appear. Thanks to the UKB algorithm, we identify the WordNet 3.0 synset that characterizes the sense of each target word (*WSD-synset*). Besides the target word, each *WSD-synset* usually has other lexicalizations, i.e. other synonyms. We retrieve the BNC frequency of all the lexicalizations of the *target-word-WSD-synset* and compute the following features:

- **Percentage of lexicalizations with higher / lower frequency than target word** (LexicHigher/LowerFreqWSD - 2 features): the percentage of the lexicalizations of the *WSD-synset* with a BNC frequency higher / lower than the target word BNC frequency.
- **Ratio of total lexicalizations' frequencies related to lexicalizations with higher / lower frequency than target word** (LexicHigher/LowerSumFreqWSD - 2 features): the ratio between the sum of BNC frequencies of the lexicalizations of the *WSD-synset* with a frequency higher / lower than the target word frequency and the sum of BNC frequencies of all the lexicalizations of the *WSD-synset*.

We also computed the previous set of 4 features without relying on the results of the UKB Word Sense Disambiguation algorithm: we considered for each target word all the lexicalizations of all the synsets that represent possible senses and have the same POS of the same target word. Similarly to the UKB based features, these features are referred to as: LexicHigher/LowerFreqALL and LexicHigher/LowerSumFreqALL.

## 6 Experiment and results

In order to identify the best approach to classify words as complex or not, we compared four classifiers by training on both the *Simple* and *Weighted* datasets. We evaluated the classification performance by means of a 10-fold cross-validation. Results are summarized in Table 1.

| Classifier                    | Dataset  | Precision | Recall | G-Score | F-Score              |
|-------------------------------|----------|-----------|--------|---------|----------------------|
| <b>Random Forest</b>          | Simple   | 0.746     | 0.756  | 0.582   | <b>0.735 (run 1)</b> |
|                               | Weighted | 0.836     | 0.823  | 0.780   | <b>0.824 (run 2)</b> |
| <b>Support Vector Machine</b> | Simple   | 0.685     | 0.707  | 0.707   | 0.650                |
|                               | Weighted | 0.728     | 0.718  | 0.718   | 0.719                |
| <b>Logistic Regression</b>    | Simple   | 0.667     | 0.697  | 0.476   | 0.659                |
|                               | Weighted | 0.733     | 0.734  | 0.745   | 0.733                |
| <b>Naïve Bayes</b>            | Simple   | 0.654     | 0.613  | 0.594   | 0.626                |
|                               | Weighted | 0.706     | 0.708  | 0.750   | 0.705                |

**Table 1:** Comparison of the performance of four complex word binary classifiers by a 10-fold cross-validation over the Task 11 training dataset.

Table 1 shows that the best performance in terms of F-Score was achieved by the Random Forest classifier for both approaches (*Simple* and *Weighted*). As a consequence, the two systems we submitted to Task 11 relied on a Random Forest model respectively trained on *Simple* (unweighted, run 1) and *Weighted* (run 2) instances. Our run based on *Weighted* instances performed quite well, ranking as the third best system in Task 11 with a G-Score of 0.772, where the G-Score of the best performing system is 0.774. With respect to F-Score our best performing run was the one based on *Simple* instances that ranked as sixth.

In Table 2 we show the top 10 features in our feature set in terms of information gain.

| Info-gain | Feature name               |
|-----------|----------------------------|
| 0.37865   | ENwikiFrequency_position_0 |
| 0.33303   | BNCFrequency_position_0    |
| 0.18752   | WNSynsetN                  |
| 0.18439   | WNGloss                    |
| 0.14452   | Dale_Chall                 |
| 0.13596   | LemmaLowerFreqALL          |
| 0.10567   | WNdepth                    |
| 0.10558   | LemmaLowerSumFreqALL       |
| 0.08037   | WNDistinctPOS              |
| 0.06244   | WNSenseN                   |

**Table 2:** Top 10 features with respect to information gain.

We can see that the frequencies of the word to evaluate in the two corpora we considered (English Wikipedia and British National Corpus) constitute the two most informative features. Five of the top 10 features are computed by relying on WordNet, without performing Word Sense Disambiguation: among them we can find the number of synsets (senses) of the word to evaluate (WNSynsetN), the average length of the glosses of these synsets (WNGloss) and the average depth of these synsets in the hypernym tree (WNDepth). Other useful indicators of word complexity are the presence of the word in the simple words list of Dale & Chall and the set of lexicalizations (of the synsets associated to the word) characterized by a frequency in the British National Corpus lower than the frequency of the word to evaluate (LexicLowerFreqALL and LexiLowerSumFreqALL).

In Table 3 we show the performance of the four classification algorithms we considered by training them on the whole *training dataset* (with *Simple* or *Weighted* instances) and testing them on the *testing dataset*. The best performance in terms of both F-Score and G-Score are achieved by the two Random Forest classifiers that were trained respectively on *Simple* (unweighted) and *Weighted* instances. In general, when we train the classifiers on *Weighted* instances in place of *Simple* ones, on the one hand both recall and accuracy improve, thus resulting in a higher G-Score, on the other hand the precision decreases, thus resulting in a lower F-Score.

| Classifier                    | Dataset  | Precision | Recall | G-Score        | F-Score |
|-------------------------------|----------|-----------|--------|----------------|---------|
| <b>Random Forest</b>          | Simple   | 0.186     | 0.673  | 0.750          | 0.292 + |
|                               | Weighted | 0.164     | 0.736  | <b>0.772 *</b> | 0.268   |
| <b>Support Vector Machine</b> | Simple   | 0.132     | 0.406  | 0.549          | 0.199   |
|                               | Weighted | 0.103     | 0.720  | 0.706          | 0.180   |
| <b>Logistic Regression</b>    | Simple   | 0.131     | 0.454  | 0.588          | 0.203   |
|                               | Weighted | 0.086     | 0.804  | 0.682          | 0.156   |
| <b>Naïve Bayes</b>            | Simple   | 0.083     | 0.769  | 0.670          | 0.151   |
|                               | Weighted | 0.079     | 0.787  | 0.656          | 0.144   |

**Table 3:** Comparison of the performance of four complex word binary classifiers. Each classifier is trained on the whole *training dataset* and tested on the annotated *testing dataset*. The asterisk symbol (\*) points out the best performing classifier by G-Score while the plus symbol (+) the best performing classifier by F-Score.

## 7 Conclusions

In this paper, we described our participation to SemEval-2016 Task 11 concerning Complex Word Identification. We presented and evaluated our system based on both the characterization of words by means of contextual, lexical and semantic features and the exploitation of a Random Forest classifier to decide if a word is complex or not.

As future work we are planning to expand the feature set that we consider to characterize words by relying on new corpora and lexical resources. Moreover, we would like to explore complementary approaches to take advantage of distributional representations of words (i.e. word embeddings) or other language models to determine words complexity.

## Abstract

This paper describes the system that was submitted to SemEval2016 Task 11: *Complex Word Identification*. It presents a preliminary investigation into exploring word difficulty for non-native English speakers. We developed two systems using Nearest Centroid Classification technique to distinguish complex words from simple words. Optimized over G-score, the presented solution obtained a G-score of 0.67, while the winner achieved a G-score of 0.77 and the average G-score of all the submitted systems in the task was 0.56.

## 1 Introduction

Lexical Simplification aims at improving the readability and comprehensibility of text by transforming complex text into simple text. Lexical Simplification (Specia et al., 2012; Belder et al., 2010; Horn et al., 2014) is the process of replacing a word in a given context with its simplest substitute to enhance the readability of the text. The process should make sure that while replacing words with other variants, the meaning of the text is preserved. Lexical Simplification (Siddharthan, 2014) is useful to a wide variety of target audience like people with aphasia, children and also non-native speakers. Complex Word Identification (Shardlow 2013; Paetzold 2015) is considered to be the first step in the pipeline of Lexical Simplification. The overall performance of a Lexical Simplification system is thus crucially dependent upon Complex Word Identification. The problem of Complex Word Identification is relatively new in the field of Natural Language

Processing. However, a few approaches have been previously proposed for this task. The simplicity score (Bott et al., 2012) of a word is computed by integrating both, frequency and length of a word. They consider a threshold value and simplify words only if the word’s frequency is lower than the fixed threshold. Matthew Shardlow (2013) explores the frequency thresholding to differentiate between simple and complex words by experimenting with each threshold value on a particular corpus. However, this approach is not practically convincing. The same author also frames the problem as a machine learning classification problem by designing a few features. We approach the problem at hand on similar lines.

The Complex Word Identification (CWI) task is framed as a binary classification problem. Given a word in a sentence, the task is to predict whether the word is simple or complex. A word is tagged with 0 if it is simple and 1 if the word is found to be complex.<sup>1</sup>

$$c(w) = \begin{cases} 1 & \text{if } w \in C \\ 0 & \text{if } w \in S \end{cases}$$

$C$  is the set of complex words,  $S$  is the set of simple words and  $c(w)$  represents the class of the word. Here is an example of a sentence taken from the training dataset provided by the organizers.

- ◊ A **frenulum** is a small fold of tissue that secures or **restricts** the **motion** of a mobile organ in the body.

<sup>1</sup>Complex: In the context of this shared task, complex words are the words which are difficult to understand for a non-native English speaker.

In the above example, the task requires a system to space the words in bold as complex. The remainder of this paper is structured as follows. In Section 2, we describe our systems and Section 3 discusses experiments and results. We conclude in Section 4.

## 2 System Description

We use the Nearest Centroid Classification technique (Manning et al., 2008) for the classification of words using Manhattan and Standardised Euclidean distance metrics. This classification method is widely used in Information Retrieval tasks. In this method, each class is represented by the mean of all the training samples belonging to that class in the training data. A new observation is assigned a class label, whose mean is closest to the observation. Given below are the labeled training samples:

$$\begin{aligned} & (\vec{x}_1, y_1), \dots, (\vec{x}_n, y_n), y_i \in Y \\ & \vec{\mu}_c = \frac{1}{|N_c|} \sum_{i \in N_c} \vec{x}_i \\ & \hat{y} = \arg \min_{c \in Y} \|\vec{\mu}_c - \vec{x}\| \end{aligned}$$

where  $Y$  is the set of classes,

$|N_c|$  is the number of samples in class  $c \in Y$ ,  
 $\mu_c$  is the centroid of all samples belonging to class  $c$ ,  
 $\hat{y}$  is the class assigned to the new observation.

We submitted two systems for this shared task. Our first system uses the Manhattan distance metric for the Nearest Centroid Classification. The Manhattan distance function computes the distance to be travelled to get from one data point to another point in a grid-like path. The Manhattan distance between two points is the sum of the differences of their corresponding components. Manhattan distance between two points  $A(x,y)$  and  $B(x,y)$  is defined as:

$$d(A, B) \equiv |A_x - B_x| + |A_y - B_y|$$

The distance metric used by System 2 in the training algorithm of the Nearest Centroid Classification was Standardised Euclidean, which is a slight variant of Euclidean distance. Euclidean distance between two points is defined as the sum of the squares of the differences between the corresponding components of the points. The Standardised Euclidean

distance between two points  $A(x,y)$  and  $B(x,y)$  is defined as:

$$d(A, B) \equiv \frac{\sqrt{(A_x - B_x)^2 + (A_y - B_y)^2}}{V}$$

where,  $V$  is the 1-D array of component variances and the numerator is the Euclidean distance between two points  $A(x,y)$  and  $B(x,y)$ .

Both, System 1 and System 2 rely on 5 features to classify the target word as simple or complex. An almost similar set of features was previously employed by Matthew Shardlow (2013) to identify complex words using Support Vector Machines. The features we considered for the classification of words are:

- **Unigram Word Probability:** We used the Google Books Ngram Viewer<sup>2</sup> to obtain the word probability of the target word in the sentence. This information was considered only for the year 2000.
- **Length:** We considered length of the target word as a feature because longer words are likely to be complex.
- **Number of Senses:** A word with higher number of senses is relatively more ambiguous in comparison to a word with fewer senses. Number of senses of a word was obtained using WordNet<sup>3</sup> from NLTK<sup>4</sup> package.
- **Syllable Count:** A word with higher number of syllables<sup>5</sup> is likely to be more difficult to be read.
- **CD Count:** The number of films in which the target word had appeared was obtained from the SUBTLEX<sup>6</sup> corpus.

## 3 Experiments and Discussions

### 3.1 Data

We used the joint dataset provided by the task organizers for training. The training and test data consisted of 2,237 and 88,221 instances, respectively.

<sup>2</sup><https://books.google.com/ngrams>

<sup>3</sup><http://www.nltk.org/howto/wordnet.html>

<sup>4</sup><http://www.nltk.org/>

<sup>5</sup><http://www.syllablecount.com/syllables>.

<sup>6</sup><http://zipf.ugent.be/open-lexicons/interfaces/subtlex-uk/>

Also, the training and test data comprised 200 and 8,929 unique sentences respectively.

### 3.2 Discussions

We discuss our experiments with respect to the training dataset. Experiments were run with a variety of machine learning algorithms using the Scikit-learn toolkit (Pedregosa et al., 2011). However, the Nearest Centroid Classification algorithm was found to outperform other algorithms like Random Forest and Support Vector Machines significantly over 5-fold cross-validation of the training dataset. We tried numerous combinations of features and finalized on the feature set described in the previous section.

There are a few features that we tried during our experimentation but did not include in the final system, as the results turned comparatively lower with their inclusion during cross-validation. We believe that the features are still worth discussing. They are:

1. *Average Word Length of Synonyms*: If the length of the given word is greater than the average length of all its synonyms, then the word is tagged as 1, else 0. This gives us a relative estimate on whether people would prefer to use a word more regularly in comparison to its synonyms. A similar feature could be tried using frequency or syllables in addition to length of the word. But for our experiments, we only used the length feature.
2. *Rank of a Sense*: We use the Lesk algorithm from Wordnet to find the sense of a word in the given sentence. We find the corresponding sense and the rank of the sense based on frequency using Wordnet. A lower rank of a sense suggests higher frequency of usage of that sense (Christiane Fellbaum, 1998). A higher frequency of a sense indicates that the word is likely to be inferred as simple. The rank of a sense is divided by the total number of senses of the word to get a normalized measure of the feature.
3. *Number of Synonyms*: Number of synonyms of a given word was considered. This information was obtained using Wordnet.
4. *Collocation Score*: Collocations are a set of words which occur together frequently. We

find collocations for the target word in each sentence. We calculate a collocation score (C-score) defined as

$$C\text{-score} = \frac{C}{N}$$

where, C is the number of collocations matched in the sentence and N is the total number of tokens in the sentence. A higher C-score value indicates that the word usage is less ambiguous. Collocations<sup>7</sup> include Noun, Verb, Adjective, Adverb and Conjunction collocations.

We believe that the first two features are very critical in differentiating simple words from complex ones as words should be inspected in a relative frame with respect to their synonyms and senses. *A complex word may have higher number of senses but it does not necessarily imply that a word with higher number of senses is always complex.* It is fairly possible that a word (with many senses) in the given sentence may turn out to be the most frequently used sense and hence appear to be simple.

Thresholding based on frequency of a word is a common and effective way to identify complex words. The PLUJAGH team submitted a frequency threshold-based system and it stood first in this shared task when evaluated on F-score. In addition to simple thresholding, it is essential to consider relative frequencies of a word with respect to their synonyms. For example, consider the words *eldest* and *oldest*. From a manual experiment, we found that *eldest* is a complex word and *oldest* is a simple word. The frequency of *oldest* is higher than the frequency of *eldest*. However, the word *unused* (from the training dataset provided by organizers) which is less frequent (google ngrams) than *eldest* is a simple word. We found 110 words in the training dataset whose frequency is lower than *eldest* and are still simple. We claim that this may be due to the relatively higher frequency/usage of *oldest* with respect to the frequency/usage of *eldest*.

In conclusion, it becomes important to speculate words in a relative frame (of frequency/senses/length) with respect to their synonyms, to improve complex word identification.

---

<sup>7</sup>Collocations were collected from <http://prowritingaid.com/free-online-collocations-dictionary.aspx>

The effectiveness of this hypothesis could have been empirically better visible with the availability of a larger training dataset.

### 3.3 Evaluation Metric

The official evaluation metric of the task is G-score. It is the harmonic mean of Accuracy (A) and Recall (R).

$$G\text{-score} = \frac{2 * A * R}{A + R}$$

### 3.4 Results

Table 1 shows the average G-score obtained using different classifiers for 5-fold cross-validation on the training data. For experiments using the Nearest Centroid Classification, we explored 24 different distance metrics, of which Manhattan and Standardised Euclidean metrics performed the best. Based on G-score, our systems were ranked 15th and 23rd in the task. Our first system was able to beat all the baseline systems including the threshold-based and the lexicon-based systems. Table 2 shows the performance of System 1 and System 2 on the test data.

| System         | G    |
|----------------|------|
| System 1       | 0.65 |
| System 2       | 0.63 |
| Decision Tree  | 0.54 |
| Naive Bayes    | 0.61 |
| AdaBoost       | 0.58 |
| Gradient Boost | 0.54 |
| SVM            | 0.44 |
| Random Forest  | 0.53 |

Table 1: Cross-validation results on Training Data

| System         | A     | R     | G            |
|----------------|-------|-------|--------------|
| System 1       | 0.546 | 0.879 | 0.674        |
| System 2       | 0.465 | 0.860 | 0.603        |
| Decision Tree  | 0.734 | 0.613 | 0.668        |
| Naive Bayes    | 0.404 | 0.924 | 0.562        |
| AdaBoost       | 0.767 | 0.777 | <b>0.772</b> |
| Gradient Boost | 0.826 | 0.705 | 0.761        |
| SVM            | 0.837 | 0.546 | 0.661        |
| Random Forest  | 0.794 | 0.641 | 0.709        |

Table 2: Results on Test Data

The reason for choosing the Nearest Centroid Classifier was its consistent and comprehensive dominance over other classifiers tuned over various parameters and different feature combinations during the 5-fold cross-validation on the joint dataset. The results shown in Table 2 pertain only to the finalized feature set discussed in Section 3. Table 2 also shows the results obtained on the test data using different classifiers with the same set of features employed for System 1 and System 2. At this point of time, we are not sure about why few classifiers like AdaBoost and Random Forest performed way better than System 1 and System 2 on the test data. A possible reason for the poor performance of the Nearest Centroid Classifier in comparison to other systems could be the imbalance between the training and the test data size. The test data being highly skewed could probably be another reason. AdaBoost<sup>8</sup> classifier (Table 2) was found to achieve a G-score of 0.772 on test data. This suggests that both, the proposed feature set and the approach presented are competent.

## 4 Conclusion and Future Work

In this paper, we described a promising approach for identifying complex words for non-native English speakers using Nearest Centroid Classification technique. Our approach is simple in terms of both, features and the learning algorithms.

We emphasized that words should be inspected in a relative frame with respect to their synonyms and senses. Testing this supposition in depth will be the subject of future work. We further look to improve the system by incorporating phonetic and semantic features. We also look to explore the problem at sentence level, as the complexity of the sentence can influence a person in comprehending a word's meaning in that sentence.

## Acknowledgment

We would like to thank the SemEval-2016 Task 11 organizers, Henry Gustavo Paetzold and Lucia Specia for conducting this interesting shared task. In addition, we thank the anonymous reviewers for their

<sup>8</sup>For the AdaBoost classifier, the number of estimators used was 10.

constructive comments and insights that helped us in improving this manuscript. We are grateful to Himani Chaudhry and Himanshu Sharma.

## Abstract

Complex word identification task focuses on identifying the difficult word from English sentence for a Non-Native speakers. Non-Native speakers are those who don't have English as their native language. It is a sub-task for lexical simplification. We have experimented with word embedding features, orthographic word features, similarity features and POS tag features which improves the performance of the classification. In addition to the SemEval 2016 results we have evaluated the training data by varying the vector dimension size and obtained the best possible size for producing better performance. The SVM learning algorithm will attains constant and maximum accuracy through linear classifier. We achieve a G-score of 0.43 and 0.54 on computing complex words for two systems.

## 1 Introduction

Complex Word Identification (CWI) is the task of identifying difficult words for a Non-Native speaker. The main objective of Complex Word Identification is to simplify and enhance the perplexing words in the sentences for Non-Native speakers. Complex Word Identification is used in Lexical Simplification (LS). The Lexical Simplification is important for all Text Simplification (Gustavo Henrique Paetzold, 2006). The perspective of each user is different therefore the task Complex Word Identification have been demanding one. For distinguish complex words for individual user will be a tedious task, therefore the CWI task is a difficult one, so we are identifying the complex words for a group of users.

CWI could be used in summarization of stories or generate abstract of a book. Shortening a paragraph would be difficult without removing the complex words, since the shortened text with complex words would be very difficult or confusing for non-native users to read and understand. We can make a story more simple for kids to read by replacing complex words with most common words (Tomoyuki Kajiwara et al., 2013). The main ways to identify the complex words are Threshold-based and Classification-based approaches (Gustavo Henrique Paetzold, 2006). In Threshold-based approach, length, number of syllables, count of ambiguity and word frequency are considered as features. If the values are above the threshold, then the word is said to be a complex word. In the Classifier-based approach, the word features are trained and the word features which are similar to the trained word features are considered to be a complex word.

## 2 Complex Word Identification (CWI) - Task Description

The SemEval-2016 organizers have released three files *cwi\_training*, *cwi\_training\_allannotations*, and *cwi\_testing*. The first two files are training files and the third file is a testing file. Our task is to find the words in the testing file and label each one as 1 if the given word is a complex word, or 0 if the word is not a complex word.

The *training\_allannotations* file contains tags of 20 authors for given sentences. The training file contains a single tag for the sentences representing the group of 20 authors in *allannotations* file. Each word is tagged complex if any of the author tagged it as 1.

If all authors tagged it as non-complex then it is tagged as 0. We trained a binary classifier on the *cwi\_training* data to identify the complex words in the testing data.

### 3 Neural word embedding

From the given sentences, unique words are converted into a more meaningful mathematical vector representation called a Neural word embedding (Tomas Mikolov et al., 2013). For a given word, the vector formed by the word is related to the semantic and syntactic contexts of the word, and also related to the neighboring occurrence of the word. To produce the maximum vector of given size. The  $w_0$  is the given word where the conditional probability is given in the Figure 1, where j is the index of actual output in the output layer.

#### 3.1 Gensim - Implementation

The Gensim word2vec uses skip-gram and CBOW models. The word2vec run two passes to the training data. The first pass will collect the required unique words and build the tree structure. The second pass will train the neural model (Tomas Mikolov et al., 2013). We can vary the dimensions of the vector space model.

## 4 Methodology

The input data to our system is in the form of sentences but the output requires only word to be tagged, so we cannot train the classifier with sentence features. The sentence with the word to be identified are tokenized. We have given the tokenized data into a word embedding models, it produced vectors for each words. We have acquired similarity features with nearby words. The other features like POS tagging and orthographic word features are obtained from the word and these features does not depend on the sentence. All the features are incorporated and saved in a text file. The text file is given to a SVM classifier which compares with the trained model and generates the result. The working process is given in Figure 1.

## 5 Feature Extraction

The features, are extracted from the given word in the testing data. We have extracted four types of fea-

tures, namely orthographic features, similarity features, word embedding features and POS tag features. In these four types of features the orthographic feature based on the word itself, it provides the shape features of the word. The other two features namely similarity features and word embedding features are extracted from the word2vec model which is mentioned above. The Part Of Speech (POS) tag features is obtained with the help of NLTK tool kit and all the features are incorporated for training.

### 5.1 Orthographic features

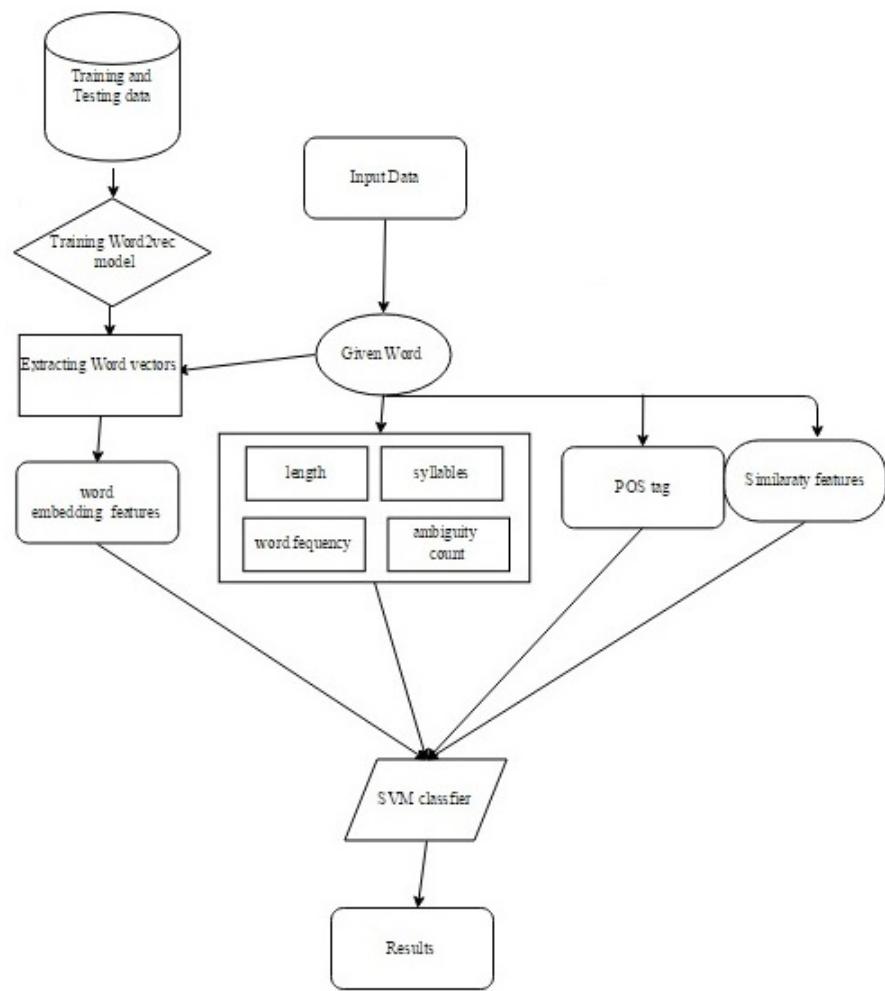

Orthographic word features do not depend on the sentence. They are generic features of a given word like length of the word, number of syllables, ambiguity count and frequency. The count of the characters in the corresponding target word which provides the length of the word. The syllable feature gives the number of syllables present in the word, using the pyhyphen package we have retrieved the features. We used NLTK WordNet synsets (Steven Bird, 2006) for obtaining the ambiguity of the word. WordNet has an built-in dictionary from which number of ambiguity present for the word is obtained (George A. Miller, 1995; ?). The ambiguity is defined as the number of words that have similar meaning. A word is said to be more familiar if the word has more meaning. In the frequency feature, we count occurrences of the word in both training and testing data. These word features improve the accuracy.

### 5.2 Similarity features

These features represent how similar the word occurs to the neighboring words. We have derived four similarity values. Let us assume that the given word is represented as  $w_0$  then the similarity values are attained as  $[w_0 \& w_{-2}][w_0 \& w_{-1}][w_0 \& w_1][w_0 \& w_2]$ . The similarity values are acquired from the word2vec model using Gensim.

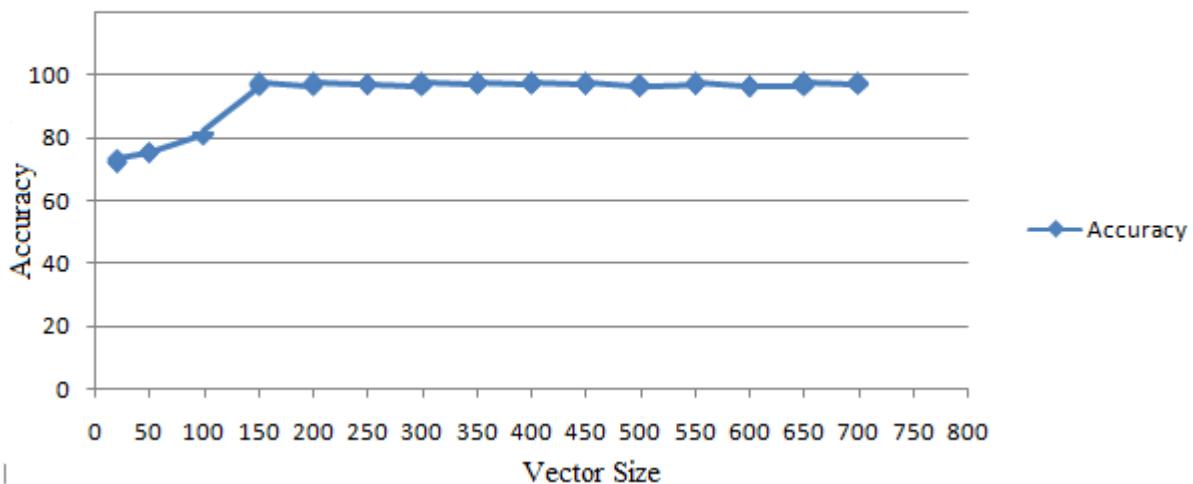

### 5.3 Word embedding features

All the training and testing data were combined and passed into word2vec model. In word2vec, the unique words are obtained and its corresponding vector representations are created for all the words. We can vary the size of the vector while creating the

**Figure 1:** Working model

## Accuracy

**Figure 2:** Training accuracy

vector representation model. We have obtained various results by varying the vector size. We varied the vector size, getting good accuracy after a vector size of 150, as shown in Figure 3. Finally concluded the best vector size as 500 at which we have obtained reasonable results for all other features. The curve tends to decrease after vector size of 500.

#### 5.4 POS tag features

The Part Of Speech tag is taken for five words, by assuming the current word as  $w_0$ , then the POS tagging is taken for  $w_{-2}, w_{-1}, w_0, w_1, w_2$ . We are using NLTK (Natural Language Tool Kit) for POS tagging. The NLTK is an open source tool kit for python[3]. We implemented 2 systems. The first system trained an SVM without including the POS tagging. In the second system, POS tagging with other features has been included. The POS tag increases the accuracy of the data but it might reduce the recall.

### 6 Classifier

The SVM classifier is used for classification. The data is classified based on the features of the test data. For a given training point  $(x^i, y^i)$  it finds out the hyper plane  $w^t(x) + b = 0$ . Here we have used LIBSVM (Chang and Lin, 2011), which is integrated tool for Support Vector Classification (SVC) with regression and distributed estimation [1]. Python LIBSVM supports cross-validation. It is built on the C/C++ core SVM performance.

### 7 Data set:

We were provided with 2,237 training words and 88,221 testing words. In the training data there are 706 (31.56%) complex words and 1531 (68.4%) non complex words. The training file is in the format of <sentences> <word> <position> <1 or 0>. 1 indicates if the word is complex and 0 indicates if the word is not complex. The test data is in the format of <sentences> <word> <position>.

### 8 Experimental results

The Figure 3 gives our system's precision, recall, and F-score on the CWI training data. We tried varying the vector size in the word2vec model. Word features include length, number of syllables, ambiguity

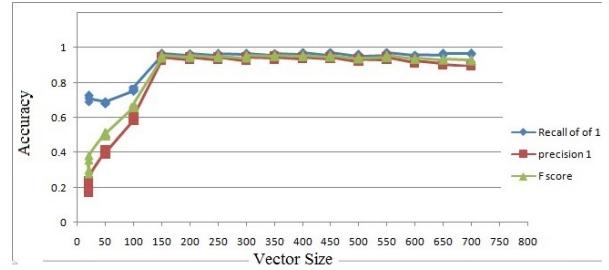

Figure 3: F-score accuracy

count, and frequency. We have four possible combinations and the test results are been tabled in Table 1. The first combination includes word2vec features. The second combination includes word2vec and word features. The third combination includes word2vec and similarity features. The fourth combination includes word2vec, similarity and word features. By varying the size and features the precision and recall tend to combine at a point called break though point. After the break through point the F-score becomes steady. The break through point for data is 150. Above which the accuracy tends to be linear, After the break through point the curve tends to decrease after 500. Therefore, we have concluded at a vector size of 500 and including all the features we have achieved the maximum accuracy. From the Figure 3 we can clearly see the F-score gradually decreasing at 550.

The accuracy graph steadily increases and reaches a maximum at 500 then accuracy tends to steadily decreases. Table 1, provides the additional results experimented by us.

#### 8.1 SemEval Results:

We have submitted 2 files w2vecSimPos and w2vecSim. The first file w2vecSimPos is extracted by including all the four features mentioned namely word embedding, similarity, special word features, and POS tag features. The second file consist of word embedding, similarity and special word features. In the second file we have not included POS tag features. From the table, we can clearly see by including POS tag features there is an improvement in the accuracy of the system. F-score denotes harmonic mean between precision and recall. G-score denotes harmonic mean between accuracy and recall. By including the POS tag as a feature the ac-

## 9 Conclusion

The proposed model with features specially derived for identifying complex words produced good results. The word embedding features played a major role compared with other features. By increasing the size of vectors our accuracy increased constantly. We tried all possible combinations with the four features mentioned in the Table 1 and conclude that the word embedding features alone also have a good accuracy. Our systems have generated a good precision compared with the baseline. Among 45 systems, we ranked 27th position for G-score evaluation. Although, the frequency counts and embedding features are reasonable for a given resource-constraint task, if we have provided for English language in general it might have provide with better accuracy.

## Abstract

We present two methods for the automatic detection of complex words in context as perceived by non-native English readers, for the SemEval 2016 Task 11 on *Complex Word Identification* (Paetzold and Specia, 2016). The submitted systems exploit the same set of features, but are highly disparate in (i) their learning algorithm and (ii) their angle on the learning objective, where especially the latter presents an effort to account for the sparsity of positive instances in the data as well as the large disparity between the distributions of positive instances in the training and test data.

We further present valuable insights that we gained during intensive and extensive post-task experiments. Those revealed that despite poor results in the task, our neural network approach is competitive with the systems achieving the best results. The central contribution of this paper is therefore a demonstration of the aptitude of deep neural networks for the task of identifying complex words.

## 1 Introduction

The identification of complex words plays an important role in the development of simplified reading resources. In particular, accurate automatic complex word identification strongly benefits lexical simplification (LS) as a first step in an LS pipeline (Paetzold and Specia, 2013; Shardlow, 2014). As such, accurate complex word identification may also be critical to higher-level tasks in text simplification, e.g. sentence compression, where the overall readability of

a text is at least partly influenced by the difficulty of its vocabulary.

However, the perceived difficulty of words does not generalise across different groups of readers. That is, a system trained on manual annotations of word difficulty among second-language learners does not necessarily perform well in predicting words that are particularly difficult to persons of reduced literacy. The 2016 SemEval Task 11 puts its focus on the identification of complex words for second-language learners of English.

We chose to explore supervised methods for the task, employing a simple feed-forward neural network as well as a logistic regression classifier for two separate system submissions. Both systems take as input a single list of word and context features that we deemed to potentially indicate the complexity of words themselves and with respect to their context in the sentence.

In this system description paper, we focus specifically on our neural network model. As noted in the task description paper (Paetzold and Specia, 2016), systems based on neural networks generally performed rather weakly in the task, which the organisers speculate to be a consequence of the small amount of training data. However, we show in post-hoc experiments how careful network design may lead to performance figures close to those of the task-winning system. We make our revised system publicly available.<sup>1</sup>

## 2 Related work

The identification of complex words in context has in the past been embedded, often implicitly, into broader (lexical) simplification endeavours (Yatskar et al., 2010; Medero and Ostendorf, 2011; Horn et al., 2014). These models usually employ lexicons or corpus frequencies to determine candidates for lexical substitution. In a corpus study of the standard/Simple English Wikipedia, Medero and Ostendorf (2009) identify a number of word-level features that are indicative of texts with more difficult vocabulary. One of their findings is that words that are typical of simple texts tend to have longer definitions and more user-entered translations in Wiktionary. They also tend to be more ambiguous with respect to word class membership.

Research explicitly dedicated to complex word identification in context, however, has only appeared recently. Shardlow (2013a) presents experiments based on his complex word dataset mined from edit histories in Simple Wikipedia (Shardlow, 2013b); his classification system uses an SVM over a small number of features, achieving an  $F$ -score above 0.8 on the named dataset, where one word per sentence is a positive instance.

## 3 Task data

The data for the task was collected in a survey with 400 non-native speakers of English, such that it may in particular serve the identification of words that pose problems to language learners.

The organisers chose to have each of the 200 sentences in the training set annotated by 20 individuals, while in the test set each of the 9,000 sentences was only seen by one annotator. This presents an effort to model “how well one’s individual vocabulary limitations can be predicted from the overall limitations of a group which they are part of” (Paetzold and Specia, 2016). The training data is released in two versions, once with the *individual* votings for each of the 20 annotators, and once with a *combined* vote that is defined as positive if at least annotator deems the word to be complex, negative otherwise. For both train training and the testing set, only a subset of the words in each sentence are annotated, resulting in 2,237 instances for training and 88,221 instances for testing, corresponding to roughly 40%

and 39% of the overall number of tokens, respectively.

**The challenge of the data.** The task at hand poses two major challenges with regard to the data, *sparsity* of positive examples and *disparity* between train and test data. Regarding sparsity, combining the individual votings as described above results in roughly one third of the train data being marked positive. A one-to-two proportion is not too skewed, but if one considers each annotator in the training set separately, a mere 4.5% of the individual votings were positive.

Regarding disparity, the share of complex examples is very different between the train and test instances (31.9% vs. 4.7%). Furthermore, the perception of word complexity shows great variation across annotators, with more than half of the complex examples in the training data (360 out of 716) marked as such by only one of the 20 annotators, and only 5.4% being perceived as difficult by the majority of the annotators.

## 4 Features

Both systems that we describe in Section 5 use the same set of features. We preprocessed the data using the Stanford NLP tools (Manning et al., 2014), obtaining for every sentence lemma forms, part-of-speech tags, name-entity types, and a dependency parse. We make use of Wikipedia and Simple Wikipedia for features based on corpus frequencies.

For a word  $w$  in a sentence  $s$ , we thus collect features from the following classes:

1. SIMPLE This feature group contains simple word properties such as length of  $w$  in characters, its named-entity type (if any) and its part-of-speech. Our feature model is delexicalised and we do not use word forms or lemmas as features.
2. POSITION This feature group contains the relative position of the  $w$  in  $s$ , and the number of commas as well as the number of verbs before or after  $w$ .
3. MORPH This feature group describes whether  $w$  has a Latin root, the length difference in characters between  $w$  and its lemma and stem, and the number of steps the Porter stemmer spends

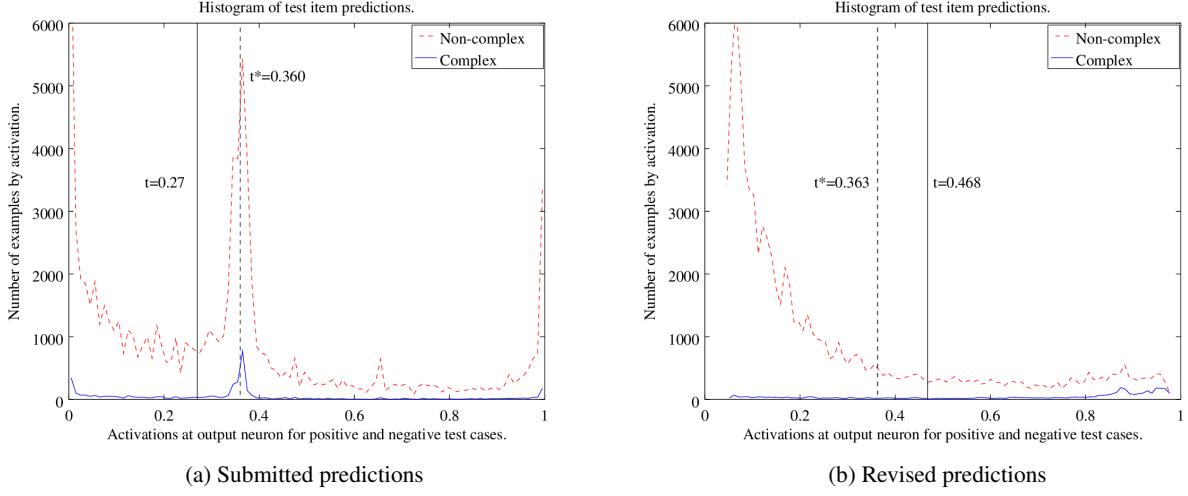

Figure 1: Histograms of submitted (left) and revised (right) Neural Network predictions. Solid vertical lines indicate the learned threshold at which we classify targets into simple and complex. The dashed vertical lines indicate the thresholds that would optimise the  $G$ -scores (cf. also Figure 3).

on  $w$  (Porter, 2001), which we use as a proxy for the number of inflectional morphemes that  $w$  has. We use the NLTK Porter for the latter and the Etymological WordNet (De Melo, 2014) for detecting Latin roots.

4. SYNTAX This class contains the distance (in tokens) between  $w$  and the root of the dependency tree, the dependency relation connecting  $w$  and its head, the distance to its head, and the number of dependents of  $w$  and its head.
5. PROB This group contains the probability of  $w$  in the English Wikipedia, in the Simple Wikipedia, and their ratio.
6. CHARCOMPLEXITY The feature group contains the character-level unigram and bigram probability of the word based on frequencies in Wikipedia and Simple Wikipedia, as well as the respective ratios. This is motivated by the observation that “words with simple grapheme-to-phoneme ratios [are] easier to learn than more phonetically complex words” (Dela Rosa and Eskenazi, 2011). Finally, this group includes the share of vowels in the word.
7. BROWN This feature group includes the Brown cluster of  $w$ , as well as height and depth of the cluster in the hierarchical clustering tree (Brown et al., 1992). We use the default 1000

clusters generated by Percy Liang’s implementation.<sup>2</sup>

8. EMBS This feature group contains the 300-dimensional GloVe embeddings of  $w$ , calculated using Word2Vec over a Wikipedia dump.<sup>3</sup>
9. WORDNET This feature reflects the semantic complexity of  $w$  as measured by its number of WordNet synsets (Fellbaum, 1998).

## 5 Our systems

**System 1: NeuralNet.** We train a deep neural network with 2 hidden layers of 150 and 50 units, respectively, using PyCnn.<sup>4</sup> At every hidden layer, we perform  $L2$ -regularisation.

The network has a single output unit that yields a value between 0 and 1, which we map to binary complexity judgements after applying a threshold. If our neural network learned a perfect fit to the data, i.e. if it assigned a value close to 0 to every negative example and a value close to 1 to every positive

<sup>2</sup><https://github.com/percyliang/brown-cluster>. We obtained the clusters from <http://derczynski.com/sheffield/brown-tuning/>.

<sup>3</sup>Downloaded from <http://nlp.stanford.edu/projects/glove/>.

<sup>4</sup>PyCnn is a Python wrapper for the C++ neural network library available at <https://github.com/clab/cnn>. The wrapper ships with the main library.

example, the natural decision boundary of 0.5 would be a good classification threshold to binarise the predicted values. However, as the model fit is far from perfect, the learning problem extends to finding an appropriate threshold (see below).

**System 2: Information Sieve.** Departing from the observation that different language learners consider different words as complex, the motivation for this system is to prevent our classifier from learning idiosyncratic annotator behaviour. To achieve this, we take an *information sieve* approach, which is meant to filter out idiosyncratic information. We train a logistic regression classifier based on the *concatenation* of all individual votings in the training set, such that every instance is seen 20 times during training, namely one per annotator. The intention behind this training method is to expose the learning algorithm to all individual annotator decisions, acquiring a preference for annotation decisions that are more consistent across annotators. We retrieve the probability outputs from the classifier and predict as positive the top decile.<sup>5</sup>

**Hyperparameter optimisation** All hyperparameter tuning for the neural network, including its architecture and the classification threshold, is based on 10-fold cross-validation over the training set. For each fold, we test the respectively trained model on each of the 20 individual votings in the test split, rather than on the combined votings. We do this in order to account for the mentioned disparity in the share of positive examples that we expect to find in the training and final testing data. Evaluating the performance of a single hyperparameter configuration thus involves training 10 models and testing on 200 sets of individual annotations.

For optimising the classification threshold, we compare the system’s predictions to the respective train/test split annotations at every cross-validation fold (again testing on the individual votings of 20 annotators), and record the decision boundary that best separates negative and positive instances. For each of the 10 cross-validation folds, we thus get an array of 20 annotator-wise optimal thresholds. We finally compute the best threshold for a single fold

---

<sup>5</sup>The decision to predict the top 10% as positive was based on our expectation of the positive share in the test data.

| System     | G-score | Recall | Acc. | Rank |
|------------|---------|--------|------|------|
| NeuralNet  | .506    | .398   | .693 | 35   |
| InfoSieve  | .285    | .171   | .869 | 41   |

| Revised NN | .756    | .725   | .791 | (8)  |

Table 1: Test set results for the two submitted systems, the winning system and our revised system.

as the median over these values, and the best overall threshold as the average over the per-fold medians.

## 6 Results and System Revision

Table 1 shows the performance of our systems as measured by the *G*-score<sup>6</sup> as well as recall and accuracy. As suggested by a post-hoc experiment on the combined training examples, the poor result obtained by the InfoSieve system is due to its sampling strategy much more than the training and inference algorithm or any hyperparameters. We therefore discard this strategy and focus on the neural network in our following analysis.

In order to get a better understanding of the neural network’s performance, Figure 1a visualises the distribution of the submitted predictions that we obtain in the original set-up. With a threshold at 0.27, we correctly discard only 43.8% of the non-complex examples, while identifying 69.3% of all complex instances. We observe that, relatively independent of the threshold, the model fails to clearly separate simple and complex instances.

With these numbers, the neural network is very far from the results achieved by the best systems in the task, which we generally observe to employ some variant of ensemble methods, most notably random forests. In the remainder of this section, we reconsider some design decisions for our neural network and introduce a revised model, which we demonstrate to obtain results on the test set that place it in the region of the mentioned ensemble systems.

**Neural network library and architecture** In a first post-task experiment, we exchange the PyCnn

---

<sup>6</sup>The task organisers define *G* as the harmonic mean between recall and accuracy. In using this metric to gauge system performance, the organisers reward systems that primarily maximise the number of true positives, while giving less weight to minimising false positives.

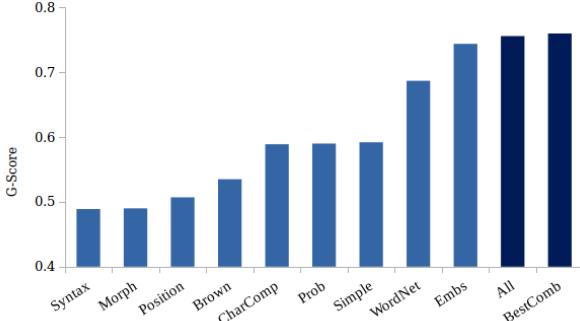

Figure 2: Contribution of feature classes in a deep neural network with three hidden layers of 50 computational units each.

implementation of deep NNs with Keras.<sup>7</sup> Surprisingly, we observe a tremendous increase in performance when using Keras: with the same set of features and the same basic network architecture, we reach a  $G$ -score that exceeds the 0.70 mark.<sup>8</sup> Subsequently, we evaluate different network architectures, including different rates of dropout after the hidden layers as an alternative way of regularising the model (Srivastava et al., 2014). Note that all hyperparameter optimisation is still performed in cross-validation experiments.

We finally find that we achieve a good fit to the data with a network of three hidden layers, each of which comprises 50 computational units, and a moderate dropout rate of 10% after every hidden layer.

**Feature contribution** To gain insights into which features are salient for our system, we train models on the individual feature classes listed in Section 4, as well as combinations of the classes. As Figure 2 shows, word embeddings are by far the most important single feature class, and they also contribute to the best combination of feature types, which is WORDNET+PROB+MORPH+EMBS. In the remain-

<sup>7</sup><https://github.com/fchollet/keras>. Keras is a Python neural networks library running on top of Theano and TensorFlow.

<sup>8</sup>The great performance differences between the two libraries are actually more than surprising. The differences are consistent across several experiments, which is why an infelicitous random initialisation or local optima can be ruled out as possible explanations. Other intuitions as to what might the reason for the different results touch on possible errors in the implementation of one of the libraries, but this is clearly very speculative.

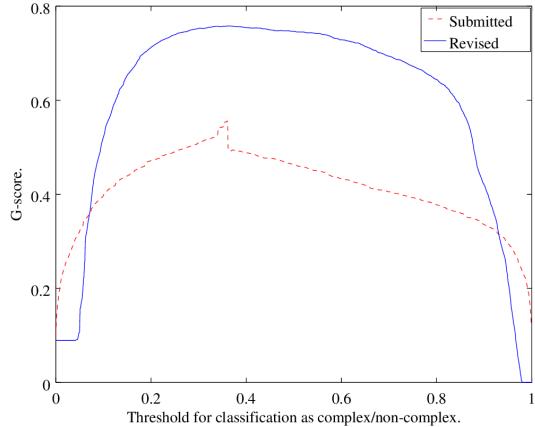

Figure 3:  $G$ -score curves in dependence of the threshold  $t$  for the submitted (red dashed) and the revised (blue solid) system.

der of the paper, we refer to the system trained on this feature combination as the ‘revised system.’

**Threshold** For the submitted as well as for the revised system, there is a certain discrepancy between the  $G$ -scores that we obtain from setting the thresholds to the value computed in the cross-validation and the figures we could achieve with optimal threshold setting. Concretely, this difference pertains to .05 in  $G$ -score (.506 vs. .556) for the submitted system and .002 (.756 vs. .758) for the revised system (cf. Figure 3).

While in Figure 1b it appears that we have missed the optimal threshold by a wide margin for the revised system, the actual difference in performance (as measured by  $G$ ) is rather small. In fact, as Figure 3 illustrates, finding the optimal threshold is considerably less critical for the revised system due to a much flatter curve between threshold values 0.2 and 0.8.

**Optimal result** In conclusion, a  $G$ -score of .758 poses an upper bound for our system architecture (a neural network with three hidden layers of 50 units and a dropout rate of 10% after each hidden layer). How closely this figure can be approximated depends on the optimisation of the threshold.

## 7 Conclusion

This paper presented our submissions to the SemEval 2016 Shared Task 11, *Complex Word Identification*, which we approached with two very disparate systems: a deep neural network trained on the combined votings from 20 annotators, and a logistic regression classifier trained on each annotator separately. While neither of these systems reaches competitive performance figures, we re-design our neural network approach to train a revised system, which shows that neural networks do have the potential to successfully identify complex words.

Specifically, we find that 300-dimensional word embeddings carry a strong signal for word complexity, such that our revised system finally reaches a  $G$ -score that would place it in the top quartile of the task submissions. The strong contribution of word embeddings is not easily explained, but we suspect that certain distributional features may encode the presence of a complex word in more specific contexts such as technical jargon.

Our results contrast with the observation that task submissions which employed neural networks and/or word embeddings generally achieved rather poor results, and it shows that competitive performance figures can be reached with neural networks despite a relatively small amount of training data.

## Abstract

We present two systems created for SemEval-2016s Task 11: Complex Word Identification. Our two systems, a regression tree and decision tree, were trained with a word’s unigram and lemma word counts, average age-of-acquisition, and a measure of concreteness. The systems ranked 5th and 6th, respectively, on the test set by G-score (the harmonic mean between accuracy and recall). With the regression tree’s predictions earning a G-score of 0.766, and the decision tree’s earning 0.765, the two systems scored within 1 percent of the score of the best-performing system in the task.

## 1 Introduction

Text simplification is the process of reducing the complexity of a text while preserving the original meaning. Text simplification may include syntactic or pragmatic aspects (Siddharthan, 2014), but much of the work that has been done has focused on lexical simplifications. In lexical simplification, difficult words or phrases are replaced to make a text more accessible. This kind of simplification can benefit several reader populations, including second-language learners (Petersen and Ostendorf, 2009).

One important first step in lexical simplification is complex word identification. This step predicts which words in a text will be difficult for a reader so that they can then be targeted for simplification.

The International Workshop on Semantic Evaluation for 2016 (SemEval-2016) hosted Task 11: Complex Word Identification (CWI), which asked participants to identify words that would be challenging

for non-native English speakers (Paetzold and Specia, 2016). Task participants were given 2,237 training examples. Each example contained a word, the sentence containing the word, and the word’s index in the sentence. In addition, each word was labeled as *complex* or *not complex* (or *simple*) by 20 human annotators, and each word was given a binary label of *complex* if at least one annotator thought the word was hard to read. The individual labels of the 20 annotators were also made available to participants.

Submissions were evaluated on a test set of 88,221 words. Test set items had the same format as the training set, except that they were only annotated by one person, so the labels indicated whether that annotator alone labeled it *complex*.

## 2 Previous Work

This is the first year of the CWI Task, so no previous work has been done on exactly the same task. However, substantial work has been done previously in the general area of characterizing word difficulty.

Traditional readability measures like Flesch-Kincaid (Kincaid and others, 1975) and Gunning Fog (Gunning, 1952) rely primarily on word length, while the Lexile framework considers word length and unigram frequency. More recent work has incorporated n-grams and part of speech information (Petersen and Ostendorf, 2009; Graesser and others, 2004), word clusters (Deane and others, 2006) to improve the accuracy of reading level predictions, while other work has used orthographic and phonemic features (Mostow and others, 2002) to predict where children would have reading difficulty.

### 3 Methodology

For each word in the training set, we extracted features that we predicted would be good indicators of a word’s complexity. We also used the labels from the individual annotators to generate continuous-valued labels for each of the training words. Finally, we trained several machine learning models as implemented using Python’s `scikit-learn` package (Pedregosa and others, 2011).

#### 3.1 Features

We investigated several potential features for the CWI Task, based on metrics across various features for words in the training set (see Table 1).

1. **Unigram** and **lemma frequency** from the Corpus of Contemporary American English (COCA) (Davies, 2008), using the WordNet lemmatizer in Python’s `nltk` package (Loper and Bird, 2002). *Complex* words are, on average, less frequent than *simple* words.
2. **Word age-of-acquisition** according to the average age-of-acquisition (AoA) for a word in a list of roughly 30,000 English words (Kuperman and others, 2012). *Complex* words, have a higher mean AoA.
3. **Word concreteness**, on a scale of 1 to 5, according to a list of roughly 40,000 English words (Brysbaert and others, 2013). *Complex* words have higher scores, possibly due to the inclusion of technical words.
4. **Word length, stem length, and lemma length** in characters. For all three, *complex* words are longer on average than *simple* words.
5. **Number of word pronunciations** in Carnegie Mellon University’s Pronouncing dictionary (Lenzo, 2007), accessed through `nltk`. *Complex* words have a lower number of pronunciations on average, possibly because these words tend to be more technical.
6. **Probability of the word’s sequence of characters** according to a character-based trigram language model created with SRILM and trained on the COCA dataset (Stolcke and

| Feature             | Simple      | Complex     |
|---------------------|-------------|-------------|
| Unigram Count       | 443k (1M)   | 151k (597k) |
| Lemma Count         | 183k (742k) | 68k (290k)  |
| Age of Acquisition  | 8.9 (3.2)   | 9.8 (3.0)   |
| Concreteness        | 2.8 (0.9)   | 3.0 (1.0)   |
| Word Length         | 6.0 (2.5)   | 6.7 (2.5)   |
| Pronunciation Count | 1.4 (0.7)   | 1.2 (0.5)   |
| Synset Count        | 9.5 (8.7)   | 6.7 (8.3)   |

**Table 1:** Summary of feature means and standard deviations.

others, 2002). *Complex* words have lower log-probabilities. This may be because *complex* words have more “unlikely” character sequences that are hard to decode.

7. **Number of synsets** in WordNet. *Complex* words belong to a lower number of synsets, possibly because they are more likely to be unique and domain-specific.
8. **Part-of-speech** (POS) given by `nltk`’s part-of-speech tagger. Nouns are more likely to be *complex* words, and verbs are more likely to be *simple* words. For models that do not support categorical features, we performed a one-hot encoding of the most common tags: NN, NNS, JJ, RB, and VBD.

We experimented with different combinations of features, but only five features were used in the predictions given by our models: unigram and lemma frequency, age-of-acquisition, concreteness, and word length. Therefore, those were the features that we used in our submitted system.

#### 3.1.1 Labels

Originally, the training set included binary labels that correspond to whether at least one annotator thought a word was *complex*. However, because these labels are binary, they are not indicative of the extent to which the annotators agreed each word was difficult. It is useful to learn the difference, for example, between a word that almost all of the annotators agree is difficult, and one that 19/20 annotators felt was *simple*, but one annotator thought was *complex*.

To help with this, we replaced every binary label with a continuous label representing the percentage of annotators who found the word to be complex.

| Description  | Regression Tree | Decision Tree |
|--------------|-----------------|---------------|
| Accuracy     | 0.838           | 0.846         |
| Precision    | 0.182           | 0.189         |
| Recall       | 0.705           | 0.698         |
| $F_1$ -score | 0.290           | 0.298         |
| $G$ -score   | 0.766           | 0.765         |

**Table 2:** Summary of system performance on the CWI test set

We used thresholding to convert the continuous labels back to binary labels as needed.

### 3.2 Models

We experimented with Support Vector Machines, Logistic Regression, and Perceptrons, but got the best results from scikit-learn’s implementation of depth-limited regression and decision trees with our features and a maximum depth of 3. These models gave the best performance on average in terms of cross-validation accuracy,  $F_1$ -score, and  $G$ -score. Regression trees and decision trees have the added benefit of providing a level of model interpretability that the other models do not.

Since decision trees require discrete categories for training, we used a threshold of 0.25 when providing the labels to the model for training. That is to say, all examples in training were labeled *complex* if at least 25 percent of annotators marked it *complex*. For each cross-validation fold, we used the proportion of the first 19 annotators who labeled a word complex as labels during training, then evaluated our model on the labels provided by the 20th annotator.

We also trained our regression tree on the proportion of the first 19 annotators who labeled each word *complex*. But since regression trees train on and predict continuous-valued labels, we used the percent of annotators directly as labels during training, then thresholded the model’s prediction for each word at test time. We got best results with a threshold of 0.05: words were interpreted as *complex* if the model predicted its measure of complexity to be 0.05 or greater. These thresholds were chosen because they gave the best  $G$ -score for 5-fold cross-validation on the training set.

## 4 Results

On the CWI test set, our regression tree and decision tree ranked 5th and 6th on  $G$ -score, respectively, out of the 40 system submissions (Paetzold and Specia,

2016). Table 2 breaks down the precision, recall, and  $G$ -score of each model. The models had  $G$ -scores of 0.765 and 0.766. By comparison, the top scoring system had a  $G$ -score of 0.774, and overall the average  $G$ -score was 0.620 with a standard deviation of 0.123 (Paetzold and Specia, 2016).

|       |             | Prediction |             |
|-------|-------------|------------|-------------|
|       |             | Complex    | Not Complex |
| Truth | Complex     | 2913       | 1218        |
|       | Not Complex | 13059      | 71031       |

**Figure 1:** Regression tree confusion matrix on the CWI test set.

|       |             | Prediction |             |
|-------|-------------|------------|-------------|
|       |             | Complex    | Not Complex |
| Truth | Complex     | 2884       | 1247        |
|       | Not Complex | 12355      | 71735       |

**Figure 2:** Decision tree confusion matrix on the CWI test set

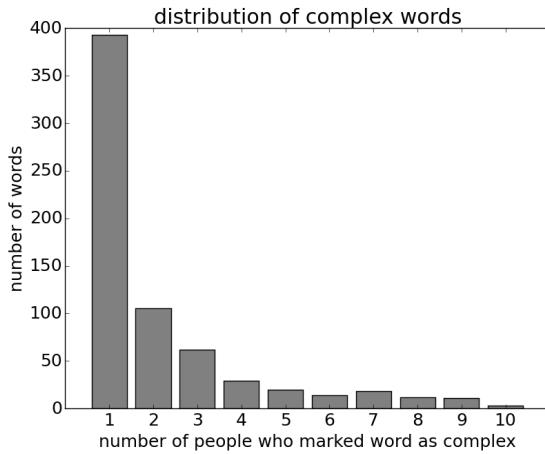

Figures 1 and 2 depict the confusion matrices generated from comparing the trees’ predictions to the testing labels. Over 90% of the misclassifications given by both trees were false positives. This indicates that the models tended to overpredict complex words, which is also seen in the relatively low precision of both systems.

## 5 Analysis

Our models relied most heavily on unigram and lemma frequency features. Even when the AoA, concreteness, and lemma length features are excluded, the regression tree and decision tree obtain a  $G$ -score of 0.735 and 0.770, respectively, on the test set. This indicates that corpus frequency alone is an extremely good indicator of a word’s complexity.

Despite our submitted models’ success with corpus-based features, we obtained low precision scores of 0.18 for each model. These scores were consistent with results for many of the other systems participating in the task. The average precision score was 0.123 with a standard deviation of 0.06 (Paetzold and Specia, 2016).

We posit that this problem is due in part to the difference in distribution between the training and testing sets for our models. Namely, our models must train on labels that are representative of the judgments of multiple annotators, but also be tested

**Figure 3:** Distribution of how often a certain number of annotators marked a word *complex*.

on labels that are representative of the judgment of *only one* annotator. The difference in distribution between the training and testing set means that the model learns to predict word complexity for a group, but is evaluated on one person’s judgments. This problem is exacerbated by the low agreement between annotators. Figure 3 shows that most words marked *complex* are labeled so by only one person.

In addition, some of the labels in the test set are possibly counterintuitive. For example, in:

The Plan of Management is the main policy document for the Park and strives to balance strategic or long-term goals and tactical or day to day goals.

the word *strives* and both instances of the word *goals* were labeled *complex*. Intuitively, those words seem less difficult to us than the words *strategic* and *tactical*, which were both labeled *not complex* by the same annotator. This example illustrates what makes the task so difficult: not only are the testing and training set distributions different, but the labels for each are subjective and possibly conflicting.

## 6 Conclusion

This paper details our submission to SemEval-2016’s Task 11: Complex Word Identification. We explored several potential features, eventually submitting a regression tree and decision tree based on unigram and lemma frequency, age-of-acquisition,

concreteness, and word length. By incorporating annotator disagreement into our models through continuous-valued labels during training and testing, our models ranked 5th and 6th overall in the Task. Error analysis reveals that our models had trouble generalizing the judgments of multiple annotators in the training set to the judgment of one annotator in the test set, leading to low precision.

## Abstract

In this paper, we present our system developed for the SemEval 2016 Task 11: Complex Word Identification. Our team achieved the 3rd place among 21 participants. Our systems ranked 4th and 13th among 42 submitted systems. We proposed multiple features suitable for complex word identification, evaluated them, and discussed their properties. According to the results of our experiments, our final system used maximum entropy classifier with a single feature – document frequency.

## 1 Introduction

This paper describes our participation in the Complex Word Identification (CWI) shared task of SemEval 2016. CWI is a subtask of text simplification. Text simplification changes the structure, grammar, and vocabulary of the text to make it easier to understand without losing information. CWI looks for the words that should be simplified. The task is motivated and described in detail by the organizers (Paetzold and Specia, 2016).

In this paper we apply a machine learning approach to CWI. Our main goal is to explore suitable features.

The paper has the following structure. Section 2 introduces the task in more detail. Section 3 presents the design of our system. In Section 4, we choose the optimal parameters and features for our final system. In Section 5, we discuss overall results of the task. Section 6 summarizes our contribution.

## 2 Task

The task is defined as a binary classification with classes *complex* and *simple*. The complex class represents words that should be simplified. Given a word in a sentence, a system decides whether the word is complex or not.

Paetzold and Specia (2016) prepared two training data sets. The first data set contains 20 decisions from unique annotators; we call it *all*. Second data set aggregates the annotations – the word becomes complex if at least one annotator considers it complex; we call it *aggregated*. Both data sets have 2 237 sentences (i.e. the all data set has 44 740 training examples, the aggregated set has only 2 237). The organizers announced that the test data set has 9 200 sentences annotated by a single annotator.

The task was evaluated using *G-score*: a harmonic mean of accuracy and recall of the complex class. Each team could submit two systems for evaluation.

## 3 System

CWI is a binary classification task. We chose the maximum entropy classifier for our system, but we believe the choice of classifier has only a small impact compared with the choice of features.

We propose features that may be suitable for the CWI task and motivate them in the following list.

**Word frequency** – A ratio of occurrences of the current token to the number of all tokens in the corpus. We expect less frequent words to be more likely complex. Also extended to n-grams.

**Document frequency** – A ratio of documents that contain the current token to the number of all documents. The motivation is the same as for word frequency. Also extended to n-grams.

**Character n-gram frequency** – The frequency of character n-grams of the current word. We expect that some character n-grams are typical for complex words.

**Language model word probability** – The probability of the current word given by a language model. The more probable words are not likely to be complex.

**Part of speech** – Part of speech tag of the current word. Some word categories are used less often by non-native speakers.

**Word length** – Length of the current word. Common words are usually shorter.

**WordNet synset size** – The size of WordNet synsets which contain the current word. Large synsets might be highly ambiguous and thus harder for a non-native speaker.

**WordNet frequency ratio** – The ratio between the current word and the most frequent word in a synset. If there is a lot more frequent word with the same meaning, the non-native speaker usually uses this word instead of the current word.

**WordNet number of synsets** – The number of synsets that contain the current word. Word with many meanings may be harder.

**Language model sentence probability** – The probability of the whole sentence. The overall probability of a sentence may indicate the sentence complexity. A complex sentence may affect the difficulty of the current word.

**Average n-gram frequency** – The average n-gram frequency of the sentence. If the sentence contains a higher number of complex words, then even a common word may become complex.

### 3.1 G-score decision boundary

A standard maximum entropy classifier is trained so that all types of errors have the same weight. This is

not the case when G-score is used as an evaluation metric. With G-score and a skewed data set, it is necessary to give higher priority to errors where complex class is incorrectly classified as simple class. This type of errors lowers the recall of the system.

To deal with it, we propose an altered decision criterion (1) for the standard classifier, where  $y^*$  is the class chosen by the system,  $p(y = c|d)$  is the probability of the complex class given the data, and  $t$  is the threshold.

$$y^* = \begin{cases} \text{complex} & p(y = c|d) > t \\ \text{simple} & \text{otherwise} \end{cases} \quad (1)$$

## 4 Optimizing parameters

Each team could submit two systems. We decided to submit two versions of the same system with different parametrization – the first one trained on the *aggregated* data and the second one on the *all* data.

### 4.1 Experimental setup

We estimated the n-gram frequencies from Wikipedia. We used the language model from (Brychcín and Konopík, 2015), Stanford CoreNLP for part-of-speech tags (Toutanova et al., 2003), the MIT Java Wordnet Interface (Finlayson, 2014), and the Brainy implementation of maximum entropy classifier (Konkol, 2014).

### 4.2 Procedure

We measure the improvement of our system with 5-fold cross-validation on the training data.

First, we optimized hyper-parameters (e.g. thresholds, discretization) of individual features.

Second, we iteratively added more features to the (initially empty) feature set. At each step we included the feature that improved G-score the most. We stopped if G-score decreased.

For each evaluation, we chose the optimal threshold  $t$  from (1).

### 4.3 Results

Table 1 shows the results for individual features (i.e. first iteration) on the *aggregated* data. We compare the features to a baseline that marks all words as complex.

We found that the unigram document and word frequencies predicted the complex words best from

| System            | Accuracy | Recall | G-score |
|-------------------|----------|--------|---------|
| all complex       | 31.6%    | 100.0% | 48.0%   |
| 1-gram freq       | 69.5%    | 65.0%  | 67.2%   |
| 2-gram freq       | 54.6%    | 77.9%  | 64.2%   |
| 3-gram freq       | 51.1%    | 71.8%  | 59.7%   |
| 1-gram doc freq   | 64.2%    | 72.5%  | 68.1%   |
| 2-gram doc freq   | 52.5%    | 80.9%  | 63.7%   |
| 3-gram doc freq   | 36.2%    | 96.9%  | 52.7%   |
| char 3-gram freq  | 58.2%    | 63.6%  | 60.8%   |
| char 4-gram freq  | 50.5%    | 83.4%  | 62.9%   |
| char 5-gram freq  | 58.5%    | 66.7%  | 62.3%   |
| lang model        | 61.0%    | 61.0%  | 61.0%   |
| pos               | 47.8%    | 67.0%  | 55.8%   |
| word length       | 48.3%    | 80.7%  | 60.4%   |
| WN synset size    | 46.9%    | 67.8%  | 55.5%   |
| WN freq ratio     | 47.3%    | 56.4%  | 51.5%   |
| WN num synsets    | 54.7%    | 62.2%  | 58.2%   |
| global lang model | 42.6%    | 91.8%  | 58.2%   |
| avg word freq     | 45.1%    | 84.5%  | 58.8%   |

**Table 1:** Results for individual features with 5-fold cross-validation on the aggregated training data. The official metric for evaluation is called G-score and it is a harmonic mean of accuracy and recall of the complex class.

all the proposed features. The unigram document frequency performed slightly better. We believe document frequency better reflected the real frequency of the words. For example the word YouGov appears almost 3000 times at a single Wikipedia page, thus we overestimated the word frequency of YouGov.

We are ambivalent about the role of the context. The global language model and the average word frequency features show that the overall complexity of a sentence affected the complexity of its words. It suggests that the context of the word plays a role. However, unigrams performed better than higher order n-grams for document and word frequencies. The complexity of the word may be thus affected by some words in the sentence but not necessarily the closest words. We believe this phenomenon requires further research.

The WordNet features revealed that the number of meanings and number of synonyms influenced the complexity of the word.

The character n-gram features might indicate that some combinations of letters were typical for com-

plex words, but it might also only identify the shorter words (and their frequencies). The latter option is supported by better scores of higher order character n-grams, because they could recognize longer words.

The word length feature showed that such a simple feature can be relatively good predictor of complex words.

The part-of-speech feature proves that some types of words are more complex than others, e.g. adverbs are more complex than verbs.

Even though all the features improved the all complex baseline, we found that adding more features to the unigram document frequency (best individual feature) did not improve the G-score. We did not expect this behavior, because the features represent different information sources. This might have many reasons, we elaborate two of them. First, we might get close to the inter-annotator agreement as the task seems to be highly subjective. Second, we use a heuristic procedure for finding the optimal feature set. This procedure might be flawed, especially choosing the discretization before we combined the features.

**The final system** used only the unigram document frequency. As we used only one feature, it might be better to drop the classifier and simply find a threshold for unigram document frequency. We believe the results would be the same, but the system could be even simpler.

## 5 Shared task evaluation

Paetzold and Specia (2016) presented complete results for all systems. 21 teams participated in the task and submitted 42 systems. The results show that the top 9 systems were over 76%, so they performed almost as good as the winner (77.4%).

We provide a summarized results of our systems in Table 2. Our team ranked third with systems on 4th (*all* data) and 13th (*aggregated* data) place. The system trained on the aggregated data predicts complex words for the worst English speakers (among the annotators); the other one for average speakers. The difference between the systems (7.4%) suggest that the difference between worst and average speakers (regarding vocabulary) is not that high.

| TR | SR  | System       | Accuracy | Recall | G-score |
|----|-----|--------------|----------|--------|---------|
| 1. | 1.  | SV000gg soft | 77.9%    | 76.9%  | 77.4%   |
| 3. | 4.  | UWB All      | 80.3%    | 73.4%  | 76.7%   |
| 3. | 13. | UWB Agg      | 56.9%    | 88.5%  | 69.3%   |
| —  | —   | Average      | 73.69%   | 59.1%  | 62.0%   |

**Table 2:** The official comparison with other systems. TR stands for team rank, SR for system rank. There were 21 teams and 42 systems. The official metric for evaluation is called G-score and it is a harmonic mean of accuracy and recall of the complex class.

## 6 Conclusion

We proposed a set of features that might be suitable for the CWI task. We showed that most of the features had some information value, even though their combination may not lead to an improvement. We can conclude that the word frequency and document frequency were the best predictors for complex words.

Our final system used a maximum entropy classifier with a single feature – document frequency. We ended up as the third best team (with the 4th best system). It proves that it is possible to achieve a state-of-the-art G-score in the CWI task with a very simple system.

# AI-KU at SemEval-2016 Task 11: Word Embeddings and Substring Features for Complex Word Identification

Onur Kuru

Artificial Intelligence Laboratory

Koc University

Istanbul, Turkey

okuru13@ku.edu.tr

## Abstract

We investigate the usage of word embeddings, namely Glove and SCODE, along with substring features on Complex Word Identification task. We introduce two systems: the first system utilizes the word embeddings of the target word and its substrings as features while the other considers the context information by using the embeddings of the surrounding words as well. Although the proposed representations perform below the average with nonlinear models, we show that word embeddings with substring features is an effective representation choice when employed with linear classifiers.

## 1 Introduction

Complex Word Identification (CWI) is the task of determining which words in a given sentence should be simplified. CWI is often considered as the first step in Lexical Simplification (LS) where the goal is to identify and replace complex words with simpler substitutes. Although CWI is considered as a vital component of Lexical Simplification pipeline, there is not a lot of work done for identifying word complexity in the context of Lexical Simplification. Horn et al. (2014) describes an LS model in which they employ a Complex Word identifier implicitly. However, their results show that the method is not able to capture complex words very accurately.

Paetzold and Specia (2016) organizes the Complex Word Identification task of SemEval 2016 with the goal of attracting systems that are able to detect complex words in given a sentence. This work

investigates the usage of word embeddings along with substrings as features to build a Complex Word Identifier. Word embeddings are unsupervised word representations which map each word to a dense, real valued, low dimensional vector. These vectors are able to capture semantic and syntactic similarities between words and proven useful as features in a variety of applications, such as, document classification (Sebastiani, 2002), named entity recognition (Turian et al., 2010), and parsing (Socher et al., 2013).

GloVe (Pennington et al., 2014) is an unsupervised learning algorithm for obtaining vector representations for words which is essentially a bilinear model with a weighted least-squares objective. Pennington et al. (2014) shows that the word embeddings produced by the model achieves state-of-the-art performance in Word Analogy task. Moreover, they also illustrate that Glove embeddings outperform embeddings induced by other methods on several word similarity tasks.

Another work (Yatbaz et al., 2012) represents the context of a word by its probable substitutes. Words with their probable substitutes are fed to a co-occurrence modeling framework (SCODE) (Maron et al., 2010). Words co-occurring in similar context are closely embedded on a sphere. These word embeddings are effective at modeling syntactic features and they achieve state-of-the-art results in inducing part-of-speech.

We conducted several experiments to examine the usage of word embeddings. First, we investigated whether pretrained word embeddings improve random embedding baseline. Second, we tried concate-

nations of word embeddings with different types and dimensions. Next, we examined context-aware representations of target words by incorporating embeddings of neighbouring words. After the release of test set annotations, we scrutinize how a linear model benefits from increasing the size of the training set.

This paper is organized as follows: Section 2 details the proposed dataset and evaluation metric, Section 3 analyzes the utilization of word embeddings for CWI, Section 4 presents results and discusses the performance of our work and Section 5 concludes the paper.

## 2 Dataset and Evaluation

Complex Word Identification task of SemEval 2016 (Paetzold and Specia, 2016) prepares a dataset with 200 sentences for training and 9000 for testing. The training set is composed of 5,362 tokens with 2,237 instances annotated, and the test set is composed of 217,902 tokens with 88,221 instances annotated. Dataset properties are summarized in Table 1.

9,200 sentences were annotated through a survey, in which 400 volunteers were presented with several sentences and asked to judge whether or not they could understand the meaning of each word in a given sentence. A set of 200 sentences is separated for training and split into 20 subsets of 10 sentences, and each subset was annotated by a total of 20 volunteers. In the training set, a word is considered as complex if at least one of the 20 annotators judged them so. To compose the test set, remaining 9,000 sentences were split into 300 subsets of 30 sentences, each of which was annotated by a single volunteer.

|           | Training | Test   |
|-----------|----------|--------|
| Annotated | 2237     | 88221  |
| Tokens    | 5362     | 217902 |
| Sentences | 200      | 9000   |

**Table 1:** Dataset Properties

Notably, training set is extremely small compared to test set. As a result of this, 92% of test set vocabulary is unknown to training set.

In the context of Lexical Simplification, a CW identifier is expected to accomplish two things. First, it should predict the complexity of words

as proficiently as possible (Accuracy). Second, it should capture as many of the complex words as possible (Recall) to maximize the simplicity of a sentence. Therefore, instead of F-Score (harmonic mean of Precision and Recall), CWI task defines and uses G-Score which measures the harmonic mean between Accuracy and Recall.

## 3 Experiments

### 3.1 Word Embeddings

To illustrate the effect of word embeddings on CWI task, we conducted several experiments. For Glove word embeddings, we used the publicly available word vectors<sup>1</sup> pretrained on a 2014 Wikipedia dump<sup>2</sup> with 1.6 billion tokens merged with Gigaword 5 which has 4.3 billion tokens. We use a sample from Wikipedia dump with approximately 150 million tokens to induce SCODE word embeddings<sup>3</sup>. For each word embedding experiment, we used Support Vector Machines with linear kernel as our classifier. We utilized scikit-learn (Buitinck et al., 2013) as our machine learning arsenal. We applied 5-fold cross validation on training set and report the result at the optimum C (penalty parameter of the error term) from a grid search in  $e^{-20}, e^{-19}, \dots, e^6, e^7$ .

| Embedding | Dimensions | G-Score |
|-----------|------------|---------|
| Random    | 50         | 0.5526  |
| Glove     | 50         | 0.6357  |
| Glove     | 100        | 0.6171  |
| Glove     | 200        | 0.6084  |
| SCODE     | 50         | 0.6013  |
| SCODE     | 100        | 0.6044  |
| SCODE     | 200        | 0.6098  |

**Table 2:** Random Embedding Baseline, Comparison of Glove and SCODE.

Firstly, each annotated word in a sentence represented with its corresponding dense real valued embedding and fed to the classifier. As a simple baseline we assigned a random embedding to each annotated word. A random embedding consists of 50 dimensions and each component is drawn from uniform distribution  $U(0, 1)$ . Table 2 holds the results

<sup>1</sup><http://nlp.stanford.edu/projects/glove/>

<sup>2</sup><http://dumps.wikimedia.org/enwiki/>

<sup>3</sup><https://github.com/ai-ku/wvec/>

for each experiment. We observe that both SCODE and Glove outperforms the random embedding baseline and Glove (trained on a much generous corpus) yields better results in general. Increasing the number of dimensions improves the performance slightly for SCODE but it hurts the performance of Glove embeddings.

|       |     | Glove         |        |        |
|-------|-----|---------------|--------|--------|
|       |     | 50            | 100    | 200    |
| SCODE | 50  | <b>0.6559</b> | 0.6317 | 0.6185 |
|       | 100 | 0.6514        | 0.6310 | 0.6174 |
|       | 200 | 0.6531        | 0.6323 | 0.6189 |

**Table 3:** Embedding Concatenations.

Subsequently, we took the cartesian product of both embeddings and experimented with concatenations. Instead of representing a word with only one embedding, we employed the concatenation of embeddings as features for each target word. Results are presented in Table 3. Experiments yield the best results when we use 50 dimensional embeddings of both methods. We show that concatenating embeddings yields better results.

|       |      | k=0    | k=1    | k=2    | k=3    |
|-------|------|--------|--------|--------|--------|
| S-50  | G-50 | 0.6559 | 0.6393 | 0.6260 | 0.6206 |
| S-100 | G-50 | 0.6514 | 0.6394 | 0.6260 | 0.6204 |
| S-200 | G-50 | 0.6531 | 0.6399 | 0.6264 | 0.6207 |

**Table 4:** Context-Aware Representations. S and G denotes SCODE and Glove respectively. k is the number of left and right neighbors.

Moreover, we took the surrounding words into account to make the representation of a target word context-aware. In this setup, each target word is represented not only by its own embedding but also with embeddings of surrounding words. As candidates, we selected the best performing concatenated embeddings from Table 3. Table 4 lists the results for context-aware representations where  $k$  is the number of left and right neighbors. Results imply that context-aware representations do not yield any improvements.

### 3.2 Final System

We submitted two systems<sup>4</sup> for the Complex Word Identification task. Both systems use SVM classifier

<sup>4</sup>Code is available at: <https://github.com/kuruonur1/cwi>

trained with Radial Basis Function. While first system (native) use the word embedding of the target word and its substrings as features, the second system (native1) uses the embeddings of preceding and following words as well. For target and surrounding words, we used the concatenation of SCODE and Glove with 50 dimensions which performed best for word embedding experiments. As substring features of the target word, we used prefixes, suffixes and character n-grams which are of length 3 and 4. We applied chi-squared test between each substring feature and class to reveal which ones are more relevant to classification and we kept the  $p$  percentile of highest scoring substring features.

|         | $C$    | $\gamma$ | $p$ | G-Score       |
|---------|--------|----------|-----|---------------|
| native  | 0.2705 | 0.1370   | 17  | <b>0.6800</b> |
| native1 | 0.0595 | 0.0251   | 20  | 0.6500        |

**Table 5:** Best performed hyperparameters and 5-fold cross validation results on training set.  $C$  is the penalty parameter of the error term for SVM,  $\gamma$  is the coefficient of RBF kernel.  $p$  denotes the percentile of substrings utilized with feature selection.

Either system has 3 parameters: the coefficient of RBF kernel ( $\gamma$ ), penalty parameter of the error term ( $C$ ), percentile ( $p$ ) of substring features. In order to tune the hyperparameters, we ran a random search (Bergstra and Bengio, 2012) using Hyperopt (Bergstra et al., 2013). For each hyperparameter configuration, we drawn  $C$  and  $\gamma$  from  $e^{U(-15,5)}$ ,  $p$  from  $U(5,30)$ . For each system, we tried 100 hyperparameter configurations and applied 5-fold cross validation. We selected the best performed hyperparameters (see Table 5) and trained our final models on the whole training set.

## 4 Results and Discussion

Complex Word Identification task has 9 baselines, 3 of which announced before system results and 6 baselines announced with system results. We have selected highest scoring 5 baselines to compare our systems' results. Baselines are either threshold-based (TB) or lexicon-based (LB). Two of the baselines, (TB) Wikipedia and (TB) Simple Wiki exploits language model probabilities. (TB) Senses and (TB) Length exploits words' number of senses and word lengths respectively. (LB) Ogdens base-

line is released before system results and classifies a word as complex only if it is not in the Ogdens vocabulary<sup>5</sup>. We present our final systems' results on test set with baselines scores in Table 6.

|                          |        |
|--------------------------|--------|
| Best Result <sup>6</sup> | 0.7740 |
| nativeLin <sup>7</sup>   | 0.7328 |
| (TB) Wikipedia           | 0.6720 |
| (TB) Simple Wiki         | 0.6540 |
| (TB) Senses              | 0.5790 |
| native1                  | 0.5450 |
| native                   | 0.5450 |
| (TB) Length              | 0.4780 |
| (LB) Ogdens              | 0.3930 |

**Table 6:** Final system results on test set along with baselines

First and foremost, we see that both of our submitted systems perform equally well on test set. Therefore, taking the surrounding words into account does not yield any improvements as we observed while validating our model on training set. Although the threshold-based baselines simply look at the frequency of a word in a corpus, they outperform our rather sophisticated systems significantly.

One may hypothesize that the small amount of training set available is the main cause of this unsatisfactory performance. After the release of annotated test set, we examined the effect of amount of training set available to our system.

| # of sentences | G-Score |
|----------------|---------|
| training set   | 0.7451  |
| +200           | 0.7475  |
| +400           | 0.7512  |
| +800           | 0.7559  |
| +1600          | 0.7588  |
| +3200          | 0.7638  |
| +6400          | 0.7670  |

**Table 7:** G-Scores on held out test set while number of sentences in training set increasing.

We held out 1000 sentences from test set as our new test set. We started with the original training set and added sentences from annotated test set. We used the same configuration as *native* system except

<sup>5</sup><http://ogden.basic-english.org/words.html>

<sup>6</sup>Best scoring system on SemEval-2016 CWI task

<sup>7</sup>This model is evaluated on test set after official results are announced

we used a linear kernel instead of nonlinear RBF kernel to speed up experiments. For each training set we cross validated the penalty parameter of the error term ( $C$ ) and evaluated it on held out test set. For each experiment, we report the mean G-Score of 5 random runs where the extra training set and held out test set splits selected from different shuffles. Table 7 illustrates that as the amount of training set increases our model performs better on held-out test set. Another key observation is that albeit our system is trained on the original training set with linear kernel, it has a high G-Score. Moreover, all other participants of CWI task which utilize word embeddings use nonlinear models. This scrutiny refutes the hypothesis that small amount of training set is the primary cause of word embeddings' unsatisfactory performance. Finally we trained *native* system with linear kernel using only the original training set and evaluated on whole test set. Native system with linear kernel (*nativeLin*) achieves a G-Score of 0.7328 on whole test set.

## 5 Conclusion

We investigated the utilization of word embeddings along with substrings as features on Complex Word Identification task. We showed that instead of representing a word with only one embedding type, word embedding concatenations yield better results. Moreover we considered context information by incorporating the embeddings of surrounding words which did not improve overall performance. Although the proposed representations perform below the average with nonlinear models, we conclude that word embeddings with substring features is an effective representation choice when employed with linear classifiers.

# Pomona at SemEval-2016 Task 11: Predicting Word Complexity Based on Corpus Frequency

**David Kauchak**  
Computer Science Department  
Pomona College  
Claremont, CA  
`david.kauchak@pomona.edu`

## Abstract

We introduce a word frequency-based classifier for the SemEval 2016 complex word identification task (#11). Words with lower frequency are predicted as complex based on a threshold optimized for G-score. We examine three different corpora for calculating frequencies and find English Wikipedia to perform best (ranked 13th on the SemEval task), followed by the Google Web Corpus and lastly Simple English Wikipedia. Bagging is also shown to slightly improve the performance of the classifier. Overall, we find word frequency to be a strong predictor of complexity. On the SemEval “test” set, a frequency classifier that uses the optimal frequency threshold performs on-par with the best submitted system and a system trained using only 500 labeled examples split from the test set achieves results that are only slightly below the best submitted system.

## 1 Introduction

Text simplification aims to transform text into more accessible versions while retaining the original meaning. A frequent subproblem of the general simplification problem is complex word identification: identify words in a text that are difficult to understand for the reader. Complex word identification is critical in lexical simplification algorithms where the simplification process is done a word at a time; frequently, simplification is broken into two steps, first identifying the complex words that need simplifying and, second, determining substitutions for these words (Shardlow, 2014). Even for simplifi-

cation systems that make sentence-level transformations (Siddharthan, 2014) complex word identification can be used as an additional feature function in the model and as a development tool to help measure progress. Additionally, in some domains such as health and medicine, accuracy is critical and semi-automated simplification tools are common (Leroy et al., 2012). In these domains, complex word identification is useful to help guide the simplification process by both identifying which words need to be simplified and filtering/ranking possible candidate substitutions (Leroy et al., 2013).

In this paper, we explore the use of word frequency as a predictor of the complexity of that word. Corpus studies have shown that simpler texts contain more frequent words than more complicated texts (Breland, 1996; Pitler and Nenkova, 2008; Leroy et al., 2012). User studies have also shown a correlation between word frequency and whether users know the definition of a word (Leroy and Kauchak, 2013). In semi-automated text simplification approaches, replacing less frequent words with higher frequency synonyms has been shown to produce text that people view as simpler and is easier to understand (Leroy et al., 2013).

## 2 Bagged Frequency Classifier

Given a sentence  $S = s_1s_2\dots s_m$  and a word in that sentence,  $s_j$ , the complex word identification task is to predict whether that word is complex (1) or not (0). Labeled examples are triples consisting of the sentence, the word and the label, i.e.  $\langle S, s_j, \{0, 1\} \rangle$ , and unlabeled examples consist only of the sentence and word  $\langle S, s_j \rangle$ . We view the problem as a super-

vised classification problem: given a collection of training examples, the goal is to learn a classifier to predict the label of unlabeled examples. See the SemEval Task 11 description for more details (Paetzold and Specia, 2016).

We utilize bagging (bootstrap resampling) to learn and combine multiple basic classifiers that predict by thresholding the frequency of occurrence of the word in question ( $s_j$ ) in an external corpus. Classification is then done by majority vote of these classifiers. The subsections below provide more details.

## 2.1 Basic frequency classifier

The basic frequency classifier predicts the word complexity using only a single feature, the frequency of the word in question ( $s_j$ ) in a corpus. Given an unlabeled example, the classifier predicts based on a learned threshold,  $\alpha$ :

$$\text{predict}(\langle S, s_j \rangle) = \begin{cases} 1 & \text{if } \text{freq}(s_j) < \alpha \\ 0 & \text{otherwise} \end{cases}$$

with the assumption that words that occur less frequently in a corpus are more complex.

To train the basic classifier, we select  $\alpha$  in an exhaustive fashion by considering all possible frequencies of seen in the training examples as candidate thresholds. Specifically, for each training example  $\langle S, s_j, \{0, 1\} \rangle$ , we consider using  $\alpha = \text{freq}(s_j)$ . We select the  $\alpha$  that maximizes the G-score on the training set, where the G-score is defined as:

$$\frac{2 * \text{accuracy} * \text{recall}}{\text{accuracy} + \text{recall}}$$

We chose to optimize the G-score since it was the metric used for evaluation in the SemEval task (Paetzold and Specia, 2016), though other metrics could be used instead.

## 2.2 Word frequencies

Word frequencies can be pre-calculated from any corpus. For this paper we examined three corpora: articles from Simple English Wikipedia<sup>1</sup>, articles from English Wikipedia<sup>2</sup> and the Google Web Corpus (Brants and Franz, 2006). For the Wikipedia articles we used the document aligned data set created

by Kauchak (2013) consisting of approximately 60K articles on the same topics from each Wikipedia.

To collect word frequencies for the two Wikipedia variants, tokenization was first performed using the Stanford CoreNLP PTBTokenizer (Manning et al., 2014) and then frequencies were calculated. For the Google Web Corpus, we used the unigram counts. In all corpora, all capitalization variants were aggregated, e.g. occurrences of “natural” and “Natural” would both be counted towards the same word form.

## 2.3 Bagging

To improve classifier performance and reduce variance we investigated the use of bagging (Breiman, 1996), also referred to as bootstrap resampling. An ensemble classifier is learned by training multiple basic frequency classifiers. Specifically, let  $\text{train}$  be a training set consisting of  $\text{size}(\text{train})$  labeled examples and  $b$  be the number of basic classifiers to be learned and combined. The bagged classifier is trained by repeatedly

- 1) generating a new training sample  $S \subseteq \text{train}$  containing  $\text{size}(\text{train})$  labeled examples by randomly sampling with replacement from  $\text{train}$  and then
- 2) training a new basic frequency classifier on  $S$ .

These two steps are repeated  $b$  times resulting in  $b$  different classifiers. To classify a new, unlabeled example, each of the  $b$  classifiers makes a prediction and the final label is the label with the majority vote, with ties going to not complex (0), since this was the more frequent class.

## 3 Experiments

We submitted two systems to the SemEval Complex Word Identification challenge (Task 11), which used the same parameter settings and only differed in where the corpus frequencies were collected, English Wikipedia (NormalBag) and the Google Web Corpus (GoogleBag). Both systems used  $b = 10$  rounds of bagging, which was shown experimentally to have the best scoring value, using repeated rounds of 10-fold validation. We also discuss results here for a system which used Simple English Wikipedia word frequencies, though we did not submit it to the challenge (for consistency, we denote it SimpleBag).

---

<sup>1</sup><https://simple.wikipedia.org/>

<sup>2</sup><https://en.wikipedia.org/>

| System    | Test    |          |        | Train   |          |        |
|-----------|---------|----------|--------|---------|----------|--------|
|           | G-score | Accuracy | Recall | G-score | Accuracy | Recall |
| NormalBag | 0.714   | 0.603    | 0.872  | 0.684   | 0.665    | 0.705  |
| GoogleBag | 0.691   | 0.568    | 0.881  | 0.675   | 0.648    | 0.704  |
| SimpleBag | 0.674   | 0.542    | 0.891  | 0.674   | 0.630    | 0.725  |

**Table 1:** Results for the bagged systems ( $b = 10$ ) with word frequencies calculated on the three different corpora. Results are shown for the test and training sets for systems trained on the training data.

The task consisted of a training data set ( $N = 2,237$ ), which was available during development, and a test data set ( $N = 88,221$ ) on which the competition was scored and the labels were only released after the competition (Paetzold and Specia, 2016). We use both data sets here to analyze the performance of the classifiers.

### 3.1 The impact of corpus choice

Table 1 shows the results for the classifiers trained using bagging with word frequencies calculated from the three different corpora. English Wikipedia performed the best, followed by Google Web Corpus and finally Simple English Wikipedia. The top two entries were entered into the SemEval competition and ranked 13th and 16th respectively out of 51 systems (42 team submitted systems and 9 baseline systems). We hypothesize that English Wikipedia represents a good compromise between size/coverage and corpus quality; even though NormalBag had slightly lower recall than the other two, it was able to achieve that recall with a significantly higher accuracy.

To verify that the differences in performance between the three systems were significant, we used bootstrap resampling with a paired sample  $t$ -test (Koehn, 2004). Based on 100 random samples, all differences between all metrics and all systems were significant ( $p < 0.0001$ , with Bonferroni correction to correct for testing multiple different comparisons).

Overall, relative to other systems that were submitted for the SemEval task, these frequency-based classifiers biased towards recall, e.g. the Google frequency and English Wikipedia frequency systems ranked 3rd and 5th with respect to recall (of the 42 team submitted systems).

| Corpus | Train         |                |
|--------|---------------|----------------|
|        | basic G-score | bagged G-score |
| Normal | 0.677         | <b>0.680</b>   |
| Google | 0.668         | 0.667          |
| Simple | 0.665         | <b>0.669</b>   |

**Table 2:** Comparison of the basic frequency classifiers and their bagged counterparts with  $b = 10$  on the training data averaged over 100 random 10-fold samples. Systems that were significantly different between the basic and bagged are in bold.

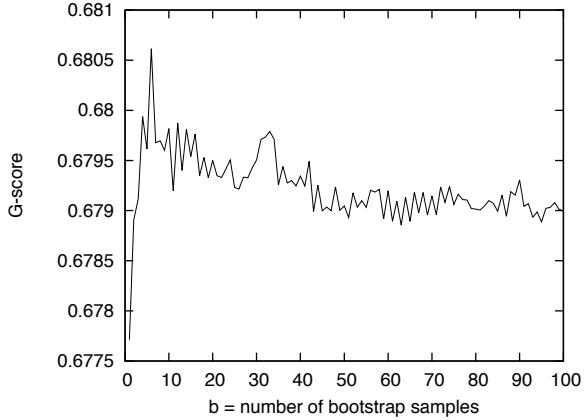

### 3.2 The impact of bagging

To measure the impact of bagging on the prediction performance of the systems, for each corpus source, we compared the basic frequency classifier to the bagged variant. We generated 100 random 10-fold partitions of the training data and performed 10-fold cross validation on each for each system variant. We averaged the results across the each 10-fold set resulting in 100 scores for each of the systems.

Table 2 shows the averages over these 100 scores. For both of the Wikipedia variants (Normal and Simple) bagging provided a small increase in performance ( $p < 0.0001$  based on a paired  $t$ -test). For the Google frequencies the performance actually decreased, though this decrease was not significant.

To understand the effect that  $b$  (the number of bootstrap samples) has on the performance of the classifier, we compared the performance of the classifier with  $b = 1, 2, \dots, 100$ . Figure 1 shows a plot of the G-score versus the number of bags used by the classifier for the NormalBag classifier on the training set. As with the previous experiment, to partially mitigate noise, we generated 100 randomly 10-fold sets and averaged the results across all of these to generate the data.

For small  $b$ , increasing the number of classifiers voting does increase the performance of the classifier. However, after around  $b = 10$  adding more

**Figure 1:** G-score for the NormalBag classifier with varying number of bootstrap samples. Results are averages over 100 random 10-fold samples of the training data.

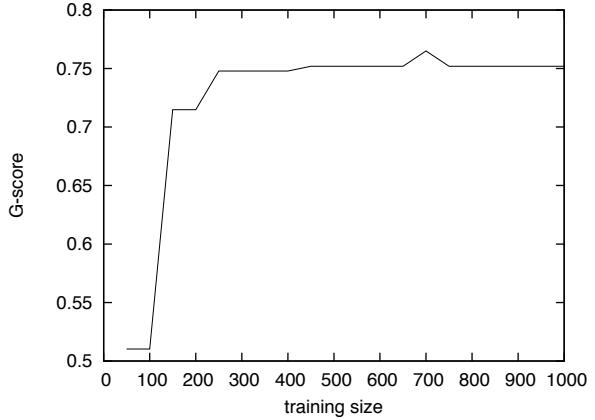

classifiers degrades the performance with the classifier. Although the difference is small for  $b = 1$  vs.  $b = 10$  (0.677 vs. 0.680), the difference is statistically significant.

### 3.3 Limits of frequency-based classification

Using English Wikipedia frequencies and the optimal frequency threshold (i.e.  $\alpha$ ), the basic threshold classifier achieves a G-score of 0.779 on the test data set. This is slightly higher than the best scoring SemEval system, which achieved 0.774. Clearly frequency provides a strong signal for word complexity.

The previous experiment assumes an unreasonable scenario where we know the labels and can pick the optimal value. To better understand the impact of frequency, we split the test data into 10-folds and performed 10-fold cross-validation analysis using the basic threshold classifier, training the threshold on 90% of the SemEval “test” data and then testing on the remaining 10%. In this scenario, the threshold classifier still achieves a G-score of 0.764, only slightly less than the score achieved using the optimal threshold.

0.764 is still significantly higher than the score achieved by the system when trained on the SemEval “training” set. Two possible differences exist between the training and testing data. First, the test data is two orders of magnitude larger than the original training data. This additional data could result in a more reliable classifier. Alternatively, train and

**Figure 2:** G-score for the basic threshold classifier using English Wikipedia frequencies for increasing training data size. Here the training data is a subset of the SemEval “test” set.

test were generated in different ways and could have different characteristics.

To investigate this, we held out 10% of the “test” data set as testing data and trained the basic threshold classifier on increasing amounts of the remaining 90%. Figure 2 shows the G-score for training sizes up to 1,000 (the G-score mostly stabilized beyond 1,000 with only minor variation). Even with only 250 training examples, the classifier already achieves a G-score of 0.748 and with 500 training examples, it achieves 0.752, only a little less than the final score using all of the training data of 0.760. For the frequency classifier, more the data domain, and less the size, accounts for the differences in performance seen.

## 4 Conclusion

In this paper, we described our entry for the complex word identification SeEval 2016 task (#11). We utilize word frequency to classify complexity, with less frequent words being classified as complex. As has been seen in previous corpus studies, frequency is a very strong predictor of the complexity of a word. However, the corpus where those frequencies are measured does play a role in performance. We found that English Wikipedia performed best for this particular task. Future research is needed to investigate this phenomena more broadly.

### Abstract

Clinical TempEval 2016 evaluated temporal information extraction systems on the clinical domain. Nine sub-tasks were included, covering problems in time expression identification, event expression identification and temporal relation identification. Participant systems were trained and evaluated on a corpus of clinical and pathology notes from the Mayo Clinic, annotated with an extension of TimeML for the clinical domain. 14 teams submitted a total of 40 system runs, with the best systems achieving near-human performance on identifying events and times. On identifying temporal relations, there was a gap between the best systems and human performance, but the gap was less than half the gap of Clinical TempEval 2015.

### 1 Introduction

The TempEval shared tasks have, since 2007, provided a focus for research on temporal information extraction (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013). Participant systems compete to identify critical components of the timeline of a text, including time expressions, event expressions and temporal relations. However, the TempEval campaigns to date have focused primarily on in-document timelines derived from news articles. In recent years, the community has moved toward testing such information extraction systems on clinical data (Sun et al., 2013; Bethard et al., 2015) to

broaden our understanding of the language of time beyond newswire expressions and structure.

Clinical TempEval focuses on discrete, well-defined tasks which allow rapid, reliable and repeatable evaluation. Participating systems are expected to take as input raw text, for example:

April 23, 2014: The patient did not have any postoperative bleeding so we'll resume chemotherapy with a larger bolus on Friday even if there is slight nausea.

The systems are then expected to output annotations over the text, for example, those shown in Figure 1. That is, the systems should identify the time expressions, event expressions, attributes of those expressions, and temporal relations between them.

Clinical TempEval 2016 addressed one of the major challenges in Clinical TempEval 2015: data distribution. Because Clinical TempEval is based on real patient notes from the Mayo Clinic, participants go through a lengthy authorization process involving a data use agreement and an interview. For Clinical TempEval 2016, we streamlined this process and were able to authorize data access for more than twice as many participants as Clinical TempEval 2015. And since all the training and evaluation data distributed for Clinical TempEval 2015 was used as the training data for Clinical TempEval 2016, participants had more than a year to work on their systems. The result was that four times as many teams participated.

**Figure 1:** Example Clinical TempEval annotations

## 2 Data

The Clinical TempEval corpus was based on a set of 600 clinical notes and pathology reports from cancer patients at the Mayo Clinic. These notes were manually de-identified by the Mayo Clinic to replace names, locations, etc. with generic placeholders, but time expressions were not altered. The notes were then manually annotated by the THYME project ([thyme.healthnlp.org](http://thyme.healthnlp.org)) using an extension of ISO TimeML for the annotation of times, events and temporal relations in clinical notes (Styler et al., 2014b). This extension includes additions such as new time expression types (e.g., PREPOSTEXP for expressions like *postoperative*), new EVENT attributes (e.g., DEGREE=LITTLE for expressions like *slight nausea*), and an increased focus on temporal relations of type CONTAINS (a.k.a. INCLUDES).

The annotation procedure was as follows:

1. Annotators identified time and event expressions, along with their attributes
2. Adjudicators revised and finalized the time and event expressions and their attributes
3. Annotators identified temporal relations between pairs of events and events and times
4. Adjudicators revised and finalized the temporal relations

More details on the corpus annotation process are documented in a separate article (Styler et al., 2014a).

Because the data contained incompletely de-

identified clinical data (the time expressions were retained), participants were required to sign a data use agreement with the Mayo Clinic to obtain the raw text of the clinical notes and pathology reports.<sup>1</sup> The event, time and temporal relation annotations were distributed separately from the text, in an open source repository<sup>2</sup> using the Anafora standoff format (Chen and Styler, 2013).

The corpus was split into three portions: Train (50%), Dev (25%) and Test (25%). Patients were sorted by patient number (an integer arbitrarily assigned by the de-identification process) and stratified across these splits. The Train and Dev portions were released to participants for training and tuning their systems. The Test portion was reserved for evaluation of the systems. Table 1 shows the number of documents, event expressions (EVENT annotations), time expressions (TIMEX3 annotations) and narrative container relations (TLINK annotations with TYPE=CONTAINS attributes) in the Train, Dev, and Test portions of the corpus.

## 3 Tasks

Nine tasks were included (the same as those of Clinical TempEval 2015), grouped into three categories:

- Identifying time expressions (TIMEX3 annotations in the THYME corpus) consisting of the

<sup>1</sup>Details on the process: <http://thyme.healthnlp.org/>

<sup>2</sup><https://github.com/stylerw/thymedata>

|                      | Train | Dev   | Test  |
|----------------------|-------|-------|-------|
| Documents            | 293   | 147   | 151   |
| TIMEX3s              | 3833  | 2078  | 1952  |
| EVENTS               | 38890 | 20974 | 18990 |
| TYPE=CONTAINS TLINKS | 11176 | 6173  | 5894  |

**Table 1:** Number of documents, event expressions, time expressions and narrative container relations in Train, Dev, and Test portions of the THYME data. Both Train and Dev were released as part of Clinical TempEval 2015.

following components:

- The span (character offsets) of the expression in the text
- Class: DATE, TIME, DURATION, QUANTIFIER, PREPOSTEXP or SET
- Identifying event expressions (EVENT annotations in the THYME corpus) consisting of the following components:
  - The span (character offsets) of the expression in the text
  - Contextual Modality: ACTUAL, HYPOTHETICAL, HEDGED or GENERIC
  - Degree: MOST, LITTLE or N/A
  - Polarity: POS or NEG
  - Type: ASPECTUAL, EVIDENTIAL or N/A
- Identifying temporal relations between events and times, focusing on the following types:
  - Relations between events and the document creation time (BEFORE, OVERLAP, BEFORE-OVERLAP or AFTER), represented by DOCTIMEREL annotations.
  - Narrative container relations (Pustejovsky and Stubbs, 2011), which indicate that an event or time is temporally contained in (i.e., occurred during) another event or time, represented by TLINK annotations with TYPE=CONTAINS.

The evaluation was run in two phases:

1. Systems were provided access only to the raw text, and were asked to identify time expressions, event expressions and temporal relations
2. Systems were provided access to the raw text and the manual event and time annotations, and were asked to identify only temporal relations

## 4 Evaluation Metrics

All of the tasks were evaluated using the standard metrics of precision ( $P$ ), recall ( $R$ ) and  $F_1$ :

$$P = \frac{|S \cap H|}{|S|} \quad R = \frac{|S \cap H|}{|H|} \quad F_1 = \frac{2 \cdot P \cdot R}{P + R}$$

where  $S$  is the set of items predicted by the system and  $H$  is the set of items annotated by the humans. Applying these metrics only requires a definition of what is considered an “item” for each task.

- For evaluating the spans of event expressions or time expressions, items were tuples of (begin, end) character offsets. Thus, systems only received credit for identifying events and times with exactly the same character offsets as the manually annotated ones.
- For evaluating the attributes of event expressions or time expressions – Class, Contextual Modality, Degree, Polarity and Type – items were tuples of (begin, end, value) where begin and end are character offsets and value is the value that was given to the relevant attribute. Thus, systems only received credit for an event (or time) attribute if they both found an event (or time) with the correct character offsets and then assigned the correct value for that attribute.
- For relations between events and the document creation time, items were tuples of (begin, end, value), just as if it were an event attribute. Thus, systems only received credit if they found a correct event and assigned the correct relation (BEFORE, OVERLAP, BEFORE-OVERLAP or AFTER) between that event and the document creation time. In the second phase of the evaluation, when manual event annotations were provided as input, only recall (which in this case is equivalent to standard classification accuracy) is reported.
- For narrative container relations, items were tuples of ((begin<sub>1</sub>, end<sub>1</sub>), (begin<sub>2</sub>, end<sub>2</sub>)), where the begins and ends corresponded to the character offsets of the events or times participating in the relation. Thus, systems only received credit for a narrative container relation if they found both events/times and correctly assigned a CONTAINS relation between them.

For event and time attributes, we also measure how accurately a system predicts the attribute values on just those events or times that the system predicted. The goal here is to allow a comparison across systems for assigning attribute values, even when different systems produce different numbers of events and times. This metric is calculated by dividing the  $F_1$  on the attribute by the  $F_1$  on identifying the spans:

$$A = \frac{\text{attribute } F_1}{\text{span } F_1}$$

For narrative container relations, the  $P$  and  $R$  definitions were modified to take into account *temporal closure*, where additional relations are deterministically inferred from other relations (e.g., A CONTAINS B and B CONTAINS C, so A CONTAINS C):

$$P = \frac{|S \cap \text{closure}(H)|}{|S|} \quad R = \frac{|\text{closure}(S) \cap H|}{|H|}$$

Similar measures were used in prior work (UzZaman and Allen, 2011) and TempEval 2013 (UzZaman et al., 2013), following the intuition that precision should measure the fraction of system-predicted relations that can be verified from the human annotations (either the original human annotations or annotations inferred from those through closure), and that recall should measure the fraction of human-annotated relations that can be verified from the system output (either the original system predictions or predictions inferred from those through closure).

## 5 Baseline Systems

Two rule-based systems were used as baselines to compare the participating systems against.

**memorize** For all tasks but the narrative container task, a memorization baseline was used.

To train the model, all phrases annotated as either events or times in the training data were collected. All exact character matches for these phrases in the training data were then examined, and only phrases that were annotated as events or times greater than 50% of the time were retained. For each phrase, the most frequently annotated type (event or time) and attribute values for instances of that phrase were determined.

To predict with the model, the raw text of the test data was searched for all exact character

matches of any of the memorized phrases, preferring longer phrases when multiple matches overlapped. Wherever a phrase match was found, an event or time with the memorized (most frequent) attribute values was predicted.

**closest** For the narrative container task, a proximity baseline was used. Each time expression was predicted to be a narrative container, containing only the closest event expression to it in the text.

## 6 Participating Systems

14 research teams submitted a total of 40 runs:

**brumblefly** (Fries, 2016) submitted 1 run for phase 1 based on recurrent neural networks, word embeddings, and logistic regression, and 1 run for phase 2 run based on the DeepDive framework (<http://deepdive.stanford.edu>).

**CDE-IIITH** (Chikka, 2016) submitted 2 runs for each phase, the first based on deep learning models, and the second based on conditional random fields and support vector machines.

**Cental** (Hansart et al., 2016) submitted 1 run for phase 1, based on conditional random fields and lexical resources.

**GUIR** (Cohan et al., 2016) submitted 2 runs for phase 1 and 1 run for phase 2, based on conditional random fields and logistic regression with lexical, morphological, syntactic, dependency, and domain specific features, combined with pattern matching rules.

**HITACHI** (Sarah P R et al., 2016) submitted 2 runs for the time portion of phase 1, based on ensembles of rule-based and machine learning systems with lexical, syntactic and morphological features. The second run included 50% more training data than the first.

**KULeuven-LIIR** (Leeuwenberg and Moens, 2016) submitted 2 runs for phase 2, based on the cTAKES-temporal machine-learning model (Lin et al., 2015), with additional features.

**LIMSI** (Grouin and Moriceau, 2016) submitted 2 runs for each phase, based on conditional random fields with lexical, morphological, and word cluster features, and the rule-based Heidelberg-Time (Strötgen and Gertz, 2013).

**LIMSI-COT** (Tourille et al., 2016) submitted 2 runs for phase 2, the first based on support vector ma-

chines with lexical, syntactic, structural, and UMLS features, and the second based on replacing the lexical features with word embeddings.

**ULISBOA** (Barros et al., 2016) submitted 2 runs for each phase, based on the IBEnt framework’s support vector machines with lexical and morphological features (<https://github.com/AndreLamurias/IBEnt>), and rule-based extensions to Stanford CoreNLP (Manning et al., 2014). The runs differed on how rules were incorporated for each subtask.

**UtahBMI** (Velupillai and Meystre, 2016) submitted 2 runs for each phase, the first based on conditional random fields and the second based on support vector machines. Both runs used lexical, morphological, syntactic, shape, character pattern, character n-gram, section type, and gazetteer features.

**UTA-MLNLP** (Li and Huang, 2016) submitted 2 runs for each phase, based on a neural network with a different window size for each run.

**UTHealth** (Lee et al., 2016) submitted 2 runs for each phase, based on linear and structural (HMM) support vector machines using lexical, morphological, syntactic, discourse, and word representation features. The runs differed on the features included.

**VUACLTL** (Caselli and Morante, 2016) submitted 2 runs for each phase, based on conditional random fields with morpho-syntactic, lexical, UMLS, and DBpedia features. The first run was a two-step approach to temporal relations, the second, a one step approach.

## 7 Human Agreement

We also provide two types of human agreement on the task, measured with the same evaluation metrics as the systems:

**ann-ann** Inter-annotator agreement between the two independent human annotators who annotated each document. This is the most commonly reported type of agreement, and often considered to be an upper bound on system performance.

**adj-ann** Inter-annotator agreement between the adjudicator and the two independent annotators. This is usually a better bound on system performance in adjudicated corpora, since the models

are trained on the adjudicated data, not on the individual annotator data.

Precision and recall are not reported in these scenarios since they depend on the arbitrary choice of one annotator as human ( $H$ ) and the other as system ( $S$ ).

Note that since temporal relations between events and the document creation time were annotated at the same time as the events themselves, agreement for this task is only reported in phase 1 of the evaluation. Similarly, since narrative container relations were only annotated after events and times had been adjudicated, agreement for this task is only reported in phase 2 of the evaluation.

## 8 Evaluation Results

### 8.1 Time Expressions

Table 2 shows results on the time expression tasks. The UTHealth systems achieved the best results on almost all time-related tasks. For finding times, while one system had comparable precision to UTHealth (0.836 UTHealth vs. 0.840 LIMSI), no system had competitive recall (0.757 UTHealth vs. 0.714 from the next best, UtahBMI), and thus the UTHealth system consistently outperformed the other systems in  $F_1$ . The results were similar for jointly finding times and assigning them a time class, though a couple systems (HITACHI, GUIR) did have more accurate predictions for the time class when scored only on the times that they were able to find (0.971 UTHealth vs. 0.975 HITACHI vs. 0.989 GUIR).

Compared to human agreement, the UTHealth and UtahBMI systems exceeded the inter-annotator agreement on times of 0.731, but even UTHealth’s  $F_1$  of 0.795 did not reach the annotator-adjudicator agreement of 0.830, and the results were similar for jointly finding times and assigning their classes (0.772 vs. 0.807). Nonetheless, these 0.025 and 0.035 gaps between the top system and the human agreement are smaller than the 0.051 and 0.038 gaps observed in Clinical TempEval 2015 (Bethard et al., 2015).

### 8.2 Event Expressions

Table 3 shows results on the event expression tasks. Again, UTHealth dominated the field, achieving the highest score on almost every event-related task. However, the gap to the second place team was much smaller for events than it was for times: only a 0.011

| Team               | span         |              |              | span + class |              |              |              |
|--------------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|
|                    | P            | R            | F1           | P            | R            | F1           | A            |
| UTHealth-1         | 0.836        | <b>0.757</b> | <b>0.795</b> | 0.812        | <b>0.735</b> | <b>0.772</b> | 0.971        |
| UTHealth-2         | 0.826        | 0.758        | 0.790        | 0.800        | 0.734        | 0.765        | 0.968        |
| UtahBMI-crf        | 0.798        | 0.714        | 0.754        | 0.771        | 0.690        | 0.729        | 0.967        |
| UtahBMI-svm        | 0.810        | 0.690        | 0.745        | 0.792        | 0.674        | 0.728        | 0.977        |
| HITACHI-1          | 0.781        | 0.685        | 0.730        | 0.759        | 0.671        | 0.712        | 0.975        |

**Table 2:** System performance and annotator agreement on TIMEX3 tasks: identifying the time expression’s span (character offsets) and class (DATE, TIME, DURATION, QUANTIFIER, PREPOSTEXP or SET). The best system score from each column is in bold. Systems marked with † were submitted after the competition deadline and are not considered official.

gap between UTHealth’s 0.903  $F_1$  and UtahBMI’s 0.892. The gap was even smaller if we look at precision and recall separately: a 0.007 gap between UTHealth’s 0.915 precision and UTA’s 0.908, and a 0.005 gap between UTHealth’s 0.891 precision and UtahBMI’s 0.886. The results were similar for most of the attributes, though the precision gaps were larger (1.1-1.4) and the recall gaps were smaller (0.3-0.7).

Compared to human agreement, UTHealth, UtahBMI, Central, GUIR, and UTA all exceeded inter-annotator agreement on identifying events, and UTHealth and UtahBMI exceeded inter-annotator agreement on all of the attributes. None of the systems reached the level of annotator-adjudicator agreement: even UTHealth’s  $F_1$  on events of 0.903 had a gap of 0.019 from the annotator-adjudicator agreement of 0.922, and the results were similar for event attributes: 0.049 for modality, 0.021 for degree, 0.029

for polarity, 0.024 for type. These gaps are almost all bigger than the gaps observed in Clinical TempEval 2015: 0.005 for event spans, 0.031 for modality, 0.007 for degree, 0.012 for polarity, 0.030 for type. However, Clinical TempEval 2016’s human agreement was substantially higher, with all annotator-adjudicator agreement above 0.90, while in Clinical TempEval 2015, annotator-adjudicator agreement ranged from 0.853 to 0.880.

### 8.3 Temporal Relations

Table 4 shows performance on the temporal relation tasks. In both phase 1 (where systems were provided only the raw text) and phase 2 (where systems were provided the manually annotated events and times), the UTHealth system was again the top system for most tasks. For relating events to the document creation time, the UTHealth system had the best precision, recall, and  $F_1$  (0.766, 0.746, and 0.756) in phase

| Team               | span         |              |              | span + modality |              |              |              | span + degree |              |              |              |

**Table 4:** System performance and annotator agreement on temporal relation tasks: identifying relations between events and the document creation time (DOCTIMEREL), and identifying narrative container relations (CONTAINS). The best system score from each column is in bold. Systems marked with † were submitted after the competition deadline and are not considered official.

1, and the second best score (0.835 vs. UtahBMI's 0.843) in phase 2. For finding narrative container relations, the UTHealth system had the best recall (0.471 in phase 1, 0.559 in phase 2), and though other systems (UtahBMI, VUACLTL, LIMSI-COT, and KULeuven-LIIR) had higher precisions, the recall gap from UTHealth to the next system was large (0.203 in phase 1 and 0.088 in phase 2) and thus UTHealth had the best  $F_1$  in both phases (0.479 in phase 1, 0.573 in phase 2).

Compared to human agreement, UTHealth and UtahBMI exceeded inter-annotator agreement on relations to the document time (while still leaving a gap of 0.088 to the annotator-adjudicator agreement), but no participant system was near the human agreement for narrative containers (a gap of 0.078 from inter-annotator agreement and a gap of 0.244 from annotator-adjudicator agreement). For relations to the document time, the 0.088 gap between systems and annotator-adjudicator agreement is slightly larger than the 0.059 of Clinical TempEval 2015, but for narrative container relations the 0.244 gap is much smaller than the 0.412 of Clinical TempEval 2015. As with other tasks, human agreement is higher this year (0.844 and 0.817 in 2016 vs. 0.761 and 0.672 in 2015), which may explain the larger gap for document time relations. The smaller gap for narrative container relations despite the increased human agreement suggests that major improvements have been made to the systems for this task.

## 9 Discussion

The results of Clinical TempEval 2016 suggest that current state-of-the-art systems are close to solving most event and time related tasks. For all of these tasks, the gap between system performance and human performance was less than 0.05, and for half the tasks (time spans, event spans, event degree, event type) it was 0.025 or less.

The temporal relation tasks were more difficult. Systems trying to predict the temporal relation between an event and the time at which the document was written lagged about 0.09 behind human performance. And systems trying to predict narrative containers (whether one event or time contains another) lagged about 0.25 behind human performance, even when provided human-annotated events and times.

Nonetheless, the latter result was a major improvement over Clinical TempEval 2015, where the gap on narrative containers was more than 0.4.

While there was variability across the subtasks in the rankings of teams, UTHealth and UtahBMI were always at the top of the lists. Both of these systems relied on structured learning models (UTHealth used HMM support vector machines; UtahBMI used conditional random fields) with a wide variety of features (lexical, morphological, syntactic, and many others). We can thus infer that such approaches hold promise for temporal information extraction. However, these two teams were also among the first to make it through the data use agreement process, so their success may in part reflect the advantage of having more time for experimentation and feature engineering on the training data.

Overall, Clinical TempEval 2016 represented a major step forward from Clinical TempEval 2015. It saw a much greater breadth of participating systems (14 teams in 2016 vs. 3 teams in 2015), with the top systems maintaining 2015's high performance on the event and time tasks, while making major progress on the harder temporal relation tasks. Future plans for Clinical TempEval target the robustness of these systems: instead of testing on only colon cancer notes from the Mayo Clinic (the same domain as the training set), systems will be tested on other types of medical conditions and notes from other institutions.

# SemEval-2016 Task 8: Meaning Representation Parsing

**Jonathan May**  
Information Sciences Institute  
University of Southern California  
jonmay@isi.edu

## Abstract

In this report we summarize the results of the SemEval 2016 Task 8: Meaning Representation Parsing. Participants were asked to generate Abstract Meaning Representation (AMR) (Banarescu et al., 2013) graphs for a set of English sentences in the news and discussion forum domains. Eleven sites submitted valid systems. The availability of state-of-the-art baseline systems was a key factor in lowering the bar to entry; many submissions relied on CAMR (Werling et al., 2015) as a baseline system and added extensions to it to improve scores. The evaluation set was quite difficult to parse, particularly due to creative approaches to word representation in the web forum portion. The top scoring systems scored 0.62 F1 according to the Smatch (Cai and Knight, 2013) evaluation heuristic. We show some sample sentences along with a comparison of system parses and perform quantitative ablative studies.

## 1 Introduction

Abstract Meaning Representation (AMR) is a compact, readable, whole-sentence semantic annotation (Banarescu et al., 2013). It includes entity identification and typing, PropBank semantic roles (Kingsbury and Palmer, 2002), individual entities playing multiple roles, as well as treatments of modality, negation, etc. AMR abstracts in numerous ways, e.g., by assigning the same conceptual structure to *fear* (v), *fear* (n), and *afraid* (adj). Figure 1 gives an example.

With the recent public release of a sizeable corpus of English/AMR pairs (LDC2014T12), there has

```
(f / fear-01
:polarity "-"
:ARG0 ( s / soldier )
:ARG1 ( d / die-01
:ARG1 s ))
```

The soldier was not afraid of dying.  
The soldier was not afraid to die.  
The soldier did not fear death.

Figure 1: An Abstract Meaning Representation (AMR) with several English renderings. Example borrowed from Pust et al. (2015).

been substantial interest in creating parsers to recover this formalism from plain text. Several parsers were released in the past couple of years (Flanigan et al., 2014; Wang et al., 2015b; Werling et al., 2015; Wang et al., 2015a; Artzi et al., 2015; Pust et al., 2015). This body of work constitutes many diverse and interesting scientific contributions, but it is difficult to adequately determine which parser is numerically superior, due to heterogeneous evaluation decisions and the lack of a controlled blind evaluation. The purpose of this task, therefore, was to provide a competitive environment in which to determine one winner and award a trophy to said winner.

## 2 Training Data

LDC released a new corpus of AMRs (LDC2015E86), created as part of the DARPA DEFT program, in August of 2015. The new corpus, which was annotated by teams at SDL, LDC, and the University of Colorado, and supervised by Ulf Hermjakob at USC/ISI, is an extension of pre-

vious releases (LDC2014E41 and LDC2014T12). It contains 19,572 sentences (subsuming, in turn, the 18,779 AMRs from LDC2014E41 and the 13,051 AMRs from LDC2014T12), partitioned into training, development, and test splits, from a variety of news and discussion forum sources.

The AMRs in this corpus have changed somewhat from their counterparts in LDC2014E41, consistent with the evolution of the AMR standard. They now contain wikification via the `:wiki` attribute, they use new (as of July 2015) PropBank framesets that are unified across parts of speech, they have been deepened in a number of ways, and various corrections have been applied.

### 3 Other Resources

We made the following resources available to participants:

- The aforementioned AMR corpus (LDC2015E86), which included automatically generated AMR-English alignments over tokenized sentences.
- The tokenizer (from Ulf Hermjakob) used to produce the tokenized sentences in the training corpus.
- The AMR specification, used by annotators in producing the AMRs.<sup>1</sup>
- A deterministic, input-agnostic trivial baseline ‘parser’ courtesy of Ulf Hermjakob.
- The JAMR parser (Flanigan et al., 2014) as a strong baseline. We provided setup scripts to process the released training data but otherwise provided the parser as is.
- An unsupervised AMR-to-English aligner (Pourdamghani et al., 2014).
- The same Smatch (Cai and Knight, 2013) scoring script used in the evaluation.
- A Python AMR manipulation library, from Nathan Schneider.

Table 2: Main Results: Mean of five runs of Smatch 2.0.2 with five restarts per run is shown; Standard deviation of F1 was about 0.0002 per system.

### 4 Evaluation Data

For the specific purposes of this task, DEFT commissioned and LDC released an additional set of English sentences along with AMR annotations<sup>2</sup> that had not been previously seen. This blind evaluation set consists of 1,053 sentences in a roughly 50/50 discussion forum/newswire split. The distribution of sentences by source is shown in Table 1.

### 5 Task Definition

We deliberately chose a single, simple task. Participants were given English sentences and had to return an AMR graph (henceforth, ‘an AMR’) for each sentence. AMRs were scored against a gold AMR with the Smatch heuristic F1-derived tool and metric. Smatch (Cai and Knight, 2013) is calculated

<sup>2</sup>LDC2015R33 for just the sentences, and LDC2015R36 for sentences with their AMRs.

by matching instance, attribute, and relation tuples to a reference AMR (See Section 7.2). Since variable naming need not be globally consistent, heuristic hill-climbing is done to search for the best match in sub-exponential time. A trophy was given to the team with the highest Smatch score under consistent heuristic conditions.<sup>3</sup>

## 6 Participants and Results

11 teams participated in the task.<sup>4</sup> Their systems and scores are shown in Table 2. Below are brief descriptions of each of the various systems, based on summaries provided by the system authors. Readers are encouraged to consult individual system description papers for more details.

### 6.1 CAMR-based systems

A number of teams made use of the CAMR system from Wang et al. (2015a). These systems proved among the highest-scoring and had little variance from each other in terms of system score.

#### 6.1.1 Brandeis / cemantix.org / RPI (Wang et al., 2016)

This team, the originators of CAMR, started with their existing AMR parser and experimented with three sets of new features: 1) rich named entities, 2) a verbalization list, and 3) semantic role labels. They also used the RPI Wikifier to wikify the concepts in the AMR graph.

#### 6.1.2 ICL-HD (Brandt et al., 2016)

This team attempted to improve AMR parsing by exploiting preposition semantic role labeling information retrieved from a multi-layer feed-forward neural network. Prepositional semantics was included as features into CAMR. The inclusion of the features modified the behavior of CAMR when creating meaning representations triggered by prepositional semantics.

#### 6.1.3 RIGA (Barzdins and Gosko, 2016)

Besides developing a novel character-level neural translation based AMR parser, this team also

<sup>3</sup>Four random restarts.

<sup>4</sup>A twelfth team, CUCLEAR, participated but produced invalid AMRs that could not be scored.

extended the Smatch scoring tool with the C6.0 rule-based classifier to produce a human-readable report on the error patterns frequency observed in the scored AMR graphs. They improved CAMR by adding to it a manually crafted wrapper fixing the identified CAMR parser errors. A small further gain was achieved by combining the neural and CAMR+wrapper parsers in an ensemble.

#### 6.1.4 M2L (Puzikov et al., 2016)

This team attempted to improve upon CAMR by using a feed-forward neural network classification algorithm. They also experimented with various ways of enriching CAMR’s feature set. Unlike ICL-HD and RIGA they were not able to benefit from feed-forward neural networks, but were able to benefit from feature enhancements.

## 6.2 Other Approaches

The other teams either improved upon their existing AMR parsers, converted existing semantic parsing tools and pipelines into AMR, or constructed AMR parsers from scratch with novel techniques.

#### 6.2.1 CLIP@UMD (Rao et al., 2016)

This team developed a novel technique for AMR parsing that uses the Learning to Search (L2S) algorithm. They decomposed the AMR prediction problem into three problems—that of predicting the concepts, predicting the root, and predicting the relations between the predicted concepts. Using L2S allowed them to model the learning of concepts and relations in a unified framework which aims to minimize the loss over the entire predicted structure, as opposed to minimizing the loss over concepts and relations in two separate stages.

#### 6.2.2 CMU (Flanigan et al., 2016)

This team’s entry is a set of improvements to JAMR (Flanigan et al., 2014). The improvements are: a novel training loss function for structured prediction, new sources for concepts, improved features, and improvements to the rule-based aligner in Flanigan et al. (2014). The overall architecture of the system and the decoding algorithms for con-

|                  | Full AMR      | Instances     | Attributes    | Relations     |
|------------------|---------------|---------------|---------------|---------------|
| Brandeis         | <b>0.6195</b> | 0.7433        | 0.6043        | 0.5494        |
| CLIP@UMD         | 0.4370        | 0.6097        | 0.4013        | 0.3712        |
| CMU              | 0.5636        | 0.7288        | 0.5433        | 0.4960        |

| UCL+Sheffield    | 0.5983        | <b>0.7545</b> | 0.5914        | 0.5155        |
| UofR             | 0.4985        | 0.7054        | 0.5586        | 0.4203        |
| Determ. baseline | 0.2440        | 0.2269        | 0.0014        | 0.3556        |
| JAMR baseline    | 0.4965        | 0.6970        | 0.3089        | 0.4562        |

Table 3: Ablation of instances, attributes, and relations.

cept identification and relation identification are unchanged from Flanigan et al. (2014).

### 6.2.3 Dynamic Power (Butler, 2016)

No use was made of the training data provided by the task. Instead, existing components were combined to form a pipeline able to take raw sentences as input and output meaning representations. The components are a part-of-speech tagger and parser trained on the Penn Parsed Corpus of Modern British English to produce syntactic parse trees, a semantic role labeler, and a named entity recognizer to supplement obtained parse trees with word sense, functional and named entity information. This information is passed into an adapted Tarskian satisfaction relation for a Dynamic Semantics that is used to transform a syntactic parse into a predicate logic based meaning representation, followed by conversion to the required Penman notation.

### 6.2.4 The Meaning Factory (Bjerva et al., 2016)

This team employed an existing open-domain semantic parser, Boxer (Curran et al., 2007), which produces semantic representations based on Discourse Representation Theory. As the meaning representations produced by Boxer are considerably different from AMRs, the team used a hybrid conversion method to map Boxer’s output to AMRs. This process involves lexical adaptation, a conver-

sion from DRT-representations to AMR, as well as post-processing of the output.

### 6.2.5 UCL+Sheffield (Goodman et al., 2016)

This team developed a novel transition-based parsing algorithm using exact imitation learning, in which the parser learns a statistical model by imitating the actions of an expert on the training data. They used the imitation learning algorithm DAGGER to improve the performance, and applied an alpha-bound as a simple noise reduction technique.

### 6.2.6 UofR (Peng and Gildea, 2016)

This team applied a synchronous-graph-grammar-based approach for string-to-AMR parsing. They applied Markov Chain Monte Carlo (MCMC) algorithms to learn Synchronous Hyperedge Replacement Grammar (SHRG) rules from a forest that represents likely derivations consistent with a fixed string-to-graph alignment (extracted using an automatic aligner). They make an analogy of string-to-AMR parsing to the task of phrase-based machine translation and came up with an efficient algorithm to learn graph grammars from string-graph pairs. They proposed an effective approximation strategy to resolve the complexity issue of graph compositions. Then they used the Earley algorithm with cube-pruning for AMR parsing given new sentences and the learned SHRG.

### 6.2.7 CU-NLP (**Foland and Martin, 2016**)

This parser does not rely on a syntactic pre-parse, or heavily engineered features, and uses five recurrent neural networks as the key architectural components for estimating AMR graph structure.

## 7 Result Ablations

We conduct several ablations to attempt to empirically determine what aspects of the AMR parsing task were more or less difficult for the various systems.

### 7.1 Impact of Wikification

The AMR standard has recently been expanded to include wikification and the data used in this task reflected that expansion. Since this is a rather recent change to the standard and requires some kind of global external knowledge of, at a minimum, Wikipedia’s ontology, we suspected performance on :wiki attributes would suffer. To measure the effect of wikification, we performed two ablation experiments, the results of which are in Figure 2. In the first (“no wiki”), we removed :wiki attributes and their values from reference and system sets before scoring. In the second (“bad wiki”), we replaced the value of all :wiki attributes with a dummy entry to artificially create systems that did not get any wikification correct.

The “no wiki” ablations show that the inclusion of wikification into the AMR standard had a very small impact on overall system scores. No system’s score changed by more than 0.01 when wikification was removed, indicating that systems appear to wikify about as well as they handle the rest of AMR’s attributes. The “bad wiki” ablations show performance drop when wikification is corrupted of around 0.02 to 0.03 for six of the systems, and a negligible performance drop for the remaining systems. This result indicates that the systems with a performance drop are doing a fairly good job at wikification.

### 7.2 Performance on different parts of the AMR

In this set of ablations we examine systems’ relative performance on correctly identifying *instances*, *attributes*, and *relations* of the AMRs. Instances are

the labeled nodes of the AMR. In the example AMR of Figure 1, the instances are `fear-01`, `soldier`, and `die-01`. To match an instance one must simply match the instance’s label.<sup>5</sup>

Attributes are labeled string properties of nodes. In the example AMR, there is a **polarity** attribute attached to the `fear-01` instance with a value of “-.” There is also an implicit attribute of “TOP” attached to the root node of the graph, with the node’s instance as the attribute value. To match an attribute one must match the attribute’s label and value, and the attribute’s instance must be aligned with the corresponding instance in the reference graph.

Relations are labeled edges between two instances. In the example AMR, the relations (`f`, `s`, ARG0), (`f`, `d`, ARG1), and (`d`, `s`, ARG1) exist. To match a relation, the labeled edge between two nodes of the hypothesis must match the label of the edge between the correspondingly aligned nodes of the reference graph.

It should not be surprising that systems tend to perform best at instance matching and worst at relation matching. Note, however, that the best performing systems on instances and relations were not the overall best performing systems. Ablation results can be seen in Table 3.

### 7.3 Performance on different data sources

As discussed in Section 8, less formal sentences, sentences with misspellings, and sentences with non-standard representations of meaning were the hardest to parse. We ablate the results by domain of origin in Table 4. While the strongest-performing systems tended to perform best across ablations, we note that the machine-translated and informal corpora were overall the hardest sections to parse.

## 8 Qualitative Comparison

In this section we examine some of the sentences that the systems found particularly easy or difficult to parse.

<sup>5</sup>That is, correctly generating a multi-set of instances with the same labels as those in the reference is sufficient for a perfect score. The task of correctly generating instances that are in proper relation to each other is handled by the relations.

## 8.1 Easiest Sentences

The easiest sentence to parse in the eval corpus was the sentence “I was tempted.”<sup>6</sup>

It has a gold AMR of:

```
(t / tempt-01
    :ARG1 (i / i))
```

The mean score for this sentence was 0.977. All submitted systems except one parsed it perfectly.

Another sentence that was quite easy to parse was the sentence “David Cameron is the prime minister of the United Kingdom.”<sup>7</sup> Two systems parsed it perfectly and a third omitted wikification but was otherwise perfect. Figure 3 shows a detailed comparison of each system’s performance on the sentence. In general we see that shorter sentences from the familiar and formal news domain are parsed best by the submitted systems.

## 8.2 Hardest Sentences

Five sentences were unable to be parsed in any way by any system.<sup>8</sup> They are shown below, along with their AMRs:

```
E-mail: mward(at)statesman.com.
(e / email-address-entity
    :value "mward@statesman.com")
x
(s / string-entity :value "x")
*sigh*
(s / sigh-01)
Yes_it_is.
(y / yes)
M E D I A A D V I S O R Y
(a / advise-01
    :ARG1 (m / media))
```

Data noise was another confounding factor. In the next example,<sup>9</sup> which had an average score of 0.17, parsers were confused both by the misspelling (“lie” for “like”) and by the quoted title, which all systems except UCL+Sheffield, tried to parse for meaning.

```

We note that all of these difficult sentences are not conceptually hard for humans to parse. Humans have far less difficulty in resolving errors or processing non-standard tokenization than do computers.

## 9 There Can Be Only One?

We intended to award a single trophy to the single best system, according to the narrow evaluation conditions (balanced F1 via Smatch 2.0.2 with 5 restarts, to two decimal places). However, the top two systems, Brandeis and RIGA, scored identically according to that metric. Hoping to elicit some consistent difference between the systems, we ran Smatch with 20 restarts, looked at four decimal places, and re-ran five times. Each system scored a mean of 0.6214 with standard deviation of 0.00013. We thus capitulate in the face of overwhelming statistics and award the inaugural trophy to both teams, equally.<sup>10</sup>

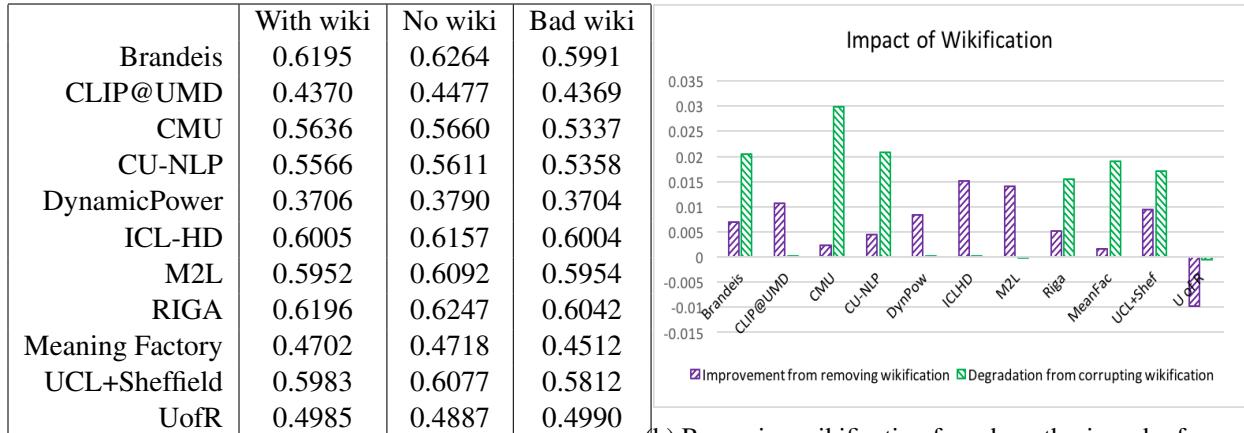

## 10 Conclusion

The results of this competition and the interest in participation in it demonstrate that AMR parsing is a difficult, competitive task. The large number of systems using released code lowered the bar to entry significantly but may have led to a narrowing of diversity in approaches. Low-level irregularities such as creative tokenization and misspellings befuddled the systems. We hope to conduct another AMR parsing competition in the future, in the biomedical domain, and also conduct a generation competition.

<sup>10</sup>Funding for trophies graciously provided by the Jelinek-Mercer Institute for Semantic Translation.

## Abstract

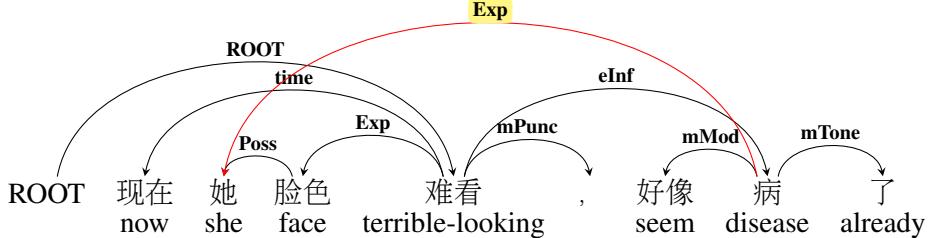

This paper describes the SemEval-2016 Shared Task 9: *Chinese semantic Dependency Parsing*. We extend the traditional tree-structured representation of Chinese sentence to directed acyclic graphs that can capture richer latent semantics, and the goal of this task is to identify such semantic structures from a corpus of Chinese sentences. We provide two distinguished corpora in the NEWS domain with 10,068 sentences and the TEXTBOOKS domain with 14,793 sentences respectively. We will first introduce the motivation for this task, and then present the task in detail including data preparation, data format, task evaluation and so on. At last, we briefly describe the submitted systems and analyze these results.

## 1 Introduction

This task is a rerun of the task 5 at SemEval 2012 (Che et al., 2012), named Chinese semantic dependency parsing (SDP). In the previous task, we aimed at investigating “deep” semantic relations within sentences through tree-structured dependencies. As traditionally defined, syntactic dependency parsing results are connected trees defined over all words of a sentence and language-specific grammatical functions. On the contrary, in semantic dependency parsing, each head-dependent arc instead bears a semantic relation, rather than grammatical relation. In this way, semantic dependency parsing results can be used to answer questions directly, like *who did what to whom when and where*.

However, according to the *meaning-text linguistic theory* (Mel’čuk and Žolkovskij, 1965), a theoretical framework for the description of natural languages, it is said that trees are not sufficient to express the complete meaning of sentences in some cases, which has been proven undoubtedly in our practice of corpus annotation. This time, not only do we refine the easy-to-understand meaning representation in Chinese in order to decrease ambiguity or fuzzy boundary of semantic relations on the basis of Chinese linguistic knowledge, we extend the dependency structure to directed acyclic graphs that conform to the characteristics of Chinese, because Chinese is an parataxis language with flexible word orders, and rich latent information is hidden in facial words.

Figure 1 illustrates an example of semantic dependency graph. Here, “她 (she)” is the argument of “脸色 (face)” and at the same time it is an argument of “病 (disease)”. Researchers in dependency parsing community realized dependency parsing restricted in a tree structure is still too shallow, so they explored semantic information beyond tree structure in task 8 at SemEval 2014 (Oepen et al., 2014) and task 18 at SemEval 2015 (Oepen et al., 2015). They provided data in similar structure with what we are going to provide, but in distinct semantic representation systems. Once again we propose this task to promote research that will lead to deeper understanding of Chinese sentences, and we believe that freely available and well annotated corpora which can be used as common testbed is necessary to promote research in data-driven statistical dependency parsing.

**Figure 1:** An example of our proposed DAG-based semantic dependency representation.

The rest of the paper is organized as follows. Section 2 gives an overview of semantic dependency parsing, with specific focus on the proposed DAG semantic representation. Section 3 describes the technical details of the task. Section 4 presents the participating systems, and Section 5 compares and analyzes the results. Finally, Section 6 concludes the paper.

## 2 Semantic Dependency Parsing

Given a complete sentence, semantic dependency parsing (SDP) aims at determining all the word pairs related to each other semantically and assigning specific predefined semantic relations. Semantic dependency analysis represents the meaning of sentences by a collection of dependency word pairs and their corresponding relations. This procedure survives from syntactic variations.

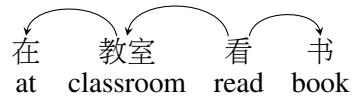

In this paper, we define a Chinese semantic dependency scheme based on Chinese-specific linguistic knowledge, which represents the meaning of sentences in graphic formats (Figure 1).

### 2.1 Structure of Chinese Semantic Dependency Graph

We used semantic dependency graphs to represent the meanings of sentences, which contain dependency relations between all the word pairs with direct semantic relations. Predicates includes most predicative constituents (i.e. most verbs and a small number of nouns and adjectives), and arguments are defined as all the possible participants in the real scene corresponding to a certain predicate (e.g. the eater, food, tool, location, time in the scene related to “eat”). One principle of building dependency arcs is to find arguments for predicates in content words preferentially because they are the ones that related

(a) syntactic dependency

(b) semantic dependency

**Figure 2:** Difference between syntactic and semantic dependency on preposition

to predicates directly. Unlike syntactic dependency, which inserts non-content words between predicate and its “real arguments” (Figure 2). Due to the completeness of the representation of relations between words, some words have relations with more than one other word (some words have more than one child, and some have more than one father), which forms direct acyclic graphs finally. We define a set of labels to describe dependency relations between words.

### 2.2 Semantic Dependency Relations

On the basis of SemEval 2012 task 5, we refined the semantic relation set in terms of more solid Chinese linguistic theories, except for the reference of HowNet (Dong and Dong, 2006), a popular Chinese semantic thesaurus. We mainly referred to the idea of semantic network of Chinese grammar defined by Lu (2001). He adapted semantic network to Chinese, which is the formal network for “semantic composition systems” by distinguishing the hierarchies of “semantic relations”, “semantic alignment” and “semantic orientation”. We borrowed his ideas

of semantic unit classification and semantic combination, and integrated them with the dependency grammar to re-divided boundary for each semantic relation and re-organized the total label set for clarity and definiteness.

Semantic units are divided from high to low into event chains, events, arguments, concepts and markers. Arguments refer to noun phrases related to certain predicates. Concepts are simple elements in basic human thought or content words in syntax. Markers represent the meaning attached to entity information conveyed by speakers (e.g., speakers' tones or moods). These semantic units correspond to compound sentences, simple sentences, chunks, content words and function words. The meaning of sentences is expressed by event chains. Event chains consist of multiple simple sentences. The meaning of simple sentences is expressed by arguments, while arguments are reflected by predicate, referential or defining concepts. Markers are attached to concepts.

The meaning of sentences consists of the meaning of semantic units and their combinations, including semantic relations and attachments. Semantic attachments refer to markers on semantic units. Semantic relations are classified into symmetric and asymmetric types. Symmetric relations include coordination, selection, and equivalence relations, while asymmetric relations include:

Collocational relations occur between core and non-core roles. For example, in “工人 (worker) 修理 (repair) 地下 (pipeline) 管道 (pipeline)” serves as a non-core role, and is the patient of “修理 (repair),” which is a verb and core role. Relations between predicates and nouns belong to collocational relations. Semantic roles usually refer to collocational relations, Table 1 presents the 32 semantic roles we defined, divided into eight small categories. Additional relations refer to the modifying relations among concepts within an argument; all semantic roles are available, e.g. in “地下 (underground) 的 (de) 管道 (pipeline)”, “地下 (underground)” is the modifier of “管道 (pipeline)”, which refers to location relation. Connectional relations are bridging relations between two events that are neither symmetric nor nested relation. For example, for “如果 (If) 天气 (weather) 好 (good) , (,) 我 (I) 就 (will) 去 (go) 故宫 (the Summer Palace),” the former event

is the hypothesis of the latter. Events in Chinese semantic dependency have 15 relations. According to the above classification of sentence hierarchies, we can get to know how each sentence component constitutes the entire meaning of sentences. We design semantic dependency relations in terms of this theoretical basis.

### 2.3 Special Situations

On the analysis of the nature of Chinese language, two special situations need special handling. we list them here and describe their annotation strategies.

- Reverse relations. When a verb modifies a noun, a reverse relation is assigned with the label r-XX (XX refers to a single-level semantic relation). Reverse relation is designed because a word pair with the same semantic relation appears in different sentences with different modifying orders. Reverse relation is used to distinguish them. For example, the verb “打 (play)” modifies the kernel word “男孩 (boy)” in (a) of Figure 3, so r-agent is assigned; while in (b) “打 (play)” is a predicate and “男孩 (boy)” is the agent role with the label agent.
- Nested events. We define another kind of special relation—nested relation to mark that one sentence is degraded as a constituent for another sentence. Two events have a nested relation, i.e., one event is degraded as a grammatical item of the other, which belong to two semantic hierarchies. For example, in the sentence in Figure 4, the event “小 (little) 孙女 (granddaughter) 在 (be) 玩 (play) 电脑 (computer)” is degraded as a content of the action of “看见 (see)”. A prefix “d” is added to single-level semantic relations as distinctive label.

Finally, we got 45 labels to describe relations between main semantic roles and relations within arguments, 19 labels for relations between different predicates. We also defined 17 labels to mark the auxiliary information of predicates. The total semantic relation set is shown in Table 1.

## 3 Task Description

This task contains two tracks, which are closed track and open track. People participating in closed track

| <b>Semantic roles</b>   |   |
|-------------------------|---|
| Subject roles           | Agt(Agent), Exp(Experiencer), Aft(Affection), Poss(Possessor)   |
| Object roles            | Pat(Patient), Cont(Content), Prod(Product), Orig(Origin), Comt(Comitative), Comp(Comparison)  |
| Copula roles            | Belg(Belongings), Clas(Classification), Accd(According)   |
| Cause roles             | Reas(Reason), Int(Intention), Cons(Consequence)   |
| Condition roles         | Mann(Manner), Tool, Matl(material)  |
| Space-time roles        | Time, Loc(Location), Dir(Direction), Proc(Process), Sco(Scope)  |
| Measurement roles       | Quan(Quantity), Qp(Quantity-phrase), Freq(Frequency), Seq(Sequence)   |
| Special attribute roles | Desc(Description), Host, Nmod(Name-modifier), Tmod(Time-modifier)   |
| Reverse relations       | r + semantic roles  |
| Nested relations        | d + semantic roles  |
| <b>Event relations</b>  |   |
| Symmetric relations     | eCoo(Coordination), eSel(tSelection), eEqu(Equivalent)  |
| Consecutive relations   | ePrec(Precedent), eSucc(Successor), eProg(Progression), eCau(Cause), eAdvt(adversative), eResu(Result), eInf(Inference), eCond(Condition), eSupp(Supposition), eConc(Concession), eAban(Abandonment), eMetd(Method), ePurp(Purpose), ePref(Preference), eSum(Summary), eRect(Recount) |
| <b>Semantic markers</b> |   |
| Relation markers        | mConj(Conjunction), mAux(Auxiliary), mPrep(Preposition)   |
| Attachment markers      | mTone, mTime, mRang(Range), mDegr(Degree), mMod(Modal), mFreq(Frequency), mDir(Direction), mPars(Parenthesis), mNeg(Negation)   |
| Auxiliary markers       | mMaj(Majority), mSepa(Separation), mRept(Repetition), mVain, mPunc(Punctuation)   |

Table 1: Label set of the semantic relation of BH-SDP-v2
