# Welcome to SemEval-2016

The Semantic Evaluation (SemEval) series of workshops focuses on the evaluation and comparison of systems that can analyse diverse semantic phenomena in text with the aim of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2016 is the tenth workshop in the series of International Workshops on Semantic Evaluation Exercises. The first three workshops, SensEval-1 (1998), SensEval-2 (2001), and SensEval-3 (2004), focused on word sense disambiguation, each time growing in the number of languages offered, in the number of tasks, and also in the number of participating teams. In 2007, the workshop was renamed to SemEval, and the subsequent SemEval workshops evolved to include semantic analysis tasks beyond word sense disambiguation. In 2012, SemEval turned into a yearly event. It currently runs every year, but on a two-year cycle, i.e., the tasks for SemEval-2016 were proposed in 2015.

SemEval-2016 was co-located with the 2016 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (NAACL-HLT'2016) in San Diego, California. It included the following 14 shared tasks organized in five tracks:

- Text Similarity and Question Answering Track
  - Task 1: Semantic Textual Similarity: A Unified Framework for Semantic Processing and Evaluation
  - Task 2: Interpretable Semantic Textual Similarity
  - Task 3: Community Question Answering
- Sentiment Analysis Track
  - Task 4: Sentiment Analysis in Twitter
  - Task 5: Aspect-Based Sentiment Analysis
  - Task 6: Detecting Stance in Tweets
  - Task 7: Determining Sentiment Intensity of English and Arabic Phrases
- Semantic Parsing Track
  - Task 8: Meaning Representation Parsing
  - Task 9: Chinese Semantic Dependency Parsing
- Semantic Analysis Track
  - Task 10: Detecting Minimal Semantic Units and their Meanings
  - Task 11: Complex Word Identification
  - Task 12: Clinical TempEval

- Semantic Taxonomy Track
  - Task 13: TExEval-2 – Taxonomy Extraction
  - Task 14: Semantic Taxonomy Enrichment

This volume contains both Task Description papers that describe each of the above tasks and System Description papers that describe the systems that participated in the above tasks. A total of 14 task description papers and 198 system description papers are included in this volume.

We are grateful to all task organisers as well as the large number of participants whose enthusiastic participation has made SemEval once again a successful event. We are thankful to the task organisers who also served as area chairs, and to task organisers and participants who reviewed paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. We also thank the NAACL 2016 conference organizers for their support. Finally, we most gratefully acknowledge the support of our sponsor, the ACL Special Interest Group on the Lexicon (SIGLEX).

The SemEval-2016 organizers,  
Steven Bethard, Daniel Cer, Marine Carpuat, David Jurgens, Preslav Nakov and Torsten Zesch

**Organizers:**

Steven Bethard, University of Alabama at Birmingham  
Daniel Cer, Google  
Marine Carpuat, University of Maryland  
David Jurgens, Stanford University  
Preslav Nakov, Qatar Computing Research Institute, HBKU  
Torsten Zesch, University of Duisburg-Essen

## Table of Contents

|   |     |
|---|-----|
| <i>SemEval-2016 Task 4: Sentiment Analysis in Twitter</i>   |     |
| Preslav Nakov, Alan Ritter, Sara Rosenthal, Fabrizio Sebastiani and Veselin Stoyanov .....  | 1   |
| <i>SemEval-2016 Task 5: Aspect Based Sentiment Analysis</i>   |     |
| Maria Pontiki, Dimitris Galanis, Haris Papageorgiou, Ion Androutsopoulos, Suresh Manandhar, Mohammad AL-Smadi, Mahmoud Al-Ayyoub, Yanyan Zhao, Bing Qin, Orphee De Clercq, Veronique Hoste, Marianna Apidianaki, Xavier Tannier, Natalia Loukachevitch, Evgeniy Kotelnikov, Núria Bel, Salud María Jiménez-Zafra and Gülsen Eryiğit ..... | 19  |
| <i>SemEval-2016 Task 6: Detecting Stance in Tweets</i>  |     |
| Saif Mohammad, Svetlana Kiritchenko, Parinaz Sobhani, Xiaodan Zhu and Colin Cherry .....  | 31  |
| <i>SemEval-2016 Task 7: Determining Sentiment Intensity of English and Arabic Phrases</i>   |     |
| Svetlana Kiritchenko, Saif Mohammad and Mohammad Salameh .....  | 42  |
| <i>CUFE at SemEval-2016 Task 4: A Gated Recurrent Model for Sentiment Classification</i>  |     |
| Mahmoud Nabil, Amir Atiya and Mohamed Aly .....   | 52  |
| <i>QCRI at SemEval-2016 Task 4: Probabilistic Methods for Binary and Ordinal Quantification</i>   |     |
| Giovanni Da San Martino, Wei Gao and Fabrizio Sebastiani .....  | 58  |
| <i>SteM at SemEval-2016 Task 4: Applying Active Learning to Improve Sentiment Classification</i>  |     |
| Stefan Räßiger, Mishal Kazmi, Yücel Saygin, Peter Schüller and Myra Spiliopoulou .....  | 64  |
| <i>I2RNTU at SemEval-2016 Task 4: Classifier Fusion for Polarity Classification in Twitter</i>  |     |
| Zhengchen Zhang, Chen Zhang, wu fuxiang, Dongyan Huang, Weisi Lin and Minghui Dong ..   | 71  |
| <i>LyS at SemEval-2016 Task 4: Exploiting Neural Activation Values for Twitter Sentiment Classification and Quantification</i>  |     |
| David Vilares, Yerai Doval, Miguel A. Alonso and Carlos Gómez-Rodríguez .....   | 79  |
| <i>TwiSE at SemEval-2016 Task 4: Twitter Sentiment Classification</i>   |     |
| Georgios Balikas and Massih-Reza Amini .....  | 85  |
| <i>ISTI-CNR at SemEval-2016 Task 4: Quantification on an Ordinal Scale</i>  |     |
| Andrea Esuli .....  | 92  |
| <i>aueb.twitter.sentiment at SemEval-2016 Task 4: A Weighted Ensemble of SVMs for Twitter Sentiment Analysis</i>  |     |
| Stavros Giorgis, Apostolos Rousas, John Pavlopoulos, Prodromos Malakasiotis and Ion Androutsopoulos .....   | 96  |
| <i>thecerealkiller at SemEval-2016 Task 4: Deep Learning based System for Classifying Sentiment of Tweets on Two Point Scale</i>  |     |
| Vikrant Yadav .....   | 100 |

|   |   |     |
|---|---|-----|
| <i>NTNUSentEval at SemEval-2016 Task 4: Combining General Classifiers for Fast Twitter Sentiment Analysis</i>                                   | Brage Ekroll Jahren, Valerij Fredriksen, Björn Gambäck and Lars Bungum.....   | 103 |
| <i>UDLAP at SemEval-2016 Task 4: Sentiment Quantification Using a Graph Based Representation</i>  | Esteban Castillo, Ofelia Cervantes, Darnes Vilariño and David Báez.....   | 109 |
| <i>GTI at SemEval-2016 Task 4: Training a Naive Bayes Classifier using Features of an Unsupervised System</i>                                   | Jonathan Juncal-Martínez, Tamara Álvarez-López, Milagros Fernández-Gavilanes, Enrique Costa-Montenegro and Francisco Javier González-Castaño .....  | 115 |
| <i>Aicyber at SemEval-2016 Task 4: i-vector based sentence representation</i>   | Steven Du and Xi Zhang .....  | 120 |
| <i>SwissCheese at SemEval-2016 Task 4: Sentiment Classification Using an Ensemble of Convolutional Neural Networks with Distant Supervision</i> | Jan Deriu, Maurice Gonzenbach, Fatih Uzdilli, Aurelien Lucchi, Valeria De Luca and Martin Jaggi   | 126 |
| <i>PUT at SemEval-2016 Task 4: The ABC of Twitter Sentiment Analysis</i>  | Mateusz Lango, Dariusz Brzezinski and Jerzy Stefanowski .....   | 131 |
| <i>mib at SemEval-2016 Task 4a: Exploiting lexicon based features for Sentiment Analysis in Twitter</i>   | Vittoria Cozza and Marinella Petrocchi .....  | 138 |
| <i>MDSENT at SemEval-2016 Task 4: A Supervised System for Message Polarity Classification</i>   | Hang Gao and Tim Oates.....   | 144 |
| <i>CICBUAPnlp at SemEval-2016 Task 4-A: Discovering Twitter Polarity using Enhanced Embeddings</i>  | Helena Gomez, Darnes Vilariño, Grigori Sidorov and David Pinto Avendaño .....   | 150 |
| <i>Finki at SemEval-2016 Task 4: Deep Learning Architecture for Twitter Sentiment Analysis</i>  | Dario Stojanovski, Gjorgji Strezoski, Gjorgji Madjarov and Ivica Dimitrovski .....  | 154 |
| <i>Tweester at SemEval-2016 Task 4: Sentiment Analysis in Twitter Using Semantic-Affective Model Adaptation</i>                                 | Elisavet Palogiannidi, Athanasia Kolovou, Fenia Christopoulou, Filippos Kokkinos, Elias Iosif, Nikolaos Malandrakis, Haris Papageorgiou, Shrikanth Narayanan and Alexandros Potamianos .... | 160 |
| <i>UofL at SemEval-2016 Task 4: Multi Domain word2vec for Twitter Sentiment Classification</i>  | Omar Abdelwahab and Adel Elmaghhraby .....  | 169 |
| <i>NRU-HSE at SemEval-2016 Task 4: Comparative Analysis of Two Iterative Methods Using Quantification Library</i>                               | Nikolay Karpov, Alexander Porshnev and Kirill Rudakov.....  | 176 |

|  |  |     |
|--|--|-----|
| <i>INSIGHT-1 at SemEval-2016 Task 4: Convolutional Neural Networks for Sentiment Classification and Quantification</i>                 | Sebastian Ruder, Parsa Ghaffari and John G. Breslin . . . . .  | 183 |
| <i>UNIMELB at SemEval-2016 Tasks 4A and 4B: An Ensemble of Neural Networks and a Word2Vec Based Model for Sentiment Classification</i> | Steven Xu, HuiZhi Liang and Timothy Baldwin . . . . .  | 188 |
| <i>SentiSys at SemEval-2016 Task 4: Feature-Based System for Sentiment Analysis in Twitter</i>   | Hussam Hamdan . . . . .  | 195 |
| <i>DSIC-ELIRF at SemEval-2016 Task 4: Message Polarity Classification in Twitter using a Support Vector Machine Approach</i>           | Victor Martinez Morant, Lluís-F Hurtado and Ferran Pla . . . . .   | 203 |
| <i>SENSEI-LIF at SemEval-2016 Task 4: Polarity embedding fusion for robust sentiment analysis</i>                                      | Mickael Rouvier and Benoit Favre . . . . .   | 207 |
| <i>DiegoLab16 at SemEval-2016 Task 4: Sentiment Analysis in Twitter using Centroids, Clusters, and Sentiment Lexicons</i>              | Abeed Sarker and Graciela Gonzalez . . . . .   | 214 |
| <i>VCU-TSA at Semeval-2016 Task 4: Sentiment Analysis in Twitter</i>   | Gerard Briones, Kasun Amarasinghe and Bridget McInnes . . . . .  | 220 |
| <i>UniPI at SemEval-2016 Task 4: Convolutional Neural Networks for Sentiment Classification</i>  | Giuseppe Attardi and Daniele Sartiano . . . . .  | 225 |
| <i>IIP at SemEval-2016 Task 4: Prioritizing Classes in Ensemble Classification for Sentiment Analysis of Tweets</i>                    | Jasper Friedrichs . . . . .  | 230 |
| <i>PotTS at SemEval-2016 Task 4: Sentiment Analysis of Twitter Using Character-level Convolutional Neural Networks.</i>                | Uladzimir Sidarenka . . . . .  | 235 |
| <i>INESC-ID at SemEval-2016 Task 4-A: Reducing the Problem of Out-of-Embedding Words</i>   | Silvio Amir, Ramón Astudillo, Wang Ling, Mario J. Silva and Isabel Trancoso . . . . .  | 243 |
| <i>SentimentalITsts at SemEval-2016 Task 4: building a Twitter sentiment analyzer in your backyard</i>                                 | Cosmin Florean, Oana Bejenaru, Eduard Apostol, Octavian Ciobanu, Adrian Iftene and Diana Trandabat . . . . .                 | 248 |
| <i>Minions at SemEval-2016 Task 4: or how to build a sentiment analyzer using off-the-shelf resources?</i>                             | Calin-Cristian Ciubotariu, Marius-Valentin Hrisca, Mihail Gliga, Diana Darabana, Diana Trandabat and Adrian Iftene . . . . . | 252 |

|   |  |     |
|---|--|-----|
| <i>YZU-NLP Team at SemEval-2016 Task 4: Ordinal Sentiment Classification Using a Recurrent Convolutional Network</i>  | Yunchao He, Liang-Chih Yu, Chin-Sheng Yang, K. Robert Lai and Weiyi Liu .....  | 256 |
| <i>ECNU at SemEval-2016 Task 4: An Empirical Investigation of Traditional NLP Features and Word Embedding Features for Sentence-level and Topic-level Sentiment Analysis in Twitter</i> | Yunxiao Zhou, Zhihua Zhang and Man Lan .....   | 261 |
| <i>OPAL at SemEval-2016 Task 4: the Challenge of Porting a Sentiment Analysis System to the "Real" World</i>  | Alexandra Balahur.....   | 267 |
| <i>Know-Center at SemEval-2016 Task 5: Using Word Vectors with Typed Dependencies for Opinion Target Expression Extraction</i>  | Stefan Falk, Andi Rexha and Roman Kern .....   | 271 |
| <i>NileTMRG at SemEval-2016 Task 5: Deep Convolutional Neural Networks for Aspect Category and Sentiment Extraction</i>   | Talaat Khalil and Samhaa R. El-Beltagy .....   | 276 |
| <i>XRCE at SemEval-2016 Task 5: Feedbacked Ensemble Modeling on Syntactico-Semantic Knowledge for Aspect Based Sentiment Analysis</i>   | Caroline Brun, Julien Perez and Claude Roux .....  | 282 |
| <i>NLANGP at SemEval-2016 Task 5: Improving Aspect Based Sentiment Analysis using Neural Network Features</i>   | Zhiqiang Toh and Jian Su .....   | 287 |
| <i>bunji at SemEval-2016 Task 5: Neural and Syntactic Models of Entity-Attribute Relationship for Aspect-based Sentiment Analysis</i>   | Toshihiko Yanase, Kohsuke Yanai, Misa Sato, Toshinori Miyoshi and Yoshiki Niwa .....   | 294 |
| <i>IHS-RD-Belarus at SemEval-2016 Task 5: Detecting Sentiment Polarity Using the Heatmap of Sentence</i>  | Maryna Chernyshevich.....  | 301 |
| <i>BUTknot at SemEval-2016 Task 5: Supervised Machine Learning with Term Substitution Approach in Aspect Category Detection</i>   | Jakub Machacek .....   | 306 |
| <i>IIT-TUDA at SemEval-2016 Task 5: Beyond Sentiment Lexicon: Combining Domain Dependency and Distributional Semantics Features for Aspect Based Sentiment Analysis</i>                 | Ayush Kumar, Sarah Kohail, Amit Kumar, Asif Ekbal and Chris Biemann .....  | 311 |
| <i>GTI at SemEval-2016 Task 5: SVM and CRF for Aspect Detection and Unsupervised Aspect-Based Sentiment Analysis</i>  | Tamara Álvarez-López, Jonathan Juncal-Martínez, Milagros Fernández-Gavilanes, Enrique Costa-Montenegro and Francisco Javier González-Castaño ..... | 318 |

|   |     |
|---|-----|
| <i>AUEB-ABSA at SemEval-2016 Task 5: Ensembles of Classifiers and Embeddings for Aspect Based Sentiment Analysis</i>                                  |     |
| Dionysios Xenos, Panagiotis Theodorakakos, John Pavlopoulos, Prodromos Malakasiotis and Ion Androutsopoulos .....                                     | 324 |

| <i>RTM at SemEval-2016 Task 1: Predicting Semantic Similarity with Referential Translation Machines and Related Statistics</i>                                       |      |
| Ergun Bicici .....   | 1327 |
| <i>DalGTM at SemEval-2016 Task 1: Importance-Aware Compositional Approach to Short Text Similarity</i>   |      |
| Jie Mei, Aminul Islam and Evangelos Milios .....   | 1334 |

# Workshop Program

**16 Jun 2016**

**09:00–09:15 Welcome**

*Opening Remarks*  
SemEval organizers

**09:15–10:30 Sentiment Analysis**

09:15–09:30 *SemEval-2016 Task 4: Sentiment Analysis in Twitter*  
Preslav Nakov, Alan Ritter, Sara Rosenthal, Fabrizio Sebastiani and Veselin Stoyanov

09:30–09:45 *SemEval-2016 Task 5: Aspect Based Sentiment Analysis*

Maria Pontiki, Dimitris Galanis, Haris Papageorgiou, Ion Androutsopoulos, Suresh Manandhar, Mohammad AL-Smadi, Mahmoud Al-Ayyoub, Yanyan Zhao, Bing Qin, Orphee De Clercq, Veronique Hoste, Marianna Apidianaki, Xavier Tannier, Natalia Loukachevitch, Evgeniy Kotelnikov, Núria Bel, Salud María Jiménez-Zafra and Gülsen Eryiğit

09:45–10:00 *SemEval-2016 Task 6: Detecting Stance in Tweets*

Saif Mohammad, Svetlana Kiritchenko, Parinaz Sobhani, Xiaodan Zhu and Colin Cherry

10:00–10:15 *SemEval-2016 Task 7: Determining Sentiment Intensity of English and Arabic Phrases*

Svetlana Kiritchenko, Saif Mohammad and Mohammad Salameh

10:15–10:30 *Sentiment Analysis Discussion*

Task Organizers

**10:30–11:00 Coffee Break**

## 16 Jun 2016 (continued)

### 11:00–12:30 Poster Session: Sentiment Analysis

*CUFE at SemEval-2016 Task 4: A Gated Recurrent Model for Sentiment Classification*

Mahmoud Nabil, Amir Atiya and Mohamed Aly

*QCRI at SemEval-2016 Task 4: Probabilistic Methods for Binary and Ordinal Quantification*

Giovanni Da San Martino, Wei Gao and Fabrizio Sebastiani

*SteM at SemEval-2016 Task 4: Applying Active Learning to Improve Sentiment Classification*

Stefan Räßiger, Mishal Kazmi, Yücel Saygin, Peter Schüller and Myra Spiliopoulou

*I2RNTU at SemEval-2016 Task 4: Classifier Fusion for Polarity Classification in Twitter*

Zhengchen Zhang, Chen Zhang, Wu Fuxiang, Dongyan Huang, Weisi Lin and Minghui Dong

*LyS at SemEval-2016 Task 4: Exploiting Neural Activation Values for Twitter Sentiment Classification and Quantification*

David Vilares, Yerai Doval, Miguel A. Alonso and Carlos Gómez-Rodríguez

*TwiSE at SemEval-2016 Task 4: Twitter Sentiment Classification*

Georgios Balikas and Massih-Reza Amini

*ISTI-CNR at SemEval-2016 Task 4: Quantification on an Ordinal Scale*

Andrea Esuli

*aueb.twitter.sentiment at SemEval-2016 Task 4: A Weighted Ensemble of SVMs for Twitter Sentiment Analysis*

Stavros Giorgis, Apostolos Rousas, John Pavlopoulos, Prodromos Malakasiotis and Ion Androutsopoulos

*thecerealkiller at SemEval-2016 Task 4: Deep Learning based System for Classifying Sentiment of Tweets on Two Point Scale*

Vikrant Yadav

*NTNUSentEval at SemEval-2016 Task 4: Combining General Classifiers for Fast Twitter Sentiment Analysis*

Brage Ekroll Jahren, Valerij Fredriksen, Björn Gambäck and Lars Bungum

*UDLAP at SemEval-2016 Task 4: Sentiment Quantification Using a Graph Based Representation*

Esteban Castillo, Ofelia Cervantes, Darnes Vilariño and David Báez

*GTI at SemEval-2016 Task 4: Training a Naive Bayes Classifier using Features of an Unsupervised System*

Jonathan Juncal-Martínez, Tamara Álvarez-López, Milagros Fernández-Gavilanes, Enrique Costa-Montenegro and Francisco Javier González-Castaño

*Aicyber at SemEval-2016 Task 4: i-vector based sentence representation*

Steven Du and Xi Zhang

*SwissCheese at SemEval-2016 Task 4: Sentiment Classification Using an Ensemble of Convolutional Neural Networks with Distant Supervision*

Jan Deriu, Maurice Gonzenbach, Fatih Uzdilli, Aurelien Lucchi, Valeria De Luca and Martin Jaggi

*PUT at SemEval-2016 Task 4: The ABC of Twitter Sentiment Analysis*

Mateusz Lango, Dariusz Brzezinski and Jerzy Stefanowski

*mib at SemEval-2016 Task 4a: Exploiting lexicon based features for Sentiment Analysis in Twitter*

Vittoria Cozza and Marinella Petrocchi

*MDSENT at SemEval-2016 Task 4: A Supervised System for Message Polarity Classification*

Hang Gao and Tim Oates

*CICBUAPnlp at SemEval-2016 Task 4-A: Discovering Twitter Polarity using Enhanced Embeddings*

Helena Gomez, Darnes Vilariño, Grigori Sidorov and David Pinto Avendaño

*Finki at SemEval-2016 Task 4: Deep Learning Architecture for Twitter Sentiment Analysis*

Dario Stojanovski, Gjorgji Strezoski, Gjorgji Madjarov and Ivica Dimitrovski

*Tweester at SemEval-2016 Task 4: Sentiment Analysis in Twitter Using Semantic-Affective Model Adaptation*

Elisavet Palogiannidi, Athanasia Kolovou, Fenia Christopoulou, Filippos Kokkinos, Elias Iosif, Nikolaos Malandrakis, Haris Papageorgiou, Shrikanth Narayanan and Alexandros Potamianos

*UofL at SemEval-2016 Task 4: Multi Domain word2vec for Twitter Sentiment Classification*

Omar Abdelwahab and Adel Elmaghreby

## 16 Jun 2016 (continued)

*NRU-HSE at SemEval-2016 Task 4: Comparative Analysis of Two Iterative Methods Using Quantification Library*

Nikolay Karpov, Alexander Porshnev and Kirill Rudakov

*INSIGHT-1 at SemEval-2016 Task 4: Convolutional Neural Networks for Sentiment Classification and Quantification*

Sebastian Ruder, Parsa Ghaffari and John G. Breslin

*UNIMELB at SemEval-2016 Tasks 4A and 4B: An Ensemble of Neural Networks and a Word2Vec Based Model for Sentiment Classification*

Steven Xu, HuiZhi Liang and Timothy Baldwin

*SentiSys at SemEval-2016 Task 4: Feature-Based System for Sentiment Analysis in Twitter*

Hussam Hamdan

*DSIC-ELIRF at SemEval-2016 Task 4: Message Polarity Classification in Twitter using a Support Vector Machine Approach*

Victor Martinez Morant, Lluís-F Hurtado and Ferran Pla

*SENSEI-LIF at SemEval-2016 Task 4: Polarity embedding fusion for robust sentiment analysis*

Mickael Rouvier and Benoit Favre

*DiegoLab16 at SemEval-2016 Task 4: Sentiment Analysis in Twitter using Centroids, Clusters, and Sentiment Lexicons*

Abeed Sarker and Graciela Gonzalez

*VCU-TSA at Semeval-2016 Task 4: Sentiment Analysis in Twitter*

Gerard Briones, Kasun Amarasinghe and Bridget McInnes

*UniPI at SemEval-2016 Task 4: Convolutional Neural Networks for Sentiment Classification*

Giuseppe Attardi and Daniele Sartiano

*IIP at SemEval-2016 Task 4: Prioritizing Classes in Ensemble Classification for Sentiment Analysis of Tweets*

Jasper Friedrichs

*PoTS at SemEval-2016 Task 4: Sentiment Analysis of Twitter Using Character-level Convolutional Neural Networks.*

Uladzimir Sidarenka

*INESC-ID at SemEval-2016 Task 4-A: Reducing the Problem of Out-of-Embedding Words*

Silvio Amir, Ramón Astudillo, Wang Ling, Mario J. Silva and Isabel Trancoso

## **16 Jun 2016 (continued)**

*SentimentITsts at SemEval-2016 Task 4: building a Twitter sentiment analyzer in your backyard*

Cosmin Florean, Oana Bejenaru, Eduard Apostol, Octavian Ciobanu, Adrian Iftene and Diana Trandabat

*Minions at SemEval-2016 Task 4: or how to build a sentiment analyzer using off-the-shelf resources?*

Calin-Cristian Ciubotariu, Marius-Valentin Hrisca, Mihail Gliga, Diana Darabana, Diana Trandabat and Adrian Iftene

*YZU-NLP Team at SemEval-2016 Task 4: Ordinal Sentiment Classification Using a Recurrent Convolutional Network*

Yunchao He, Liang-Chih Yu, Chin-Sheng Yang, K. Robert Lai and Weiyi Liu

*ECNU at SemEval-2016 Task 4: An Empirical Investigation of Traditional NLP Features and Word Embedding Features for Sentence-level and Topic-level Sentiment Analysis in Twitter*

Yunxiao Zhou, Zhihua Zhang and Man Lan

*OPAL at SemEval-2016 Task 4: the Challenge of Porting a Sentiment Analysis System to the "Real" World*

Alexandra Balahur

*Know-Center at SemEval-2016 Task 5: Using Word Vectors with Typed Dependencies for Opinion Target Expression Extraction*

Stefan Falk, Andi Rexha and Roman Kern

*NileTMRG at SemEval-2016 Task 5: Deep Convolutional Neural Networks for Aspect Category and Sentiment Extraction*

Talaat Khalil and Samhaa R. El-Beltagy

*XRCE at SemEval-2016 Task 5: Feedbacked Ensemble Modeling on Syntactico-Semantic Knowledge for Aspect Based Sentiment Analysis*

Caroline Brun, Julien Perez and Claude Roux

*NLANGP at SemEval-2016 Task 5: Improving Aspect Based Sentiment Analysis using Neural Network Features*

Zhiqiang Toh and Jian Su

*bunji at SemEval-2016 Task 5: Neural and Syntactic Models of Entity-Attribute Relationship for Aspect-based Sentiment Analysis*

Toshihiko Yanase, Kohsuke Yanai, Misa Sato, Toshinori Miyoshi and Yoshiki Niwa

*IHS-RD-Belarus at SemEval-2016 Task 5: Detecting Sentiment Polarity Using the Heatmap of Sentence*

Maryna Chernyshevich

**16 Jun 2016 (continued)**

*BUTknot at SemEval-2016 Task 5: Supervised Machine Learning with Term Substitution Approach in Aspect Category Detection*

Jakub Machacek

*IIT-TUDA at SemEval-2016 Task 5: Beyond Sentiment Lexicon: Combining Domain Dependency and Distributional Semantics Features for Aspect Based Sentiment Analysis*

Ayush Kumar, Sarah Kohail, Amit Kumar, Asif Ekbal and Chris Biemann

*GTI at SemEval-2016 Task 5: SVM and CRF for Aspect Detection and Unsupervised Aspect-Based Sentiment Analysis*

Tamara Álvarez-López, Jonathan Juncal-Martínez, Milagros Fernández-Gavilanes, Enrique Costa-Montenegro and Francisco Javier González-Castaño

*AUEB-ABSA at SemEval-2016 Task 5: Ensembles of Classifiers and Embeddings for Aspect Based Sentiment Analysis*

Dionysios Xenos, Panagiotis Theodorakakos, John Pavlopoulos, Prodromos Malakasiotis and Ion Androutsopoulos

*AKTSKI at SemEval-2016 Task 5: Aspect Based Sentiment Analysis for Consumer Reviews*

Shubham Pateria and Prafulla Choubey

*MayAnd at SemEval-2016 Task 5: Syntactic and word2vec-based approach to aspect-based polarity detection in Russian*

Vladimir Mayorov and Ivan Andrianov

*INSIGHT-1 at SemEval-2016 Task 5: Deep Learning for Multilingual Aspect-based Sentiment Analysis*

Sebastian Ruder, Parsa Ghaffari and John G. Breslin

*TGB at SemEval-2016 Task 5: Multi-Lingual Constraint System for Aspect Based Sentiment Analysis*

Fatih Samet Çetin, Ezgi Yıldırım, Can Özbeý and Gülsen Eryiğit

*UWB at SemEval-2016 Task 5: Aspect Based Sentiment Analysis*

Tomáš Hercig, Tomáš Brychcín, Lukáš Svoboda and Michal Konkol

*SentiSys at SemEval-2016 Task 5: Opinion Target Extraction and Sentiment Polarity Detection*

Hussam Hamdan

*COMMIT at SemEval-2016 Task 5: Sentiment Analysis with Rhetorical Structure Theory*

Kim Schouten and Flavius Frasincar

**16 Jun 2016 (continued)**

*ECNU at SemEval-2016 Task 5: Extracting Effective Features from Relevant Fragments in Sentence for Aspect-Based Sentiment Analysis in Reviews*  
Mengxiao Jiang, Zhihua Zhang and Man Lan

*UFAL at SemEval-2016 Task 5: Recurrent Neural Networks for Sentence Classification*  
Aleš Tamchyna and Kateřina Veselovská

*UWaterloo at SemEval-2016 Task 5: Minimally Supervised Approaches to Aspect-Based Sentiment Analysis*  
Olga Vechtomova and Anni He

*INF-UFRGS-OPINION-MINING at SemEval-2016 Task 6: Automatic Generation of a Training Corpus for Unsupervised Identification of Stance in Tweets*  
Marcelo Dias and Karin Becker

*pkudblab at SemEval-2016 Task 6 : A Specific Convolutional Neural Network System for Effective Stance Detection*  
Wan Wei, Xiao Zhang, Xuqin Liu, Wei Chen and Tengjiao Wang

*USFD at SemEval-2016 Task 6: Any-Target Stance Detection on Twitter with Autoencoders*  
Isabelle Augenstein, Andreas Vlachos and Kalina Bontcheva

*IUCL at SemEval-2016 Task 6: An Ensemble Model for Stance Detection in Twitter*  
Can Liu, Wen Li, Bradford Demarest, Yue Chen, Sara Couture, Daniel Dakota, Nikita Haduong, Noah Kaufman, Andrew Lamont, Manan Pancholi, Kenneth Steimel and Sandra Kübler

*Tohoku at SemEval-2016 Task 6: Feature-based Model versus Convolutional Neural Network for Stance Detection*  
Yuki Igarashi, Hiroya Komatsu, Sosuke Kobayashi, Naoaki Okazaki and Kentaro Inui

*UWB at SemEval-2016 Task 6: Stance Detection*  
Peter Krejzl and Josef Steinberger

*DeepStance at SemEval-2016 Task 6: Detecting Stance in Tweets Using Character and Word-Level CNNs*  
Prashanth Vijayaraghavan, Ivan Sysoev, Soroush Vosoughi and Deb Roy

*NLDS-UCSC at SemEval-2016 Task 6: A Semi-Supervised Approach to Detecting Stance in Tweets*  
Amita Misra, Brian Ecker, Theodore Handleman, Nicolas Hahn and Marilyn Walker

## **16 Jun 2016 (continued)**

*ttl.uni-due at SemEval-2016 Task 6: Stance Detection in Social Media Using Stacked Classifiers*

Michael Wojatzki and Torsten Zesch

*CU-GWU Perspective at SemEval-2016 Task 6: Ideological Stance Detection in Informal Text*

Heba Elfardy and Mona Diab

*JU\_NLP at SemEval-2016 Task 6: Detecting Stance in Tweets using Support Vector Machines*

Braja Gopal Patra, Dipankar Das and Sivaji Bandyopadhyay

*IDI@NTNU at SemEval-2016 Task 6: Detecting Stance in Tweets Using Shallow Features and GloVe Vectors for Word Representation*

Henrik Bøhler, Petter Asla, Erwin Marsi and Rune Sætre

*ECNU at SemEval 2016 Task 6: Relevant or Not? Supportive or Not? A Two-step Learning System for Automatic Detecting Stance in Tweets*

Zhihua Zhang and Man Lan

*MITRE at SemEval-2016 Task 6: Transfer Learning for Stance Detection*

Guido Zarrella and Amy Marsh

*TakeLab at SemEval-2016 Task 6: Stance Classification in Tweets Using a Genetic Algorithm Based Ensemble*

Martin Tutek, Ivan Sekulic, Paula Gombar, Ivan Paljak, Filip Culinovic, Filip Boltuzic, Mladen Karan, Domagoj Alagić and Jan Šnajder

*LSIS at SemEval-2016 Task 7: Using Web Search Engines for English and Arabic Unsupervised Sentiment Intensity Prediction*

Amal Htait, Sébastien Fournier and Patrice Bellot

*iLab-Edinburgh at SemEval-2016 Task 7: A Hybrid Approach for Determining Sentiment Intensity of Arabic Twitter Phrases*

Eshrag Refae and Verena Rieser

*UWB at SemEval-2016 Task 7: Novel Method for Automatic Sentiment Intensity Determination*

Ladislav Lenc, Pavel Král and Václav Rajtmajer

*NileTMRG at SemEval-2016 Task 7: Deriving Prior Polarities for Arabic Sentiment Terms*

Samhaa R. El-Beltagy

## **16 Jun 2016 (continued)**

*ECNU at SemEval-2016 Task 7: An Enhanced Supervised Learning Method for Lexicon Sentiment Intensity Ranking*  
Feixiang Wang, Zhihua Zhang and Man Lan

**12:30–02:00    *Lunch***

**02:00–03:30    *Textual Similarity, Question Answering and Semantic Analysis***

02:15–02:30    *SemEval-2016 Task 2: Interpretable Semantic Textual Similarity*  
Eneko Agirre, Aitor Gonzalez-Agirre, Iñigo Lopez-Gazpio, Montse Maritxalar, German Rigau and Larraitz Uria

02:30–02:45    *SemEval-2016 Task 3: Community Question Answering*  
Preslav Nakov, Lluís Márquez, Alessandro Moschitti, Walid Magdy, Hamdy Mubarak, abed Alhakim Freihat, Jim Glass and Bilal Randeree

02:45–03:00    *SemEval-2016 Task 10: Detecting Minimal Semantic Units and their Meanings (DiMSUM)*  
Nathan Schneider, Dirk Hovy, Anders Johannsen and Marine Carpuat

03:00–03:15    *SemEval 2016 Task 11: Complex Word Identification*  
Gustavo Paetzold and Lucia Specia

03:15–03:30    *Textual Similarity and Question Answering Discussion*  
Task Organizers

**03:30–04:00    *Coffee Break***

## **16 Jun 2016 (continued)**

### **04:00–05:30 Poster Session: Textual Similarity, and Question Answering**

*FBK HLT-MT at SemEval-2016 Task 1: Cross-lingual Semantic Similarity Measurement Using Quality Estimation Features and Compositional Bilingual Word Embeddings*

Duygu Ataman, Jose G. C. De Souza, Marco Turchi and Matteo Negri

*VRep at SemEval-2016 Task 1 and Task 2: A System for Interpretable Semantic Similarity*

Sam Henry and Allison Sands

*UTA DLNLP at SemEval-2016 Task 1: Semantic Textual Similarity: A Unified Framework for Semantic Processing and Evaluation*

Peng Li and Heng Huang

*UWB at SemEval-2016 Task 1: Semantic Textual Similarity using Lexical, Syntactic, and Semantic Information*

Tomáš Brychcín and Lukáš Svoboda

*HHU at SemEval-2016 Task 1: Multiple Approaches to Measuring Semantic Textual Similarity*

Matthias Liebeck, Philipp Pollack, Pashutan Modaresi and Stefan Conrad

*Samsung Poland NLP Team at SemEval-2016 Task 1: Necessity for diversity; combining recursive autoencoders, WordNet and ensemble methods to measure semantic similarity.*

Barbara Rychalska, Katarzyna Pakulska, Krystyna Chodorowska, Wojciech Walczak and Piotr Andruszkiewicz

*USFD at SemEval-2016 Task 1: Putting different State-of-the-Arts into a Box*

Ahmet Aker, Frederic Blain, Andres Duque, Marina Fomicheva, Jurica Seva and Kashif Shah

*NaCTeM at SemEval-2016 Task 1: Inferring sentence-level semantic similarity from an ensemble of complementary lexical and sentence-level features*

Piotr Przybyła, Nhungh T. H. Nguyen, Matthew Shardlow, Georgios Kontonatsios and Sophia Ananiadou

*ECNU at SemEval-2016 Task 1: Leveraging Word Embedding From Macro and Micro Views to Boost Performance for Semantic Textual Similarity*

Junfeng Tian and Man Lan

## **16 Jun 2016 (continued)**

*SAARSHEFF at SemEval-2016 Task 1: Semantic Textual Similarity with Machine Translation Evaluation Metrics and (eXtreme) Boosted Tree Ensembles*  
Liling Tan, Carolina Scarton, Lucia Specia and Josef van Genabith

*WOLVESaar at SemEval-2016 Task 1: Replicating the Success of Monolingual Word Alignment and Neural Embeddings for Semantic Textual Similarity*  
Hannah Bechara, Rohit Gupta, Liling Tan, Constantin Orasan, Ruslan Mitkov and Josef van Genabith

*DTSim at SemEval-2016 Task 1: Semantic Similarity Model Including Multi-Level Alignment and Vector-Based Compositional Semantics*  
Rajendra Banjade, Nabin Maharjan, Dipesh Gautam and Vasile Rus

*ISCAS\_NLP at SemEval-2016 Task 1: Sentence Similarity Based on Support Vector Regression using Multiple Features*  
Cheng Fu, Bo An, Xianpei Han and Le Sun

*UMD-TTIC-UW at SemEval-2016 Task 1: Attention-Based Multi-Perspective Convolutional Neural Networks for Textual Similarity Measurement*  
Hua He, John Wieting, Kevin Gimpel, Jinfeng Rao and Jimmy Lin

*DLS@CU at SemEval-2016 Task 1: Supervised Models of Sentence Similarity*  
Md Arafat Sultan, Steven Bethard and Tamara Sumner

*DCU-SEManiacs at SemEval-2016 Task 1: Synthetic Paragraph Embeddings for Semantic Textual Similarity*  
Chris Hokamp and Piyush Arora

*iUBC at SemEval-2016 Task 2: RNNs and LSTMs for interpretable STS*  
Inigo Lopez-Gazpio, Eneko Agirre and Montse Maritxalar

*Rev at SemEval-2016 Task 2: Aligning Chunks by Lexical, Part of Speech and Semantic Equivalence*  
ping tan, Karin Verspoor and Timothy Miller

*Inspire at SemEval-2016 Task 2: Interpretable Semantic Textual Similarity Alignment based on Answer Set Programming*  
Mishal Kazmi and Peter Schüller

*FBK-HLT-NLP at SemEval-2016 Task 2: A Multitask, Deep Learning Approach for Interpretable Semantic Textual Similarity*  
Simone Magnolini, Anna Feltracco and Bernardo Magnini

**16 Jun 2016 (continued)**

*IISCNLP at SemEval-2016 Task 2: Interpretable STS with ILP based Multiple Chunk Aligner*

Lavanya Tekumalla and Sharmistha Jat

*VENSEEVAL at Semeval-2016 Task 2 iSTS - with a full-fledged rule-based approach*

Rodolfo Delmonte

*UWB at SemEval-2016 Task 2: Interpretable Semantic Textual Similarity with Distributional Semantics for Chunks*

Miloslav Konopik, Ondrej Prazak, David Steinberger and Tomáš Brychcín

*DTSim at SemEval-2016 Task 2: Interpreting Similarity of Texts Based on Automated Chunking, Chunk Alignment and Semantic Relation Prediction*

Rajendra Banjade, Nabin Maharjan, Nobal Bikram Niraula and Vasile Rus

*UH-PRHLT at SemEval-2016 Task 3: Combining Lexical and Semantic-based Features for Community Question Answering*

Marc Franco-Salvador, Sudipta Kar, Thamar Solorio and Paolo Rosso

*RDI\_Team at SemEval-2016 Task 3: RDI Unsupervised Framework for Text Ranking*

Ahmed Magooda, Amr Gomaa, Ashraf Mahgoub, Hany Ahmed, Mohsen Rashwan, Hazem Raafat, Eslam Kamal and Ahmad Al Sallab

*KeLP at SemEval-2016 Task 3: Learning Semantic Relations between Questions and Answers*

Simone Filice, Danilo Croce, Alessandro Moschitti and Roberto Basili

*SLS at SemEval-2016 Task 3: Neural-based Approaches for Ranking in Community Question Answering*

Mitra Mohtarami, Yonatan Belinkov, Wei-Ning Hsu, Yu Zhang, Tao Lei, Kfir Bar, Scott Cyphers and Jim Glass

*SUPER Team at SemEval-2016 Task 3: Building a Feature-Rich System for Community Question Answering*

Tsvetomila Mihaylova, Pepa Gencheva, Martin Boyanov, Ivana Yovcheva, Todor Mihaylov, Momchil Hardalov, Yasen Kiprov, Daniel Balchev, Ivan Koychev, Preslav Nakov, Ivelina Nikolova and Galia Angelova

*PMI-cool at SemEval-2016 Task 3: Experiments with PMI and Goodness Polarity Lexicons for Community Question Answering*

Daniel Balchev, Yasen Kiprov, Ivan Koychev and Preslav Nakov

## **16 Jun 2016 (continued)**

*UniMelb at SemEval-2016 Task 3: Identifying Similar Questions by combining a CNN with String Similarity Measures*

Timothy Baldwin, Huizhi Liang, Bahar Salehi, Doris Hoogeveen, Yitong Li and Long Duong

*ICL00 at SemEval-2016 Task 3: Translation-Based Method for CQA System*

Yunfang Wu and Minghua Zhang

*Overfitting at SemEval-2016 Task 3: Detecting Semantically Similar Questions in Community Question Answering Forums with Word Embeddings*

Hujie Wang and Pascal Poupart

*QU-IR at SemEval 2016 Task 3: Learning to Rank on Arabic Community Question Answering Forums with Word Embedding*

Rana Malhas, Marwan Torki and Tamer Elsayed

*ECNU at SemEval-2016 Task 3: Exploring Traditional Method and Deep Learning Method for Question Retrieval and Answer Ranking in Community Question Answering*

Guoshun Wu and Man Lan

*SemanticZ at SemEval-2016 Task 3: Ranking Relevant Answers in Community Question Answering Using Semantic Similarity Based on Fine-tuned Word Embeddings*

Todor Mihaylov and Preslav Nakov

*MTE-NN at SemEval-2016 Task 3: Can Machine Translation Evaluation Help Community Question Answering?*

Francisco Guzmán, Preslav Nakov and Lluís Màrquez

*ConvKN at SemEval-2016 Task 3: Answer and Question Selection for Question Answering on Arabic and English Fora*

Alberto Barrón-Cedeño, Giovanni Da San Martino, Shafiq Joty, Alessandro Moschitti, Fahad Al-Obaidli, Salvatore Romeo, Kateryna Tymoshenko and Antonio Uva

*ITNLP-AiKF at SemEval-2016 Task 3 a question answering system using community QA repository*

Chang e Jia

*UFRGS&LIF at SemEval-2016 Task 10: Rule-Based MWE Identification and Predominant-Supersense Tagging*

Silvio Cordeiro, Carlos Ramisch and Aline Villavicencio

## **16 Jun 2016 (continued)**

*WHUNlp at SemEval-2016 Task DiMSUM: A Pilot Study in Detecting Minimal Semantic Units and their Meanings using Supervised Models*  
Xin Tang, Fei Li and Donghong Ji

*UTU at SemEval-2016 Task 10: Binary Classification for Expression Detection (BCED)*  
Jari Björne and Tapani Salakoski

*UW-CSE at SemEval-2016 Task 10: Detecting Multiword Expressions and Supersenses using Double-Chained Conditional Random Fields*  
Mohammad Javad Hosseini, Noah A. Smith and Su-In Lee

*ICL-HD at SemEval-2016 Task 10: Improving the Detection of Minimal Semantic Units and their Meanings with an Ontology and Word Embeddings*  
Angelika Kirilin, Felix Krauss and Yannick Versley

*VectorWeavers at SemEval-2016 Task 10: From Incremental Meaning to Semantic Unit (phrase by phrase)*  
Andreas Scherbakov, Ekaterina Vylomova, Fei Liu and Timothy Baldwin

*PLUJAGH at SemEval-2016 Task 11: Simple System for Complex Word Identification*  
Krzysztof Wróbel

*USAAR at SemEval-2016 Task 11: Complex Word Identification with Sense Entropy and Sentence Perplexity*  
José Manuel Martínez Martínez and Liling Tan

*Sensible at SemEval-2016 Task 11: Neural Nonsense Mangled in Ensemble Mess*  
Gillin Nat

*SV000gg at SemEval-2016 Task 11: Heavy Gauge Complex Word Identification with System Voting*  
Gustavo Paetzold and Lucia Specia

*Melbourne at SemEval 2016 Task 11: Classifying Type-level Word Complexity using Random Forests with Corpus and Word List Features*  
Julian Brooke, Alexandra Uitdenbogerd and Timothy Baldwin

*CLaC at SemEval-2016 Task 11: Exploring linguistic and psycho-linguistic Features for Complex Word Identification*  
Elnaz Davoodi and Leila Kosseim

**16 Jun 2016 (continued)**

*JU\_NLP at SemEval-2016 Task 11: Identifying Complex Words in a Sentence*  
Niloy Mukherjee, Braja Gopal Patra, Dipankar Das and Sivaji Bandyopadhyay

*MAZA at SemEval-2016 Task 11: Detecting Lexical Complexity Using a Decision Stump Meta-Classifier*  
Shervin Malmasi and Marcos Zampieri

*LTG at SemEval-2016 Task 11: Complex Word Identification with Classifier Ensembles*  
Shervin Malmasi, Mark Dras and Marcos Zampieri

*MacSaar at SemEval-2016 Task 11: Zipfian and Character Features for Complex-Word Identification*  
Marcos Zampieri, Liling Tan and Josef van Genabith

*Garuda & Bhasha at SemEval-2016 Task 11: Complex Word Identification Using Aggregated Learning Models*  
Prafulla Choube and Shubham Pateria

*TALN at SemEval-2016 Task 11: Modelling Complex Words by Contextual, Lexical and Semantic Features*  
Francesco Ronzano, Ahmed Abura'ed, Luis Espinosa Anke and Horacio Saggion

*IIT at SemEval-2016 Task 11: Complex Word Identification using Nearest Centroid Classification*  
Ashish Palakurthi and Radhika Mamidi

*AmritaCEN at SemEval-2016 Task 11: Complex Word Identification using Word Embedding*  
sanjay sp, Anand Kumar and Soman K P

*CoastalCPH at SemEval-2016 Task 11: The importance of designing your Neural Networks right*  
Joachim Bingel, Natalie Schluter and Héctor Martínez Alonso

*HMC at SemEval-2016 Task 11: Identifying Complex Words Using Depth-limited Decision Trees*  
Maury Quijada and Julie Medero

*UWB at SemEval-2016 Task 11: Exploring Features for Complex Word Identification*  
Michał Konkol

*AI-KU at SemEval-2016 Task 11: Word Embeddings and Substring Features for Complex Word Identification*  
Onur Kuru

## **16 Jun 2016 (continued)**

*Pomona at SemEval-2016 Task 11: Predicting Word Complexity Based on Corpus Frequency*  
David Kauchak

## **17 Jul 2016**

### **09:00–10:30 Perspectives**

09:00–09:30 *SemEval-2017 Preview*  
SemEval organizers

### **09:30–10:30 Invited Talk**

### **10:30–11:00 Coffee Break**

### **11:00–12:30 Semantic Analysis, Semantic Parsing and Semantic Taxonomy**

11:00–11:15 *SemEval-2016 Task 12: Clinical TempEval*

## Abstract

This paper discusses the fourth year of the "Sentiment Analysis in Twitter Task". SemEval-2016 Task 4 comprises five subtasks, three of which represent a significant departure from previous editions. The first two subtasks are reruns from prior years and ask to predict the overall sentiment, and the sentiment towards a topic in a tweet. The three new subtasks focus on two variants of the basic "sentiment classification in Twitter" task. The first variant adopts a five-point scale, which confers an *ordinal* character to the classification task. The second variant focuses on the correct estimation of the prevalence of each class of interest, a task which has been called *quantification* in the supervised learning literature. The task continues to be very popular, attracting a total of 43 teams.

## 1 Introduction

Sentiment classification is the task of detecting whether a textual item (e.g., a product review, a blog post, an editorial, etc.) expresses a POSITIVE or a NEGATIVE opinion in general or about a given entity, e.g., a product, a person, a political party, or a policy. Sentiment classification has become a ubiquitous enabling technology in the Twittersphere. Classifying tweets according to sentiment has many applications in political science, social sciences, market research, and many others (Martínez-Cámara et al., 2014; Mejova et al., 2015).

\*Fabrizio Sebastiani is currently on leave from Consiglio Nazionale delle Ricerche, Italy.

As a testament to the prominence of research on sentiment analysis in Twitter, the tweet sentiment classification (TSC) task has attracted the highest number of participants in the last three SemEval campaigns (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016b).

Previous editions of the SemEval task involved binary (POSITIVE vs. NEGATIVE) or *single-label multi-class* classification (SLMC) when a NEUTRAL<sup>1</sup> class is added (POSITIVE vs. NEGATIVE vs. NEUTRAL). SemEval-2016 Task 4 represents a significant departure from these previous editions. Although two of the subtasks (Subtasks A and B) are reincarnations of previous editions (SLMC classification for Subtask A, binary classification for Subtask B), SemEval-2016 Task 4 introduces two completely new problems, taken individually (Subtasks C and D) and in combination (Subtask E):

### 1.1 Ordinal Classification

We replace the two- or three-point scale with a five-point scale {HIGHLYPOSITIVE, POSITIVE, NEUTRAL, NEGATIVE, HIGHLYNEGATIVE}, which is now ubiquitous in the corporate world where human ratings are involved: e.g., Amazon, TripAdvisor, and Yelp, all use a five-point scale for rating sentiment towards products, hotels, and restaurants.

Moving from a categorical two/three-point scale to an ordered five-point scale means, in machine learning terms, moving from binary to *ordinal classification* (a.k.a. *ordinal regression*).

<sup>1</sup>We merged OBJECTIVE under NEUTRAL, as previous attempts to have annotators distinguish between the two have consistently resulted in very low inter-annotator agreement.

## 1.2 Quantification

We replace classification with *quantification*, i.e., supervised class prevalence estimation. With regard to Twitter, hardly anyone is interested in whether *a specific person* has a positive or a negative view of the topic. Rather, applications look at estimating the *prevalence* of positive and negative tweets about a given topic. Most (if not all) tweet sentiment classification studies conducted within political science (Borge-Holthoefer et al., 2015; Kaya et al., 2013; Marchetti-Bowick and Chambers, 2012), economics (Bollen et al., 2011; O’Connor et al., 2010), social science (Dodds et al., 2011), and market research (Burton and Soboleva, 2011; Qureshi et al., 2013), use Twitter with an interest in aggregate data and *not* in individual classifications.

Estimating prevalences (more generally, estimating the *distribution* of the classes in a set of unlabelled items) by leveraging training data is called *quantification* in data mining and related fields. Previous work has argued that quantification is not a mere byproduct of classification, since (a) a good classifier is not necessarily a good quantifier, and vice versa, see, e.g., (Forman, 2008); (b) quantification requires evaluation measures different from classification. Quantification-specific learning approaches have been proposed over the years; Sections 2 and 5 of (Esuli and Sebastiani, 2015) contain several pointers to such literature.

Note that, in Subtasks B to E, tweets come labelled with the *topic* they are about and participants need not classify whether a tweet is about a given topic. A topic can be anything that people express opinions about; for example, a product (e.g., iPhone6), a political candidate (e.g., Hillary Clinton), a policy (e.g., Obamacare), an event (e.g., the Pope’s visit to Palestine), etc.

The rest of the paper is structured as follows. In Section 2, we give a general overview of SemEval-2016 Task 4 and the five subtasks. Section 3 focuses on the datasets, and on the data generation procedure. In Section 4, we describe in detail the evaluation measures for each subtask. Section 5 discusses the results of the evaluation and the techniques and tools that the top-ranked participants used. Section 6 concludes, discussing the lessons learned and some possible ideas for a followup at SemEval-2017.

## 2 Task Definition

SemEval-2016 Task 4 consists of five subtasks:

1. **Subtask A:** Given a tweet, predict whether it is of positive, negative, or neutral sentiment.
2. **Subtask B:** Given a tweet known to be about a given topic, predict whether it conveys a positive or a negative sentiment towards the topic.
3. **Subtask C:** Given a tweet known to be about a given topic, estimate the sentiment it conveys towards the topic on a five-point scale ranging from HIGHLYNEGATIVE to HIGHLYPOSITIVE.
4. **Subtask D:** Given a set of tweets known to be about a given topic, estimate the distribution of the tweets in the POSITIVE and NEGATIVE classes.
5. **Subtask E:** Given a set of tweets known to be about a given topic, estimate the distribution of the tweets across the five classes of a five-point scale, ranging from HIGHLYNEGATIVE to HIGHLYPOSITIVE.

Subtask A is a rerun – it was present in all three previous editions of the task. In the 2013–2015 editions, it was known as Subtask B.<sup>2</sup> We ran it again this year because it was the most popular subtask in the three previous task editions. It was the most popular subtask this year as well – see Section 5.

Subtask B is a variant of SemEval-2015 Task 10 Subtask C (Rosenthal et al., 2015; Nakov et al., 2016b), with POSITIVE, NEUTRAL, and NEGATIVE as the classification labels.

Subtask E is similar to SemEval-2015 Task 10 Subtask D, which consisted of the following problem: *Given a set of messages on a given topic from the same period of time, classify the overall sentiment towards the topic in these messages as strongly positive, weakly positive, neutral, weakly negative, or strongly negative.* Note that in SemEval-2015 Task 10 Subtask D, exactly one of the five classes had to be chosen, while in our Subtask E, a distribution across the five classes has to be estimated.

<sup>2</sup>Note that we retired the expression-level subtask A, which was present in SemEval 2013–2015 (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016b).

As per the above discussion, Subtasks B to E are new. Conceptually, they form a  $2 \times 2$  matrix, as shown in Table 1, where the rows indicate the *goal* of the task (classification vs. quantification) and the columns indicate the *granularity* of the task (two- vs. five-point scale).

|      |                | Granularity           |                         |
|------|----------------|-----------------------|-------------------------|
|      |                | Two-point<br>(binary) | Five-point<br>(ordinal) |
| Goal | Classification | Subtask B             | Subtask C               |
|      | Quantification | Subtask D             | Subtask E               |

**Table 1:** A  $2 \times 2$  matrix summarizing the similarities and the differences between Subtasks B-E.

### 3 Datasets

In this section, we describe the process of collection and annotation of the training, development and testing tweets for all five subtasks. We dub this dataset the *Tweet 2016* dataset in order to distinguish it from datasets generated in previous editions of the task.

#### 3.1 Tweet Collection

We provided the datasets from the previous editions<sup>3</sup> (see Table 2) of this task (Nakov et al., 2013; Rosenthal et al., 2014; Rosenthal et al., 2015; Nakov et al., 2016b) for training and development. In addition we created new training and testing datasets.

| Dataset              | POSITIVE | NEGATIVE | NEUTRAL | Total |
|----------------------|----------|----------|---------|-------|
| Twitter2013-train    | 3,662    | 1,466    | 4,600   | 9,728 |
| Twitter2013-dev      | 575      | 340      | 739     | 1,654 |
| Twitter2013-test     | 1,572    | 601      | 1,640   | 3,813 |
| SMS2013-test         | 492      | 394      | 1,207   | 2,093 |
| Twitter2014-test     | 982      | 202      | 669     | 1,853 |
| Twitter2014-sarcasm  | 33       | 40       | 13      | 86    |
| LiveJournal2014-test | 427      | 304      | 411     | 1,142 |
| Twitter2015-test     | 1,040    | 365      | 987     | 2,392 |

**Table 2:** Statistics about data from the 2013–2015 editions of the SemEval task on Sentiment Analysis in Twitter, which could be used for training and development for SemEval-2016 Task 4.

<sup>3</sup>For Subtask A, we did not allow training on the testing datasets from 2013–2015, as we used them for progress testing.

We employed the following annotation procedure. As in previous years, we first gathered tweets that express sentiment about popular topics. For this purpose, we extracted named entities from millions of tweets, using a Twitter-tuned named entity recognition system (Ritter et al., 2011). The collected tweets were greatly skewed towards the neutral class. In order to reduce the class imbalance, we removed those that contained no sentiment-bearing words. We used SentiWordNet 3.0 (Baccianella et al., 2010) as a repository of sentiment words. Any word listed in SentiWordNet 3.0 with at least one sense having a positive or a negative sentiment score greater than 0.3 was considered sentiment-bearing.<sup>4</sup>

The training and development tweets were collected from July to October 2015. The test tweets were collected from October to December 2015. We used the public streaming Twitter API to download the tweets.<sup>5</sup>

We then manually filtered the resulting tweets to obtain a set of 200 meaningful topics with at least 100 tweets each (after filtering out near-duplicates). We excluded topics that were incomprehensible, ambiguous (e.g., *Barcelona*, which is the name both of a city and of a sports team), or too general (e.g., *Paris*, which is the name of a big city). We then discarded tweets that were just mentioning the topic but were not really about the topic.

Note that the topics in the training and in the test sets do not overlap, i.e., the test set consists of tweets about topics different from the topics the training and development tweets are about.

#### 3.2 Annotation

The 2016 data consisted of four parts: TRAIN (for training models), DEV (for tuning models), DEVTEST (for development-time evaluation), and TEST (for the official evaluation). The first three datasets were annotated using Amazon’s Mechanical Turk, while the TEST dataset was annotated on CrowdFlower.

<sup>4</sup>Filtering based on an existing lexicon does bias the dataset to some degree; however, the text still contains sentiment expressions outside those in the lexicon.

<sup>5</sup>We distributed the datasets to the task participants in a similar way: we only released the annotations and the tweet IDs, and the participants had to download the actual tweets by themselves via the API, for which we provided a script: [https://github.com/aritter/twitter\\_download](https://github.com/aritter/twitter_download)

**Instructions:** Given a Twitter message and a topic, identify whether the message is highly positive, positive, neutral, negative, or highly negative (a) in general and (b) with respect to the provided topic. If a tweet is sarcastic, please select the checkbox “The tweet is sarcastic”. Please read the examples and the invalid responses before beginning if this is the first time you are working on this HIT.

Sentence: We're excited to announce that AC/DC tribute band Big Jack will take the main stage at Fall Jam on Sunday September 27th!

Overall, the tweet is  Highly Positive  Positive  Neutral  Negative  Highly Negative  
 The sentiment towards the topic ac/dc is  Highly Positive  Positive  Neutral  Negative  Highly Negative  
 The tweet is sarcastic.

Figure 1: The instructions provided to the Mechanical Turk annotators, followed by a screenshot.

**Annotation with Amazon’s Mechanical Turk.** A Human Intelligence Task (HIT) consisted of providing all required annotations for a given tweet message. In order to qualify to work on our HITs, a Mechanical Turk annotator (a.k.a. “Turker”) had to have an approval rate greater than 95% and to have completed at least 50 approved HITs. Each HIT was carried out by five Turkers and consisted of five tweets to be annotated. A Turker had to indicate the overall polarity of the tweet message (on a five-point scale) as well as the overall polarity of the message towards the given target topic (again, on a five-point scale). The annotation instructions along with an example are shown in Figure 1. We made available to the Turkers several additional examples, which are shown in Table 3.

We rejected HITs with the following problems:

- one or more responses do not have the overall sentiment marked;
- one or more responses do not have the sentiment towards the topic marked;
- one or more responses appear to be randomly selected.

**Annotation with CrowdFlower.** We annotated the TEST data using CrowdFlower, as it allows better quality control of the annotations across a number of dimensions. Most importantly, it allows us to find and exclude unreliable annotators based on hidden tests, which we created starting with the highest-confidence and highest-agreement annotations from Mechanical Turk. We added some more tests manually. Otherwise, we setup the annotation task giving exactly the same instructions and examples as in Mechanical Turk.

**Consolidation of annotations.** In previous years, we used majority voting to select the true label (and discarded cases where a majority had not emerged, which amounted to about 50% of the tweets). As this year we have a five-point scale, where the expected agreement is lower, we used a two-step procedure. If three out of the five annotators agreed on a label, we accepted the label. Otherwise, we first mapped the categorical labels to the integer values -2, -1, 0, 1, 2. Then we calculated the average, and finally we mapped that average to the closest integer value. In order to counter-balance the tendency of the average to stay away from -2 and 2, and also to prefer 0, we did not use rounding at  $\pm 0.5$  and  $\pm 1.5$ , but at  $\pm 0.4$  and  $\pm 1.4$  instead.

To give the reader an idea about the degree of agreement, we will look at the TEST dataset as an example. It included 20,632 tweets. For 2,760, all five annotators assigned the same value, and for another 9,944 there was a majority value. For the remaining 7,928 cases, we had to perform averaging as described above.

The consolidated statistics from the five annotators on a three-point scale for Subtask A are shown in Table 4. Note that, for consistency, we annotated the data for Subtask A on a five-point scale, which we then converted to a three-point scale.

The topic annotations on a two-point scale for Subtasks B and D are shown in Table 5, while those on a five-point scale for Subtasks C and E are in Table 6. Note that, as for Subtask A, the two-point scale annotation counts for Subtasks B and D derive from summing the POSITIVES with the HIGHLYPOSITIVES, and the NEGATIVES with the HIGHLYNEGATIVES from Table 6; moreover, this time we also remove the NEUTRALS.

| Tweet   |          |         |          | Overall Sentiment | Topic Sentiment              |
|---|----------|---------|----------|-------------------|------------------------------|
|   | POSITIVE | NEUTRAL | NEGATIVE |                   |                              |
| Why would you still wear shorts when it's this cold?! I love how Britain see's a bit of sun and they're like 'OOOH LET'S STRIP! |          |         |          | POSITIVE          | Britain: NEGATIVE            |
| Saturday without Leeds United is like Sunday dinner it doesn't feel normal at all (Ryan)  |          |         |          | NEGATIVE          | Leeds United: HIGHLYPOSITIVE |
| Who are you tomorrow? Will you make me smile or just bring me sorrow? #HottieOfTheWeek Demi Lovato                              |          |         |          | NEUTRAL           | Demi Lovato: POSITIVE        |

**Table 3:** List of example tweets and annotations that were provided to the annotators.

|          | POSITIVE | NEUTRAL | NEGATIVE | Total  |
|----------|----------|---------|----------|--------|
| TRAIN    | 3,094    | 863     | 2,043    | 6,000  |
| DEV      | 844      | 765     | 391      | 2,000  |
| DEVTTEST | 994      | 681     | 325      | 2,000  |
| TEST     | 7,059    | 10,342  | 3,231    | 20,632 |

**Table 4:** 2016 data statistics (Subtask A).

|          | Topics | POSITIVE | NEGATIVE | Total  |
|----------|--------|----------|----------|--------|
| TRAIN    | 60     | 3,591    | 755      | 4,346  |
| DEV      | 20     | 986      | 339      | 1,325  |
| DEVTTEST | 20     | 1,153    | 264      | 1,417  |
| TEST     | 100    | 8,212    | 2,339    | 10,551 |

**Table 5:** 2016 data statistics (Subtasks B and D).

|          | Topics | HIGHLYPOSITIVE | POSITIVE | NEUTRAL | NEGATIVE | HIGHLYNEGATIVE | Total  |
|----------|--------|----------------|----------|---------|----------|----------------|--------|
| TRAIN    | 60     | 437            | 3,154    | 1,654   | 668      | 87             | 6,000  |
| DEV      | 20     | 53             | 933      | 675     | 296      | 43             | 2,000  |
| DEVTTEST | 20     | 148            | 1,005    | 583     | 233      | 31             | 2,000  |
| TEST     | 100    | 382            | 7,830    | 10,081  | 2,201    | 138            | 20,632 |

**Table 6:** 2016 data statistics (Subtasks C and E).

As we use the same test tweets for all subtasks, the submission of results by participating teams was subdivided in two stages: (*i*) participants had to submit results for Subtasks A, C, E, and (*ii*) only after the submission deadline for A, C, E had passed, we distributed to participants the unlabelled test data for Subtasks B and D.

Otherwise, since for Subtasks B and D we filter out the NEUTRALS, we would have leaked information about which the NEUTRALS are, and this information could have been used in Subtasks C and E.

Finally, as the same tweets can be selected for different topics, we ended up with some duplicates; arguably, these are true duplicates for Subtask A only, as for the other subtasks the topics still differ. This includes 25 duplicates in TRAIN, 3 in DEV, 2 in DEVTTEST, and 116 in TEST. There is a larger number in TEST, as TEST is about twice as large as TRAIN, DEV, and DEVTTEST combined. This is because we wanted a large TEST set with 100 topics and 200 tweets per topic on average for Subtasks C and E.

#### 4 Evaluation Measures

This section discuss the evaluation measures for the five subtasks of our SemEval-2016 Task 4. A document describing the evaluation measures in detail<sup>6</sup> (Nakov et al., 2016a), and a scoring software implementing all the five “official” measures, were made available to the participants via the task website together with the training data.<sup>7</sup>

For Subtasks B to E, the datasets are each subdivided into a number of “topics”, and the subtask needs to be carried out independently for each topic. As a result, each of the evaluation measures will be “macroaveraged” across the topics, i.e., we compute the measure individually for each topic, and we then average the results across the topics.

<sup>6</sup><http://alt.qcri.org/semeval2016/task4/>

<sup>7</sup>An earlier version of the scoring script contained a bug, to the effect that for Subtask B it was computing  $F_1^{PN}$ , and not  $\rho^{PN}$ . This was detected only after the submissions were closed, which means that participants to Subtask B who used the scoring system (and not their own implementation of  $\rho^{PN}$ ) for parameter optimization, may have been penalized in the ranking as a result.

#### 4.1 Subtask A: Message polarity classification

Subtask A is a *single-label multi-class* (SLMC) classification task. Each tweet must be classified as belonging to exactly one of the following three classes  $\mathcal{C}=\{\text{POSITIVE}, \text{NEUTRAL}, \text{NEGATIVE}\}$ .

We adopt the same evaluation measure as the 2013-2015 editions of this subtask,  $F_1^{PN}$ :

$$F_1^{PN} = \frac{F_1^P + F_1^N}{2} \quad (1)$$

$F_1^P$  is the  $F_1$  score for the POSITIVE class:

$$F_1^P = \frac{2\pi^P \rho^P}{\pi^P + \rho^P} \quad (2)$$

Here,  $\pi^P$  and  $\rho^P$  denote precision and recall for the POSITIVE class, respectively:

$$\pi^P = \frac{PP}{PP + PU + PN} \quad (3)$$

$$\rho^P = \frac{PP}{PP + UP + NP} \quad (4)$$

where  $PP, UP, NP, PU, PN$  are the cells of the confusion matrix shown in Table 7.

|           |          | Gold Standard |         |          |
|-----------|----------|---------------|---------|----------|
|           |          | POSITIVE      | NEUTRAL | NEGATIVE |
| Predicted | POSITIVE | PP            | PU      | PN       |
|           | NEUTRAL  | UP            | UU      | UN       |
|           | NEGATIVE | NP            | NU      | NN       |

**Table 7:** The confusion matrix for Subtask A. Cell  $XY$  stands for “the number of tweets that the classifier labeled  $X$  and the gold standard labells as  $Y$ ”.  $P, U, N$  stand for POSITIVE, NEUTRAL, NEGATIVE, respectively.

$F_1^N$  is defined analogously, and the measure we finally adopt is  $F_1^{PN}$  as from Equation 1.

#### 4.2 Subtask B: Tweet classification according to a two-point scale

Subtask B is a *binary classification* task. Each tweet must be classified as either POSITIVE or NEGATIVE.

For this subtask we adopt *macroaveraged recall*:

$$\begin{aligned} \rho^{PN} &= \frac{1}{2}(\rho^P + \rho^N) \\ &= \frac{1}{2}\left(\frac{PP}{PP + NP} + \frac{NN}{NN + PN}\right) \end{aligned} \quad (5)$$

In the above formula,  $\rho^P$  and  $\rho^N$  are the positive and the negative class recall, respectively. Note that  $U$  terms are entirely missing in Equation 5; this is because we do not have the NEUTRAL class for SemEval-2016 Task 4, subtask A.

$\rho^{PN}$  ranges in  $[0, 1]$ , where a value of 1 is achieved only by the perfect classifier (i.e., the classifier that correctly classifies all items), a value of 0 is achieved only by the perverse classifier (the classifier that misclassifies all items), while 0.5 is both (i) the value obtained by a trivial classifier (i.e., the classifier that assigns all tweets to the same class – be it POSITIVE or NEGATIVE), and (ii) the expected value of a random classifier. The advantage of  $\rho^{PN}$  over “standard” accuracy is that it is more robust to class imbalance. The accuracy of the majority-class classifier is the relative frequency (aka “prevalence”) of the majority class, that may be much higher than 0.5 if the test set is imbalanced. Standard  $F_1$  is also sensitive to class imbalance for the same reason. Another advantage of  $\rho^{PN}$  over  $F_1$  is that  $\rho^{PN}$  is invariant with respect to switching POSITIVE with NEGATIVE, while  $F_1$  is not. See (Sebastiani, 2015) for more details on  $\rho^{PN}$ .

As we noted before, the training dataset, the development dataset, and the test dataset are each subdivided into a number of topics, and Subtask B needs to be carried out independently for each topic. As a result, the evaluation measures discussed in this section are computed individually for each topic, and the results are then averaged across topics to yield the final score.

#### 4.3 Subtask C: Tweet classification according to a five-point scale

Subtask C is an *ordinal classification* (OC – also known as *ordinal regression*) task, in which each tweet must be classified into exactly one of the classes in  $\mathcal{C}=\{\text{HIGHLYPOSITIVE}, \text{POSITIVE}, \text{NEUTRAL}, \text{NEGATIVE}, \text{HIGHLYNEGATIVE}\}$ , represented in our dataset by numbers in  $\{+2, +1, 0, -1, -2\}$ , with a total order defined on  $\mathcal{C}$ . The essential difference between SLMC (see Section 4.1 above) and OC is that not all mistakes weigh equally in the latter. For example, misclassifying a HIGHLYNEGATIVE example as HIGHLYPOSITIVE is a bigger mistake than misclassifying it as NEGATIVE or NEUTRAL.

As our evaluation measure, we use *macroaveraged mean absolute error* ( $MAE^M$ ):

$$MAE^M(h, Te) = \frac{1}{|\mathcal{C}|} \sum_{j=1}^{|\mathcal{C}|} \frac{1}{|Te_j|} \sum_{\mathbf{x}_i \in Te_j} |h(\mathbf{x}_i) - y_i|$$

where  $y_i$  denotes the true label of item  $\mathbf{x}_i$ ,  $h(\mathbf{x}_i)$  is its predicted label,  $Te_j$  denotes the set of test documents whose true class is  $c_j$ ,  $|h(\mathbf{x}_i) - y_i|$  denotes the “distance” between classes  $h(\mathbf{x}_i)$  and  $y_i$  (e.g., the distance between HIGHLYPOSITIVE and NEGATIVE is 3), and the “M” superscript indicates “macroaveraging”.

The advantage of  $MAE^M$  over “standard” mean absolute error, which is defined as:

$$MAE^\mu(h, Te) = \frac{1}{|Te|} \sum_{\mathbf{x}_i \in Te} |h(\mathbf{x}_i) - y_i| \quad (6)$$

is that it is robust to class imbalance (which is useful, given the imbalanced nature of our dataset). On perfectly balanced datasets  $MAE^M$  and  $MAE^\mu$  are equivalent.

Unlike the measures discussed in Sections 4.1 and 4.2,  $MAE^M$  is a measure of error, and not accuracy, and thus lower values are better. See (Baccianella et al., 2009) for more detail on  $MAE^M$ .

Similarly to Subtask B, Subtask C needs to be carried out independently for each topic. As a result,  $MAE^M$  is computed individually for each topic, and the results are then averaged across all topics to yield the final score.

#### 4.4 Subtask D: Tweet quantification according to a two-point scale

Subtask D also assumes a *binary quantification* setup, in which each tweet is classified as POSITIVE or NEGATIVE. The task is to compute an estimate  $\hat{p}(c_j)$  of the relative frequency (in the test set) of each of the classes.

The difference between binary classification (as from Section 4.2) and binary quantification is that errors of different polarity (e.g., a false positive and a false negative for the same class) can compensate each other in the latter. Quantification is thus a more lenient task since a perfect classifier is also a perfect quantifier, but a perfect quantifier is not necessarily a perfect classifier.

We adopt *normalized cross-entropy*, better known as *Kullback-Leibler Divergence* (KLD). KLD was proposed as a quantification measure in (Forman, 2005), and is defined as follows:

$$KLD(\hat{p}, p, \mathcal{C}) = \sum_{c_j \in \mathcal{C}} p(c_j) \log_e \frac{p(c_j)}{\hat{p}(c_j)} \quad (7)$$

$KLD$  is a measure of the error made in estimating a true distribution  $p$  over a set  $\mathcal{C}$  of classes by means of a predicted distribution  $\hat{p}$ . Like  $MAE^M$  in Section 4.3,  $KLD$  is a measure of error, which means that lower values are better.  $KLD$  ranges between 0 (best) and  $+\infty$  (worst).

Note that the upper bound of  $KLD$  is not finite since Equation 7 has predicted prevalences, and not true prevalences, at the denominator: that is, by making a predicted prevalence  $\hat{p}(c_j)$  infinitely small we can make  $KLD$  infinitely large. To solve this problem, in computing  $KLD$  we smooth both  $p(c_j)$  and  $\hat{p}(c_j)$  via additive smoothing, i.e.,

$$\begin{aligned} p^s(c_j) &= \frac{p(c_j) + \epsilon}{(\sum_{c_j \in \mathcal{C}} p(c_j)) + \epsilon \cdot |\mathcal{C}|} \\ &= \frac{p(c_j) + \epsilon}{1 + \epsilon \cdot |\mathcal{C}|} \end{aligned} \quad (8)$$

where  $p^s(c_j)$  denotes the smoothed version of  $p(c_j)$  and the denominator is just a normalizer (same for the  $\hat{p}^s(c_j)$ ’s); the quantity  $\epsilon = \frac{1}{2 \cdot |Te|}$  is used as a smoothing factor, where  $Te$  denotes the test set.

The smoothed versions of  $p(c_j)$  and  $\hat{p}(c_j)$  are used in place of their original versions in Equation 7; as a result,  $KLD$  is always defined and still returns a value of 0 when  $p$  and  $\hat{p}$  coincide.

$KLD$  is computed individually for each topic, and the results are averaged to yield the final score.

#### 4.5 Subtask E: Tweet quantification according to a five-point scale

Subtask E is an *ordinal quantification* (OQ) task, in which (as in OC) each tweet belongs exactly to one of the classes in  $\mathcal{C}=\{\text{HIGHLYPOSITIVE}, \text{POSITIVE}, \text{NEUTRAL}, \text{NEGATIVE}, \text{HIGHLYNEGATIVE}\}$ , where there is a total order on  $\mathcal{C}$ . As in binary quantification, the task is to compute an estimate  $\hat{p}(c_j)$  of the relative frequency  $p(c_j)$  in the test tweets of all the classes  $c_j \in \mathcal{C}$ .

The measure we adopt for OQ is the *Earth Mover’s Distance* (Rubner et al., 2000) (also known as the *Vaserštejn metric* (Rüschorf, 2001)), a measure well-known in the field of computer vision. *EMD* is currently the only known measure for ordinal quantification. It is defined for the general case in which a distance  $d(c', c'')$  is defined for each  $c', c'' \in \mathcal{C}$ . When there is a total order on the classes in  $\mathcal{C}$  and  $d(c_i, c_{i+1}) = 1$  for all  $i \in \{1, \dots, (\mathcal{C} - 1)\}$  (as in our application), the Earth Mover’s Distance is defined as

$$EMD(\hat{p}, p) = \sum_{j=1}^{|\mathcal{C}|-1} \left| \sum_{i=1}^j \hat{p}(c_i) - \sum_{i=1}^j p(c_i) \right| \quad (9)$$

and can be computed in  $|\mathcal{C}|$  steps from the estimated and true class prevalences.

Like *KLD* in Section 4.4, *EMD* is a measure of error, so lower values are better; *EMD* ranges between 0 (best) and  $|\mathcal{C}| - 1$  (worst). See (Esuli and Sebastiani, 2010) for more details on *EMD*.

As before, *EMD* is computed individually for each topic, and the results are then averaged across all topics to yield the final score.

## 5 Participants and Results

A total of 43 teams (see Table 15 at the end of the paper) participated in SemEval-2016 Task 4, representing 25 countries; the country with the highest participation was China (5 teams), followed by Italy, Spain, and USA (4 teams each). The subtask with the highest participation was Subtask A (34 teams), followed by Subtask B (19 teams), Subtask D (14 teams), Subtask C (11 teams), and Subtask E (10 teams).

It was not surprising that Subtask A proved to be the most popular – it was a rerun from previous years; conversely, none among Subtasks B to E had previously been offered in precisely the same form. Quantification-related subtasks (D and E) generated 24 participations altogether, while subtasks with an ordinal nature (C and E) attracted 21 participations. Only three teams participated in all five subtasks; conversely, no less than 23 teams took part in one subtask only (with a few exceptions, Subtask A). Many teams that participated in more than one subtask used essentially the same system for all of them, with little tuning to the specifics of each subtask.

Few trends stand out among the participating systems. In terms of the supervised learning methods used, there is a clear dominance of methods based on deep learning, including convolutional neural networks and recurrent neural networks (and, in particular, long short-term memory networks); the software libraries for deep learning most frequently used by the participants are Theano and Keras. Conversely, kernel machines seem to be less frequently used than in the past, and the use of learning methods other than the ones mentioned above is scarce.

The use of distant supervision is ubiquitous; this is natural, since there is an abundance of freely available tweets labelled according to sentiment (possibly with silver labels only, e.g., emoticons), and it is intuitive that their use as additional training data could be helpful. Another ubiquitous technique is the use of word embeddings, usually generated via either word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014); most authors seem to use general-purpose, pre-trained embeddings, while some authors also use customized word embeddings, trained either on the Tweet 2016 dataset or on tweet datasets of some sort.

Nothing radically new seems to have emerged with respect to text preprocessing; as in previous editions of this task, participants use a mix of by now obvious techniques, such as negation scope detection, elongation normalization, detection of amplifiers and diminishers, plus the usual extraction of word  $n$ -grams, character  $n$ -grams, and POS  $n$ -grams. The use of sentiment lexicons (alone or in combination with each other; general-purpose or Twitter-specific) is obviously still frequent.

In the next five subsections, we discuss the results of the participating systems in the five subtasks, focusing on the techniques and tools that the top-ranked participants have used. We also focus on how the participants tailored (if at all) their approach to the specific subtask. When discussing a specific subtask, we will adopt the convention of adding to a team name a subscript which indicates the position in the ranking for that subtask that the team obtained; e.g., when discussing Subtask E, “Finki<sub>2</sub>” indicates team “Finki, which placed 2nd in the ranking for Subtask E”. The papers describing the participants’ approach are quoted in Table 15.

## 5.1 Subtask A: Message polarity classification

Table 8 ranks the systems submitted by the 34 teams who participated in Subtask A “Message Polarity Classification” in terms of the official measure  $F_1^{PN}$ . We further show the result for two other measures,  $\rho^{PN}$  (the measure that we adopted for Subtask B) and accuracy ( $Acc = \frac{TP+TN}{TP+TN+FP+FN}$ ). We also report the result for a baseline classifier that assigns to each tweet the POSITIVE class. For Subtask A evaluated using  $F_1^{PN}$ , this is the equivalent of the majority class classifier for (binary or SLMC) classification evaluated via vanilla accuracy, i.e., this is the “smartest” among the trivial policies that attempt to maximize  $F_1^{PN}$ .

| #  | System                 | $F_1^{PN}$                | $\rho^{PN}$         | Acc                 |
|----|------------------------|---------------------------|---------------------|---------------------|
| 1  | SwissCheese            | <b>0.633<sub>1</sub></b>  | 0.667 <sub>2</sub>  | 0.646 <sub>1</sub>  |

**Table 8:** Results for Subtask A “Message Polarity Classification” on the Tweet 2016 dataset. The systems are ordered by their  $F_1^{PN}$  score. In each column the rankings according to the corresponding measure are indicated with a subscript. Teams marked as “(\*)” are late submitters, i.e., their original submission was deemed irregular by the organizers, and a revised submission was entered after the deadline.

All 34 participating systems were able to outperform the baseline on all three measures, with the exception of one system that scored below the baseline on  $Acc$ . The top-scoring team (SwissCheese<sub>1</sub>) used an ensemble of convolutional neural networks, differing in their choice of filter shapes, pooling shapes and usage of hidden layers. Word embeddings generated via word2vec were also used, and the neural networks were trained by using distant supervision. Out of the 10 top-ranked teams, 5 teams (SwissCheese<sub>1</sub>, SENSEI-LIF<sub>2</sub>, UNIMELB<sub>3</sub>, INESC-ID<sub>4</sub>, INSIGHT-1<sub>8</sub>) used deep NNs of some sort, and 7 teams (SwissCheese<sub>1</sub>, SENSEI-LIF<sub>2</sub>, UNIMELB<sub>3</sub>, INESC-ID<sub>4</sub>, aueb.twitter.sentiment<sub>5</sub>, I2RNTU<sub>7</sub>, INSIGHT-1<sub>8</sub>) used either general-purpose or task-specific word embeddings, generated via word2vec or GloVe.

**Historical results.** We also tested the participating systems on the test sets from the three previous editions of this subtask. Participants were not allowed to use these test sets for training. Results (measured on  $F_1^{PN}$ ) are reported in Table 9. The top-performing systems on Tweet 2016 are also top-ranked on the test datasets from previous years. There is a general pattern: the top-ranked system in year  $x$  outperforms the top-ranked system in year  $(x - 1)$  on the official dataset of year  $(x - 1)$ . Top-ranked systems tend to use approaches that are universally strong, even when tested on out-of-domain test sets such as SMS, LiveJournal, or sarcastic tweets (yet, for sarcastic tweets, there are larger differences in rank compared to systems rankings on Tweet 2016). It is unclear where improvements come from: (a) the additional training data that we made available this year (in addition to Tweet-train-2013, which was used in 2013–2015), thus effectively doubling the amount of training data, or (b) because of advancement of learning methods.

We further look at the top scores achieved by any system in the period 2013–2016. The results are shown in Table 10. Interestingly, the results for a test set improve in the second year it is used (i.e., the year after it was used as an official test set) by 1–3 points absolute, but then do not improve further and stay stable, or can even decrease a bit. This might be due to participants optimizing their systems primarily on the test set from the preceding year.

**Table 9:** Historical results for Subtask A “Message Polarity Classification”. The systems are ordered by their score on the Tweet 2016 dataset; the rankings on the individual datasets are indicated with a subscript. The meaning of “(\*)” is as in Table 8.

## 5.2 Subtask B: Tweet classification according to a two-point scale

Table 11 ranks the 19 teams who participated in Subtask B “Tweet classification according to a two-point scale” in terms of the official measure  $\rho^{PN}$ . Two other measures are reported,  $F_1^{PN}$  (the measure adopted for Subtask A) and accuracy ( $Acc$ ). We also report the result of a baseline that assigns to each tweet the positive class. This is the “smartest” among the trivial policies that attempt to maximize  $\rho^{PN}$ . This baseline always returns  $\rho^{PN} = 0.500$ .

Note however that this is also (i) the value returned by the classifier that assigns to each tweet the negative class, and (ii) the expected value returned by the random classifier; for more details see (Sebastiani, 2015, Section 5), where  $\rho^{PN}$  is called  $K$ .

The top-scoring team (Tweester<sub>1</sub>) used a combination of convolutional neural networks, topic modeling, and word embeddings generated via word2vec. Similar to Subtask A, the main trend among all participants is the widespread use of deep learning techniques.

| Year         | 2013  |       | 2014  |         | 2015         |       | 2016  |

|           | Baseline          | <b>0.500</b>               | 0.438               | 0.778               |

**Table 11:** Results for Subtask B “Tweet classification according to a two-point scale” on the Tweet 2016 dataset. The systems are ordered by their  $\rho^{PN}$  score (higher is better). The meaning of “(\*)” is as in Table 8.

Out of the 10 top-ranked participating teams, 5 teams ( $\text{Tweester}_1$ ,  $\text{LYS}_2$ ,  $\text{INSIGHT-1}_5$ ,  $\text{UNIMELB}_7$ ,  $\text{Finki}_{10}$ ) used convolutional neural networks; 3 teams ( $\text{thecerealkiller}_3$ ,  $\text{UNIMELB}_7$ ,  $\text{Finki}_{10}$ ) submitted systems using recurrent neural networks; and 7 teams ( $\text{Tweester}_1$ ,  $\text{LYS}_2$ ,  $\text{INSIGHT-1}_5$ ,  $\text{UNIMELB}_7$ ,  $\text{Finki}_{10}$ ) incorporated in their participating systems either general-purpose or task-specific word embeddings (generated via toolkits such as GloVe or word2vec).

Conversely, the use of classifiers such as support vector machines, which were dominant until a few years ago, seems to have decreased, with only one team ( $\text{TwiSE}_8$ ) in the top 10 using them.

### 5.3 Subtask C: Tweet classification according to a five-point scale

Table 12 ranks the 11 teams who participated in Subtask C “Tweet classification according to a five-point scale” in terms of the official measure  $MAE^M$ ; we also show  $MAE^\mu$  (see Equation 6). We also report the result of a baseline system that assigns to each tweet the middle class (i.e., NEUTRAL); for ordinal classification evaluated via  $MAE^M$ , this is the majority-class classifier for (binary or SLMC) classification evaluated via vanilla accuracy, i.e., this is (Baccianella et al., 2009) the “smartest” among the trivial policies that attempt to maximize  $MAE^M$ .

| #         | System            | $MAE^M$                    | $MAE^\mu$           |
|-----------|-------------------|----------------------------|---------------------|
| <b>1</b>  | TwiSE             | <b>0.719</b> <sub>1</sub>  | 0.632 <sub>5</sub>  |
| <b>2</b>  | ECNU (*)          | <b>0.806</b> <sub>2</sub>  | 0.726 <sub>8</sub>  |
| <b>3</b>  | PUT               | <b>0.860</b> <sub>3</sub>  | 0.773 <sub>9</sub>  |
| <b>4</b>  | LYS               | <b>0.864</b> <sub>4</sub>  | 0.694 <sub>7</sub>  |
| <b>5</b>  | Finki             | <b>0.869</b> <sub>5</sub>  | 0.672 <sub>6</sub>  |
| <b>6</b>  | INSIGHT-1         | <b>1.006</b> <sub>6</sub>  | 0.607 <sub>3</sub>  |
| <b>7</b>  | ISTI-CNR          | <b>1.074</b> <sub>7</sub>  | 0.580 <sub>1</sub>  |
| <b>8</b>  | YZU-NLP           | <b>1.111</b> <sub>8</sub>  | 0.588 <sub>2</sub>  |
| <b>9</b>  | SentimentalITists | <b>1.148</b> <sub>9</sub>  | 0.625 <sub>4</sub>  |
| <b>10</b> | PotTS             | <b>1.237</b> <sub>10</sub> | 0.860 <sub>10</sub> |
| <b>11</b> | pkudblab          | <b>1.697</b> <sub>11</sub> | 1.300 <sub>11</sub> |
|           | Baseline          | <b>1.200</b>               | 0.537               |

**Table 12:** Results for Subtask C “Tweet classification according to a five-point scale” on the Tweet 2016 dataset. The systems are ordered by their  $MAE^M$  score (lower is better). The meaning of “(\*)” is as in Table 8.

The top-scoring team ( $\text{TwiSE}_1$ ) used a single-label multi-class classifier to classify the tweets according to their overall polarity. In particular, they used logistic regression that minimizes the multinomial loss across the classes, with weights to cope with class imbalance. Note that they ignored the given topics altogether.

| #         | System                | KLD                        | AE                  | RAE                 |

| <b>12</b> | SwissCheese           | <b>0.191</b> <sub>12</sub> | 0.147 <sub>9</sub>  | 0.638 <sub>2</sub>  |
| <b>13</b> | UDLAP                 | <b>0.261</b> <sub>13</sub> | 0.274 <sub>13</sub> | 2.973 <sub>13</sub> |
| <b>14</b> | HSENN                 | <b>0.399</b> <sub>14</sub> | 0.336 <sub>14</sub> | 3.930 <sub>14</sub> |
|           | Baseline <sub>1</sub> | <b>0.175</b>               | 0.184               | 2.110               |
|           | Baseline <sub>2</sub> | <b>0.887</b>               | 0.242               | 1.155               |

**Table 13:** Results for Subtask D “Tweet quantification according to a two-point scale” on the Tweet 2016 dataset. The systems are ordered by their *KLD* score (lower is better). The meaning of “(\*)” is as in Table 8.

Only 2 of the 11 participating teams tuned their systems to exploit the ordinal (as opposed to binary, or single-label multi-class) nature of this subtask. The two teams who did exploit the ordinal nature of the problem are PUT<sub>3</sub>, which uses an ensemble of ordinal regression approaches, and ISTI-CNR<sub>7</sub>, which uses a tree-based approach to ordinal regression. All other teams used general-purpose approaches for single-label multi-class classification, in many cases relying (as for Subtask B) on convolutional neural networks, recurrent neural networks, and word embeddings.

#### 5.4 Subtask D: Tweet quantification according to a two-point scale

Table 13 ranks the 14 teams who participated in Subtask D “Tweet quantification according to a two-point scale” on the official measure *KLD*. Two other measures are reported, *absolute error* (*AE*):

$$AE(p, \hat{p}, \mathcal{C}) = \frac{1}{|\mathcal{C}|} \sum_{c \in \mathcal{C}} |\hat{p}(c) - p(c)| \quad (10)$$

and *relative absolute error* (*RAE*):

$$RAE(p, \hat{p}, \mathcal{C}) = \frac{1}{|\mathcal{C}|} \sum_{c \in \mathcal{C}} \frac{|\hat{p}(c) - p(c)|}{p(c)} \quad (11)$$

where the notation is the same as in Equation 7.

We also report the result of a “maximum likelihood” baseline system (dubbed Baseline<sub>1</sub>). This system assigns to each test topic the distribution of the training tweets (the union of TRAIN, DEV, DEVTEST) across the classes. This is the “smartest” among the trivial policies that attempt to maximize *KLD*. We also report the result of a further (less smart) baseline system (dubbed Baseline<sub>2</sub>), i.e., one that assigns a prevalence of 1 to the majority class (which happens to be the POSITIVE class) and a prevalence of 0 to the other class.

The top-scoring team (Finki<sub>1</sub>) adopts an approach based on “classify and count”, a classification-oriented (instead of quantification-oriented) approach, using recurrent and convolutional neural networks, and GloVe word embeddings.

Indeed, only 5 of the 14 participating teams tuned their systems to the fact that it deals with quantification (as opposed to classification). Among the teams who do rely on quantification-oriented approaches, teams LYS<sub>2</sub> and HSENN<sub>14</sub> used an existing structured prediction method that directly optimizes *KLD*; teams QCRI<sub>5</sub> and ISTI-CNR<sub>11</sub> use existing probabilistic quantification methods; team NRU-HSE<sub>7</sub> uses an existing iterative quantification method based on cost-sensitive learning. Interestingly, team TwiSE<sub>2</sub> uses a “classify and count” approach after comparing it with a quantification-oriented method (similar to the one used by teams LYS<sub>2</sub> and HSENN<sub>14</sub>) on the development set, and concluding that the former works better than the latter. All other teams used “classify and count” approaches, mostly based on convolutional neural networks and word embeddings.

#### 5.5 Subtask E: Tweet quantification according to a five-point scale

Table 14 lists the results obtained by the 10 participating teams on Subtask E “Tweet quantification according to a five-point scale”. We also report the result of a “maximum likelihood” baseline system (dubbed Baseline<sub>1</sub>), i.e., one that assigns to each test topic the same distribution, namely the distribution of the training tweets (the union of TRAIN, DEV, DEVTEST) across the classes; this is the “smartest” among the trivial policies (i.e., those that do not require any genuine work) that attempt to maximize *EMD*.

We further report the result of less smart baseline system (dubbed Baseline<sub>2</sub>) – one that assigns a prevalence of 1 to the majority class (which coincides with the POSITIVE class) and a prevalence of 0 to all other classes.

| #         | System                | EMD                        |
|-----------|-----------------------|----------------------------|
| <b>1</b>  | QCRI                  | <b>0.243</b> <sub>1</sub>  |
| <b>2</b>  | Finki                 | <b>0.316</b> <sub>2</sub>  |
| <b>3</b>  | pkudblab              | <b>0.331</b> <sub>3</sub>  |
| <b>4</b>  | NRU-HSE               | <b>0.334</b> <sub>4</sub>  |
| <b>5</b>  | ECNU (*)              | <b>0.341</b> <sub>5</sub>  |
| <b>6</b>  | ISTI-CNR              | <b>0.358</b> <sub>6</sub>  |
| <b>7</b>  | LYS                   | <b>0.360</b> <sub>7</sub>  |
| <b>8</b>  | INSIGHT-1             | <b>0.366</b> <sub>8</sub>  |
| <b>9</b>  | HSENN                 | <b>0.545</b> <sub>9</sub>  |
| <b>10</b> | PotTS                 | <b>0.818</b> <sub>10</sub> |
|           | Baseline <sub>1</sub> | <b>0.474</b>               |
|           | Baseline <sub>2</sub> | <b>0.734</b>               |

**Table 14:** Results for Subtask E “Tweet quantification according to a five-point scale” on the Tweet 2016 dataset. The systems are ordered by their *EMD* score (lower is better). The meaning of “(\*)” is as in Table 8.

Only 3 of the 10 participants tuned their systems to the specific characteristics of this subtask, i.e., to the fact that it deals with quantification (as opposed to classification) *and* to the fact that it has an ordinal (as opposed to binary) nature.

In particular, the top-scoring team (QCRI<sub>1</sub>) used a novel algorithm explicitly designed for ordinal quantification, that leverages an ordinal hierarchy of binary probabilistic quantifiers.

Team NRU-HSE<sub>4</sub> uses an existing quantification approach based on cost-sensitive learning, and adapted it to the ordinal case.

Team ISTI-CNR<sub>6</sub> instead used a novel adaptation to quantification of a tree-based approach to ordinal regression.

Teams LYS<sub>7</sub> and HSENN<sub>9</sub> also used an existing quantification approach, but did not exploit the ordinal nature of the problem.

The other teams mostly used approaches based on “classify and count” (see Section 5.4), and viewed the problem as single-label multi-class (instead of ordinal) classification; some of these teams (notably, team Finki<sub>2</sub>) obtained very good results, which testifies to the quality of the (general-purpose) features and learning algorithm they used.

## 6 Conclusion and Future Work

We described SemEval-2016 Task 4 “Sentiment Analysis in Twitter”, which included five subtasks including three that represent a significant departure from previous editions. The three new subtasks focused, individually or in combination, on two variants of the basic “sentiment classification in Twitter” task that had not been previously explored within SemEval. The first variant adopts a five-point scale, which confers an *ordinal* character to the classification task. The second variant focuses on the correct estimation of the prevalence of each class of interest, a task which has been called *quantification* in the supervised learning literature. In contrast, previous years’ subtasks have focused on the correct labeling of individual tweets. As in previous years (2013–2015), the 2016 task was very popular and attracted a total of 43 teams.

A general trend that emerges from SemEval-2016 Task 4 is that most teams who were ranked at the top in the various subtasks used deep learning, including convolutional NNs, recurrent NNs, and (general-purpose or task-specific) word embeddings. In many cases, the use of these techniques allowed the teams using them to obtain good scores even without tuning their system to the specifics of the subtask at hand, e.g., even without exploiting the ordinal nature of the subtask – for Subtasks C and E – or the quantification-related nature of the subtask – for Subtasks D and E. Conversely, several teams that have indeed tuned their system to the specifics of the subtask at hand, but have not used deep learning techniques, have performed less satisfactorily. This is a further confirmation of the power of deep learning techniques for tweet sentiment analysis.

Concerning Subtasks D and E, if quantification-based subtasks are proposed again, we think it might be a good idea to generate, for each test topic  $t_i$ , multiple “artificial” test topics  $t_i^1, t_i^2, \dots$ , where class prevalences are altered with respect to the ones of  $t_i$  by means of selectively removing from  $t_i$  tweets belonging to a certain class. In this way, the evaluation can take into consideration (i) class prevalences in the test set and (ii) levels of distribution drift (i.e., of the divergence of the test distribution from the training distribution) that are not present in the “naturally occurring” data.

By varying the amount of removed tweets at will, one may obtain *many* test topics, thus augmenting the magnitude of the experimentation at will while at the same time keeping constant the amount of manual annotation needed.

In terms of possible follow-ups of this task, it might be interesting to have a subtask whose goal is to distinguish tweets that are NEUTRAL about the topic (i.e., do not express any opinion about the topic) from tweets that express a FAIR opinion (i.e., lukewarm, intermediate between POSITIVE and NEGATIVE) about the topic.

Another possibility is to have a multi-lingual tweet sentiment classification subtask, where training examples are provided for the same topic for two languages (e.g., English and Arabic), and where participants can improve their performance on one language by leveraging the training examples for the other language via transfer learning. Alternatively, it might be interesting to include a cross-lingual tweet sentiment classification subtask, where training examples are provided for a given language (e.g., English) but not for the other (e.g., Arabic); the second language could be also a surprise language, which could be announced at the last moment.

## Abstract

This paper describes the SemEval 2016 shared task on Aspect Based Sentiment Analysis (ABSA), a continuation of the respective tasks of 2014 and 2015. In its third year, the task provided 19 training and 20 testing datasets for 8 languages and 7 domains, as well as a common evaluation procedure. From these datasets, 25 were for sentence-level and 14 for text-level ABSA; the latter was introduced for the first time as a subtask in SemEval. The task attracted 245 submissions from 29 teams.

## 1 Introduction

Many consumers use the Web to share their experiences about products, services or travel destinations (Yoo and Gretzel, 2008). Online opinionated texts (e.g., reviews, tweets) are important for consumer decision making (Chevalier and Mayzlin, 2006) and constitute a source of valuable customer feedback that can help companies to measure satisfaction and improve their products or services. In this setting, Aspect Based Sentiment Analysis (ABSA) - i.e., mining opinions from text about specific entities and their aspects (Liu, 2012) - can provide valuable insights to both consumers and businesses. An ABSA

**Figure 1:** Table summarizing the average sentiment for each aspect of an entity.

method can analyze large amounts of unstructured texts and extract (coarse- or fine-grained) information not included in the user ratings that are available in some review sites (e.g., Fig. 1).

Sentiment Analysis (SA) touches every aspect (e.g., entity recognition, coreference resolution, negation handling) of Natural Language Processing (Liu, 2012) and as Cambria et al. (2013) mention “*it requires a deep understanding of the explicit and implicit, regular and irregular, and syntactic and semantic language rules*”. Within the last few years several SA-related shared tasks have been organized in the context of workshops and conferences focus-

\*Corresponding author: mpontiki@ilsp.gr.

ing on somewhat different research problems (Seki et al., 2007; Seki et al., 2008; Seki et al., 2010; Mitchell, 2013; Nakov et al., 2013; Rosenthal et al., 2014; Pontiki et al., 2014; Rosenthal et al., 2015; Ghosh et al., 2015; Pontiki et al., 2015; Mohammad et al., 2016; Recupero and Cambria, 2014; Ruppenhofer et al., 2014; Loukachevitch et al., 2015). Such competitions provide training datasets and the opportunity for direct comparison of different approaches on common test sets.

Currently, most of the available SA-related datasets, whether released in the context of shared tasks or not (Socher et al., 2013; Ganu et al., 2009), are monolingual and usually focus on English texts. Multilingual datasets (Klinger and Cimiano, 2014; Jiménez-Zafra et al., 2015) provide additional benefits enabling the development and testing of cross-lingual methods (Lambert, 2015). Following this direction, this year the SemEval ABSA task provided datasets in a variety of languages.

ABSA was introduced as a shared task for the first time in the context of SemEval in 2014; SemEval-2014 Task 4<sup>1</sup> (SE-ABSA14) provided datasets of English reviews annotated at the sentence level with aspect terms (e.g., “mouse”, “pizza”) and their polarity for the laptop and restaurant domains, as well as coarser aspect categories (e.g., “FOOD”) and their polarity only for restaurants (Pontiki et al., 2014). SemEval-2015 Task 12<sup>2</sup> (SE-ABSA15) built upon SE-ABSA14 and consolidated its subtasks into a unified framework in which all the identified constituents of the expressed opinions (i.e., aspects, opinion target expressions and sentiment polarities) meet a set of guidelines and are linked to each other within sentence-level tuples (Pontiki et al., 2015). These tuples are important since they indicate the part of text within which a specific opinion is expressed. However, a user might also be interested in the overall rating of the text towards a particular aspect. Such ratings can be used to estimate the mean sentiment per aspect from multiple reviews (McAuley et al., 2012). Therefore, in addition to sentence-level annotations, SE-ABSA16<sup>3</sup> accommodated also text-level ABSA annotations and provided the respective training and testing data. Fur-

thermore, the SE-ABSA15 annotation framework was extended to new domains and applied to languages other than English (Arabic, Chinese, Dutch, French, Russian, Spanish, and Turkish).

The remainder of this paper is organized as follows: the task set-up is described in Section 2. Section 3 provides information about the datasets and the annotation process, while Section 4 presents the evaluation measures and the baselines. General information about participation in the task is provided in Section 5. The evaluation scores of the participating systems are presented and discussed in Section 6. The paper concludes with an overall assessment of the task.

## 2 Task Description

The SE-ABSA16 task consisted of the following subtasks and slots. Participants were free to choose the subtasks, slots, domains and languages they wished to participate in.

**Subtask 1 (SB1): Sentence-level ABSA.** Given an opinionated text about a target entity, identify all the opinion tuples with the following types (tuple slots) of information:

- **Slot1: Aspect Category.** Identification of the entity E and attribute A pairs towards which an opinion is expressed in a given sentence. E and A should be chosen from predefined inventories<sup>4</sup> of entity types (e.g., “RESTAURANT”, “FOOD”) and attribute labels (e.g., “PRICE”, “QUALITY”).
- **Slot2: Opinion Target Expression (OTE).** Extraction of the linguistic expression used in the given text to refer to the reviewed entity E of each E#A pair. The OTE is defined by its starting and ending offsets. When there is no explicit mention of the entity, the slot takes the value “NULL”. The identification of Slot2 values was required only in the restaurants, hotels, museums and telecommunications domains.
- **Slot3: Sentiment Polarity.** Each identified E#A pair has to be assigned one of the following polarity labels: “positive”, “negative”, “neutral” (mildly positive or mildly negative).

Table 1: Datasets provided for SE-ABSA16.

An example of opinion tuples with Slot1-3 values from the restaurants domain is shown below: “*Their sake list was extensive, but we were looking for Purple Haze, which wasn’t listed but made for us upon request!*” → {cat: “DRINKS#STYLE\_OPTIONS”, trg: “sake list”, fr: “6”, to: “15”, pol: “positive”}, {cat: “SERVICE#GENERAL”, trg: “NULL”, fr: “0”, to: “0”, pol: “positive”}. The variable *cat* indicates the aspect category (Slot1), *pol* the polarity (Slot3), and *trg* the OTE (Slot2); *fr*, *to* are the starting/ending offsets of OTE.

**Subtask 2 (SB2): Text-level ABSA.** Given a customer review about a target entity, the goal was to identify a set of  $\{cat, pol\}$  tuples that summarize the opinions expressed in the review. *cat* can be assigned the same values as in SB1 (E#A tuple), while *pol* can be set to “positive”, “negative”, “neutral”, or “conflict”. For example, for the review text “*The So called laptop Runs to Slow and I hate it! Do not buy it! It is the worst laptop ever*”, a system should return the following opinion tuples: {cat: “LAPTOP#GENERAL”, pol: “negative”}, {cat: “LAPTOP#OPERATION\_PERFORMANCE”, pol: “negative”}.

**Subtask 3 (SB3): Out-of-domain ABSA.** In SB3 participants had the opportunity to test their systems

in domains for which no training data was made available; the domains remained unknown until the start of the evaluation period. Test data for SB3 were provided only for the museums domain in French.

### 3 Datasets

#### 3.1 Data Collection and Annotation

A total of 39 datasets were provided in the context of the SE-ABSA16 task; 19 for training and 20 for testing. The texts were from 7 domains and 8 languages; English (EN), Arabic (AR), Chinese (CH), Dutch (DU), French (FR), Russian (RU), Spanish (ES) and Turkish (TU). The datasets for the domains of restaurants (REST), laptops (LAPT), mobile phones (PHNS), digital cameras (CAME), hotels (HOTE) and museums (MUSE) consist of customer reviews, whilst the telecommunication domain (TELC) data consists of tweets. A total of 70790 manually annotated ABSA tuples were provided for training and testing; 47654 sentence-level annotations (SB1) in 8 languages for 7 domains, and 23136 text-level annotations (SB2) in 6 languages for 3 domains. Table 1 provides more information on the distribution of texts, sentences and annotated tuples per dataset.

The REST, HOTE, and LAPT datasets were annotated

at the sentence-level (SB1) following the respective annotation schemas of SE-ABSA15 (Pontiki et al., 2015). Below are examples<sup>5</sup> of annotated sentences for the aspect category “SERVICE#GENERAL” in EN (1), DU (2), FR (3), RU (4), ES (5), and TU (6) for the REST domain and in AR (7) for the HOTE domain:

1. Service was slow, but the people were friendly.  
→ {trg: “Service”, pol: “negative”}, {trg: “people”, pol: “positive”}
2. Snelle bediening en vriendelijk personeel moet ook gemeld worden!! → {trg: “bediening”, pol: “positive”}, {trg: “personeel”, pol: “positive”}
3. Le service est impeccable, personnel agréable.  
→ {trg: “service”, pol: “positive”}, {trg: “personnel”, pol: “positive”}
4. Про сервис ничего негативного не скажешь – быстро подходят, все улыбаются, подходят спрашивают, всё ли нравится. → {trg: “сервис”, pol: “neutral” }
5. También la rapidez en el servicio. → {trg: “servicio”, pol: “positive” }
6. Servisi hızlı valesi var. → {trg: “Servisi”, pol: “positive”}
7. الخدمة“ .. → الخدمة جيدة جدا و سريعة .. {trg: “الخدمة” , pol: “positive”}

The LAPT annotation schema was extended to two other domains of consumer electronics, CAME and PHNS. Examples of annotated sentences in the LAPT (EN), PHNS (DU and CH) and CAME (CH) domains are shown below:

1. It is extremely portable and easily connects to WIFI at the library and elsewhere. → {cat: “LAPTOP#PORTABILITY”, pol: “positive”} , {cat: “LAPTOP#CONNECTIVITY”, pol: “positive”}
2. Apps starten snel op en werken vlot, internet gaat prima. → {cat: “SOFTWARE#OPERATION\_PERFORMANCE”, pol: “positive”}, {cat: “PHONE#CONNECTIVITY”, pol: “positive”}

---

<sup>5</sup>The offsets of the opinion target expressions are omitted.

3. 当然屏幕这么好 →{cat: “DISPLAY#QUALITY”, pol: “positive”}

4. 更轻便的机身也便于携带。 → {cat: “CAMERA# PORTABILITY”, pol: “positive”}

In addition, the SE-ABSA15 framework was extended to two new domains for which annotation guidelines were compiled: TELC for TU and MUSE for FR. Below are two examples:

1. #Internet kopuyor sürekli :( @turkcell → {cat: “INTERNET#COVERAGE”, trg: “Internet”, pol: “positive”}
2. 5€ pour les étudiants, ça vaut le coup. → {cat: “MUSEUM#PRICES”, “NULL”, “positive”}

The text-level (SB2) annotation task was based on the sentence-level annotations; given a customer review about a target entity (e.g., a restaurant) that included sentence-level annotations of ABSA tuples, the goal was to identify a set of {cat, pol} tuples that summarize the opinions expressed in it. This was not a simple summation/aggregation of the sentence-level annotations since an aspect may be discussed with different sentiment in different parts of the review. In such cases the dominant sentiment had to be identified. In case of conflicting opinions where the dominant sentiment was not clear, the “conflict” label was assigned. In addition, each review was assigned an overall sentiment label about the target entity (e.g., “RESTAURANT#GENERAL”, “LAPTOP#GENERAL”), even if it was not included in the sentence-level annotations.

### 3.2 Annotation Process

All datasets for each language were prepared by one or more research groups as shown in Table 2. The EN, DU, FR, RU and ES datasets were annotated using BRAT (Stenetorp et al., 2012), a web-based annotation tool, which was configured appropriately for the needs of the task. The TU datasets were annotated using a customized version of TURKSENT (Eryigit et al., 2013), a sentiment annotation tool for social media. For the AR and the CH data in-house tools<sup>6</sup> were used.

---

<sup>6</sup>The AR annotation tool was developed by the technical team of the Advanced Arabic Text Mining group at Jordan University of Science and Technology. The CH tool was developed by the Research Center for Social Computing and Information Retrieval at Harbin Institute of Technology.

**Table 2:** Research teams that contributed to the creation of the datasets for each language.

Below are some further details about the annotation process for each language.

*English.* The SE-ABSA15 (Pontiki et al., 2015) training and test datasets (with some minor corrections) were merged and provided for training (REST and LAPT domains). New data was collected and annotated from scratch for testing. In a first phase, the REST test data was annotated by an experienced<sup>7</sup> linguist (annotator A), and the LAPT data by 5 undergraduate computer science students. The resulting annotations for both domains were then inspected and corrected (if needed) by a second expert linguist, one of the task organizers (annotator B). Borderline cases were resolved collaboratively by annotators A and B.

*Arabic.* The HOTE dataset was annotated in repeated cycles. In a first phase, the data was annotated by three native Arabic speakers, all with a computer science background; then the output was validated by a senior researcher, one of the task organizers. If needed (e.g. when inconsistencies were found) they were given back to the annotators.

*Chinese.* The datasets presented by Zhao et al. (2015) were re-annotated by three native Chinese speakers according to the SE-ABSA16 annotation schema and were provided for training and testing (PHNS and CAME domains).

*Dutch.* The REST and PHNS datasets (De Clercq and Hoste, 2016) were initially annotated by a trained linguist, native speaker of Dutch. Then, the output was verified by another Dutch linguist and disagreements were resolved between them. Fi-

nally, the task organizers inspected collaboratively all the annotated data and corrections were made when needed.

*French.* The train (REST) and test (REST, MUSE) datasets were annotated from scratch by a linguist, native speaker of French. When the annotator was not confident, a decision was made collaboratively with the organizers. In a second phase, the task organizers checked all the annotations for mistakes and inconsistencies and corrected them, when necessary. For more information on the French datasets consult Apidianaki et al. (2016).

*Russian.* The REST datasets of the SentiRuEval-2015 task (Loukachevitch et al., 2015) were automatically converted to the SE-ABSA16 annotation schema; then a linguist, native speaker of Russian, checked them and added missing information. Finally, the datasets were inspected by a second linguist annotator (also native speaker of Russian) for mistakes and inconsistencies, which were resolved along with one of the task organizers.

*Spanish.* Initially, 50 texts (134 sentences) from the whole available data were annotated by 4 annotators. The inter-annotator agreement (IAA) in terms of F-1 was 91% for the identification of OTE, 88% for the aspect category detection (E#A pair), and 80% for opinion tuples extraction (E#A, OTE, polarity). Provided that the IAA was substantially high for all slots, the rest of the data was divided into 4 parts and each one was annotated by a different native Spanish speakers (2 linguists and 2 software engineers). Subsequently, the resulting annotations were validated and corrected (if needed) by the task organizers.

<sup>7</sup>Also annotator for SE-ABSA14 and 15.

*Turkish*. The TELC dataset was based on the data used in (Yıldırım et al., 2015), while the REST dataset was created from scratch. Both datasets were annotated simultaneously by two linguists. Then, one of the organizers validated/inspected the resulting annotations and corrected them when needed.

### 3.3 Datasets Format and Availability

Similarly to SE-ABSA14 and SE-ABSA15, the datasets<sup>8</sup> of SE-ABSA16 were provided in an XML format and they are available under specific license terms through META-SHARE<sup>9</sup>, a repository devoted to the sharing and dissemination of language resources (Piperidis, 2012).

## 4 Evaluation Measures and Baselines

The evaluation ran in two phases. In the first phase (Phase A), the participants were asked to return separately the aspect categories (Slot1), the OTEs (Slot2), and the {Slot1, Slot2} tuples for SB1. For SB2 the respective text-level categories had to be identified. In the second phase (Phase B), the gold annotations for the test sets of Phase A were provided and participants had to return the respective sentiment polarity values (Slot3). Similarly to SE-ABSA15, F-1 scores were calculated for Slot1, Slot2 and {Slot1, Slot2} tuples, by comparing the annotations that a system returned to the gold annotations (using micro-averaging). For Slot1 evaluation, duplicate occurrences of categories were ignored in both SB1 and SB2. For Slot2, the calculation for each sentence considered only distinct targets and discarded “NULL” targets, since they do not correspond to explicit mentions. To evaluate sentiment polarity classification (Slot3) in Phase B, we calculated the accuracy of each system, defined as the number of correctly predicted polarity labels of the (gold) aspect categories, divided by the total number of the gold aspect categories. Furthermore, we implemented and provided baselines for all slots of SB1 and SB2. In particular, the SE-ABSA15 baselines that were implemented for the English language

<sup>8</sup>The data are available at: <http://metashare.ilsp.gr:8080/repository/search/?q=semeval+2016>

<sup>9</sup>META-SHARE (<http://www.metashare.org/>) was implemented in the framework of the META-NET Network of Excellence (<http://www.meta-net.eu/>).

(Pontiki et al., 2015), were adapted for the other languages by using appropriate stopword lists and tokenization functions. The baselines are briefly discussed below:

**SB1-Slot1:** For category (E#A) extraction, a Support Vector Machine (SVM) with a linear kernel is trained. In particular,  $n$  unigram features are extracted from the respective sentence of each tuple that is encountered in the training data. The category value (e.g., “SERVICE#GENERAL”) of the tuple is used as the correct label of the feature vector. Similarly, for each test sentence  $s$ , a feature vector is built and the trained SVM is used to predict the probabilities of assigning each possible category to  $s$  (e.g., {“SERVICE#GENERAL”, 0.2}, {“RESTAURANT#GENERAL”, 0.4}). Then, a threshold<sup>10</sup>  $t$  is used to decide which of the categories will be assigned<sup>11</sup> to  $s$ . As features, we use the 1,000 most frequent unigrams of the training data excluding stopwords.

**SB1-Slot2:** The baseline uses the training reviews to create for each category  $c$  (e.g., “SERVICE#GENERAL”) a list of OTEs (e.g., “SERVICE#GENERAL” → {“staff”, “waiter”}). These are extracted from the (training) opinion tuples whose category value is  $c$ . Then, given a test sentence  $s$  and an assigned category  $c$ , the baseline finds in  $s$  the first occurrence of each OTE of  $c$ ’s list. The OTE slot is filled with the first of the target occurrences found in  $s$ . If no target occurrences are found, the slot is assigned the value “NULL”.

**SB1-Slot3:** For polarity prediction we trained a SVM classifier with a linear kernel. Again, as in Slot1,  $n$  unigram features are extracted from the respective sentence of each tuple of the training data. In addition, an integer-valued feature<sup>12</sup> that indicates the category of the tuple is used. The correct label for the extracted training feature vector is the corresponding polarity value (e.g., “positive”). Then, for each tuple {category, OTE} of a test sentence  $s$ , a feature vector is built and classified using the trained SVM.

**SB2-Slot1:** The sentence-level tuples returned by the SB1 baseline are copied to the text level and duplicates are removed.

<sup>10</sup>The threshold  $t$  was set to 0.2 for all datasets.

<sup>11</sup>We use the –b 1 option of LibSVM to obtain probabilities.

<sup>12</sup>Each E#A pair has been assigned a distinct integer value.

Table 3: English REST results for SB1.

**SB2-Slot3:** For each text-level aspect category  $c$  the baseline traverses the predicted sentence-level tuples of the same category returned by the respective SB1 baseline and counts the polarity labels (positive, negative, neutral). Finally, the polarity label with the highest frequency is assigned to the text-level category  $c$ . If there are no sentence-level tuples for the same  $c$ , the polarity label is determined based on all tuples regardless of  $c$ .

The baseline systems and evaluation scripts are implemented in Java and are available for download from the SE-ABSA16 website<sup>13</sup>. The LibSVM package<sup>14</sup> (Chang and Lin, 2011) is used for SVM training and prediction. The scores of the baselines

in the test datasets are presented in Section 6 along with the system scores.

## 5 Participation

The task attracted in total 245 submissions from 29 teams. The majority of the submissions (216 runs) were for SB1. The newly introduced SB2 attracted 29 submissions from 5 teams in 2 languages (en and sp). Most of the submissions (168) were runs for the REST domain. This was expected, mainly for two reasons; first, the REST classification schema is less fine-grained (complex) compared to the other domains (e.g., LAPT). Secondly, this domain was supported for 6 languages enabling also multilingual or language-agnostic approaches. The remaining submissions were distributed as follows: 54 in LAPT, 12 in PHNS, 7 in CAME and 4 in HOTE.

Table 4: REST and HOTE results for SB1.

An interesting observation is that, unlike SE-ABSA15, Slot1 (aspect category detection) attracted significantly more submissions than Slot2 (OTE extraction); this may indicate a shift towards concept-level approaches. Regarding participation per language, the majority of the submissions (156/245) were for EN; see more information in Table 5. Most teams (20) submitted results only for one language (18 for EN and 2 for RU). Of the remaining teams, 3 submitted results for 2 languages, 5 teams submitted results for 3-7 languages, while only one team participated in all languages.

## 6 Evaluation Results

The evaluation results are presented in Tables 3 (SB1: REST-EN), 4 (SB1: REST-ES, FR, RU, DU, TU & HOTE-AR), 6 (SB1: LAPT, CAME, PHNS), and 7 (SB2)<sup>15</sup>. Each participating team was allowed to submit up to two runs per slot and domain in each phase; one constrained (C), where only the provided training data could be used, and one unconstrained (U), where other resources (e.g., publicly available

<sup>15</sup>No submissions were made for sb3-MUSE-FR & sb1-TELC-TU.

| Language | Teams | Submissions |
|----------|-------|-------------|
| English  | 27    | 156         |
| Arabic   | 3     | 4           |
| Chinese  | 3     | 14          |
| Dutch    | 4     | 16          |
| French   | 5     | 13          |
| Russian  | 5     | 15          |
| Spanish  | 6     | 21          |
| Turkish  | 3     | 6           |
| All      | 29    | 245         |

**Table 5:** Number of participating teams and submitted runs per language.

lexica) and additional data of any kind could be used for training. In the latter case, the teams had to report the resources used. Delayed submissions (i.e., runs submitted after the deadline and the release of the gold annotations) are marked with “\*”.

As revealed by the results, in both SB1 and SB2 the majority of the systems surpassed the baseline by a small or large margin and, as expected, the unconstrained systems achieved better results than the constrained ones. In SB1, the teams with the highest scores for Slot1 and Slot2 achieved similar F-1 scores (see Table 3) in most cases (e.g., EN/REST, ES/REST, DU/REST, FR/REST), which shows that the two slots have a similar level of difficulty. However, as expected, the {Slot1, Slot2} scores were significantly lower since the linking of the target expressions to the corresponding aspects is also required. The highest scores in SB1 for all slots (Slot1, Slot2, {Slot1, Slot2}, Slot3) were achieved in the EN/REST; this is probably due to the high participation and to the lower complexity of the REST annotation schema compared to the other domains. If we compare the results for SB1 and SB2, we notice that the SB2 scores for Slot1 are significantly higher (e.g., EN/LAPT, EN/REST, ES/REST) even though the respective annotations are for the same (or almost the same) set of texts. This is due to the fact that it is easier to identify whether a whole text discusses an aspect  $c$  than finding all the sentences in the text discussing  $c$ . On the other hand, for Slot3, the SB2 scores are lower (e.g., EN/REST, ES/REST, RU/REST, EN/LAPT) than the respective SB1 scores. This is mainly because an aspect may be discussed at different points in a text and often with different sentiment. In such cases a system has to identify the dominant sentiment, which

| Lang./Dom. | Slot1 F-1   | Slot3 Acc.  |

usually is not trivial.

## 7 Conclusions

In its third year, the SemEval ABSA task provided 19 training and 20 testing datasets, from 7 domains and 8 languages, attracting 245 submissions from 29 teams. The use of the same annotation guidelines for domains addressed in different languages gives the opportunity to experiment also with cross-lingual or language-agnostic approaches. In addition, SE-ABSA16 included for the first time a text-

level subtask. Future work will address the creation of datasets in more languages and domains and the enrichment of the annotation schemas with other types of SA-related information like topics, events and figures of speech (e.g., irony, metaphor).

## Acknowledgments

The authors are grateful to all the annotators and contributors for their valuable support to the task: Konstantina Papanikolaou, Juli Bakagianni, Omar Qwasmeh, Nesreen Alqasem, Areen Magableh, Saja Alzoubi, Bashar Talafha, Zekui Li, Binbin Li, Shengqiu Li, Aaron Gevaert, Els Lefever, Cécile Richart, Pavel Blinov, Maria Shatalova, M. Teresa Martín-Valdivia, Pilar Santolaria, Fatih Samet Çetin, Ezgi Yıldırım, Can Özbeý, Leonidas Valavanis, Stavros Giorgis, Dionysios Xenos, Panos Theodor-

akakos, and Apostolos Rousas. The work described in this paper is partially funded by the projects EOX GR07/3712 and “Research Programs for Excellence 2014-2016 / CitySense-ATHENA R.I.C.”. The Arabic track was partially supported by the Jordan University of Science and Technology, Research Grant Number: 20150164. The Dutch track has been partly funded by the PARIS project (IWT-SBO-Nr. 110067). The French track was partially supported by the French National Research Agency under project ANR-12-CORD-0015/TransRead. The Russian track was partially supported by the Russian Foundation for Basic Research (RFBR) according to the research projects No. 14-07-00682a, 16-07-00342a, and No. 16-37-00311mol\_a. The Spanish track has been partially supported by a grant from the Ministerio de Educación, Cultura y Deporte (MECD - scholarship FPU014/00983) and REDES project (TIN2015-65136-C2-1-R) from the Ministerio de Economía y Competitividad. The Turkish track was partially supported by TUBITAK-TEYDEB (The Scientific and Technological Research Council of Turkey – Technology and Innovation Funding Programs Directorate) project (grant number: 3140671).

## Abstract

Here for the first time we present a shared task on detecting stance from tweets: given a tweet and a target entity (person, organization, etc.), automatic natural language systems must determine whether the tweeter is in favor of the given target, against the given target, or whether neither inference is likely. The target of interest may or may not be referred to in the tweet, and it may or may not be the target of opinion. Two tasks are proposed. Task A is a traditional supervised classification task where 70% of the annotated data for a target is used as training and the rest for testing. For Task B, we use as test data all of the instances for a new target (not used in task A) and no training data is provided. Our shared task received submissions from 19 teams for Task A and from 9 teams for Task B. The highest classification F-score obtained was 67.82 for Task A and 56.28 for Task B. However, systems found it markedly more difficult to infer stance towards the target of interest from tweets that express opinion towards another entity.

## 1 Introduction

Stance detection is the task of automatically determining from text whether the author of the text is in favor of, against, or neutral towards a proposition or target. The target may be a person, an organization, a government policy, a movement, a product, etc. For example, one can infer from Barack Obama’s speeches that he is in favor of stricter gun laws in the US. Similarly, people often express stance towards various target entities through posts on online

forums, blogs, Twitter, Youtube, Instagram, etc. Automatically detecting stance has widespread applications in information retrieval, text summarization, and textual entailment.

The task we explore is formulated as follows: given a tweet text and a target entity (person, organization, movement, policy, etc.), automatic natural language systems must determine whether the tweeter is in favor of the given target, against the given target, or whether neither inference is likely. For example, consider the target–tweet pair:

Target: legalization of abortion (1)

Tweet: *The pregnant are more than walking incubators, and have rights!*

We can deduce from the tweet that the tweeter is likely in favor of the target.<sup>1</sup>

We annotated 4870 English tweets for stance towards six commonly known targets in the United States. The data corresponding to five of the targets (‘Atheism’, ‘Climate Change is a Real Concern’, ‘Feminist Movement’, ‘Hillary Clinton’, and ‘Legalization of Abortion’) was used in a standard supervised stance detection task – *Task A*. About 70% of the tweets per target were used for training and the remaining for testing. All of the data corresponding to the target ‘Donald Trump’ was used as test set in a separate task – *Task B*. No training data labeled with stance towards ‘Donald Trump’ was provided. However, participants were free to use data from Task A to develop their models for Task B.

<sup>1</sup>Note that we use ‘tweet’ to refer to the text of the tweet and not to its meta-information. In our annotation task, we asked respondents to label for stance towards a given target based on the tweet text alone. However, automatic systems may benefit from exploiting tweet meta-information.

Task A received submissions from 19 teams, wherein the highest classification F-score obtained was 67.82. Task B, which is particularly challenging due to lack of training data, received submissions from 9 teams wherein the highest classification F-score obtained was 56.28. The best performing systems used standard text classification features such as those drawn from  $n$ -grams, word vectors, and sentiment lexicons. Some teams drew additional gains from noisy stance-labeled data created using distant supervision techniques. A large number of teams used word embeddings and some used deep neural networks such as RNNs and convolutional neural nets. Nonetheless, for Task A, none of these systems surpassed a baseline SVM classifier that uses word and character  $n$ -grams as features (Mohammad et al., 2016b). Further, results are markedly worse for instances where the target of interest is not the target of opinion.

More gains can be expected in the future on both tasks, as researchers better understand this new task and data. All of the data, an interactive visualization of the data, and the evaluation scripts are available on the task website as well as the homepage for this Stance project.<sup>2</sup>

## 2 Subtleties of Stance Detection

In the sub-sections below we discuss some of the nuances of stance detection, including a discussion on neutral stance and the relationship between stance and sentiment.

### 2.1 Neutral Stance

The classification task formulated here does not include an explicit neutral class. The lack of evidence for ‘favor’ or ‘against’ does not imply that the tweeter is neutral towards the target. It may just be that one cannot deduce stance from the tweet. In fact, this is fairly common. On the other hand, the number of tweets from which we can infer neutral stance is expected to be small. An example is shown below:

Target: Hillary Clinton (2)  
 Tweet: *Hillary Clinton has some strengths and some weaknesses.*

<sup>2</sup><http://alt.qcri.org/semeval2016/task6/>  
<http://www.saifmohammad.com/WebPages/StanceDataset.htm>

Thus, even though we obtain annotations for neutral stance, we eventually merge all classes other than ‘favor’ and ‘against’ into one ‘neither’ class.

### 2.2 Stance and Sentiment

Stance detection is related to, but different from, sentiment analysis. Sentiment analysis tasks are usually formulated as: determining whether a piece of text is positive, negative, or neutral, OR determining from text the speaker’s opinion and the target of the opinion (the entity towards which opinion is expressed). However, in stance detection, systems are to determine favorability towards a given (pre-chosen) target of interest. The target of interest may not be explicitly mentioned in the text and it may not be the target of opinion in the text. For example, consider the target–tweet pair below:

Target: Donald Trump (3)  
 Tweet: *Jeb Bush is the only sane candidate in this republican lineup.*

The target of opinion in the tweet is Jeb Bush, but the given target of interest is Donald Trump. Nonetheless, we can infer that the tweeter is likely to be unfavorable towards Donald Trump. Also note that in stance detection, the target can be expressed in different ways which impacts whether the instance is labeled favour or against. For example, the target in example 1 could have been phrased as ‘pro-life movement’, in which case the correct label for that instance is ‘against’. Also, the same stance (favour or against) towards a given target can be deduced from positive tweets and negative tweets. See Mohammad et al. (2016b) for a quantitative exploration of this interaction between stance and sentiment.

## 3 A Dataset for Stance from Tweets

The stance annotations we use are described in detail in Mohammad et al. (2016a). The same dataset was subsequently also annotated for target of opinion and sentiment (in addition to stance towards a given target) (Mohammad et al., 2016b). These additional annotations are not part of the SemEval-2016 competition, but are made available for future research. We summarize below all relevant details for this shared task: how we compiled a set of tweets and targets for stance annotation (Section 3.1), the questionnaire and crowdsourcing setup used for stance annotation (Section 3.2), and an analysis of the stance annotations (Section 3.3).

### 3.1 Selecting the Tweet–Target Pairs

We wanted to create a dataset of stance-labeled tweet–target pairs with the following properties:

- 1: The tweet and target are commonly understood by a wide number of people in the US. (The data was also eventually annotated for stance by respondents living in the US.)
- 2: There must be a significant amount of data for the three classes: favor, against, and neither.
- 3: Apart from tweets that explicitly mention the target, the dataset should include a significant number of tweets that express opinion towards the target without referring to it by name.
- 4: Apart from tweets that express opinion towards the target, the dataset should include a significant number of tweets in which the target of opinion is different from the given target of interest. Downstream applications often require stance towards particular pre-chosen targets of interest (for example, a company might be interested in stance towards its product). Having data where the target of opinion is some other entity (for example, a competitor’s product) helps test how well stance detection systems can cope with such instances.

To help with Property 1, the authors of this paper compiled a list of target entities commonly known in the United States. (See Table 1 for the list.)

We created a small list of hashtags, which we will call *query hashtags*, that people use when tweeting about the targets. We split these hashtags into three categories: (1) *favor hashtags*: expected to occur in tweets expressing favorable stance towards the target (for example, *#Hillary4President*), (2) *against hashtags*: expected to occur in tweets expressing opposition to the target (for example, *#HillNo*), and (3) *stance-ambiguous hashtags*: expected to occur in tweets about the target, but are not explicitly indicative of stance (for example, *#Hillary2016*). Next, we polled the Twitter API to collect over two million tweets containing these query hashtags. We discarded retweets and tweets with URLs. We kept only those tweets where the query hashtags appeared at the end. We removed the query hashtags from the tweets to exclude obvious cues for the classification task. Since we only select tweets that have the query

hashtag at the end, removing them from the tweet often still results in text that is understandable and grammatical.

Note that the presence of a stance-indicative hashtag is not a guarantee that the tweet will have the same stance.<sup>3</sup> Further, removal of query hashtags may result in a tweet that no longer expresses the same stance as with the query hashtag. Thus we manually annotate the tweet–target pairs after the pre-processing described above. For each target, we sampled an equal number of tweets pertaining to the favor hashtags, the against hashtags, and the stance-ambiguous hashtags—up to 1000 tweets at most per target. This helps in obtaining a sufficient number of tweets pertaining to each of the stance categories (Property 2). Properties 3 and 4 are addressed to some extent by the fact that removing the query hashtag can sometimes result in tweets that do not explicitly mention the target. Consider:

Target: Hillary Clinton (4)  
Tweet: *Benghazi must be answered for #Jeb16*

The query hashtags ‘#HillNo’ was removed from the original tweet, leaving no mention of Hillary Clinton. Yet there is sufficient evidence (through references to Benghazi and #Jeb16) that the tweeter is likely against Hillary Clinton. Further, conceptual targets such as ‘legalization of abortion’ (much more so than person-name targets) have many instances where the target is not explicitly mentioned.

### 3.2 Stance Annotation

The core instructions given to annotators for determining stance are shown below.<sup>4</sup> Additional descriptions within each option (not shown here) make clear that stance can be expressed in many different ways, for example by explicitly supporting or opposing the target, by supporting an entity aligned with or opposed to the target, by re-tweeting somebody else’s tweet, etc.

---

Target of Interest: [target entity]

Tweet: [tweet with query hashtag removed]

Q: From reading the tweet, which of the options below is most likely to be true about the tweeter’s stance or outlook towards the target:

<sup>3</sup>A tweet that has a seemingly favorable hashtag may in fact oppose the target; and this is not uncommon. Similarly unfavorable hashtags may occur in tweets that favor the target.

<sup>4</sup>The full set of instructions is made available on the shared task website (<http://alt.qcri.org/semeval2016/task6/>).

1. We can infer from the tweet that the tweeter supports the target
2. We can infer from the tweet that the tweeter is against the target
3. We can infer from the tweet that the tweeter has a neutral stance towards the target
4. There is no clue in the tweet to reveal the stance of the tweeter towards the target (support/against/neutral)

Each of the tweet-target pairs selected for annotation was uploaded on CrowdFlower for annotation with the questionnaire shown above.<sup>5</sup> Each instance was annotated by at least eight respondents.

### 3.3 Analysis of Stance Annotations

The number of instances that were marked as neutral stance (option 3) was less than 1%. Thus we merged options 3 and 4 into one ‘neither in favor nor against’ option (‘neither’ for short). The inter-annotator agreement was 73.1%. These statistics are for the complete annotated dataset, which include instances that were genuinely difficult to annotate for stance (possibly because the tweets were too ungrammatical or vague) and/or instances that received poor annotations from the crowd workers (possibly because the particular annotator did not understand the tweet or its context). We selected instances with agreement equal to or greater than 60% (at least 5 out of 8 annotators must agree) to create the test and training sets for this task.<sup>6</sup> We will refer to this dataset as the *Stance Dataset*. The inter-annotator agreement on this set is 81.85%. The rest of the instances are kept aside for future investigation. We partitioned the Stance Dataset into training and test sets based on the timestamps of the tweets. All annotated tweets were ordered by their timestamps, and the first 70% of the tweets formed the training set and the last 30% formed the test set. Table 1 shows the number and distribution of instances in the Stance Dataset.

Inspection of the data revealed that often the target is not directly mentioned, and yet stance towards the target was determined by the annotators. About 30% of the ‘Hillary Clinton’ instances and 65% of the ‘Legalization of Abortion’ instances were found to

<sup>5</sup><http://www.crowdflower.com>

<sup>6</sup>The 60% threshold is somewhat arbitrary, but it seemed appropriate in terms of balancing quality and quantity.

be of this kind—they did not mention ‘Hillary’ or ‘Clinton’ and did not mention ‘abortion’, ‘pro-life’, and ‘pro-choice’, respectively (case insensitive; with or without hashtag; with or without hyphen). Examples (1) and (4) shown earlier are instances of this, and are taken from our dataset.

An interactive visualization of the Stance Dataset that shows various statistics about the data is available at the task website. Note that it also shows sentiment and target of opinion annotations (in addition to stance). Clicking on various visualization elements filters the data. For example, clicking on ‘Feminism’ and ‘Favor’ will show information pertaining to only those tweets that express favor towards feminism. One can also use the check boxes on the left to view only test or training data, or data on particular targets.

## 4 Task Setup: Automatic Stance Classification

The Stance Dataset was partitioned so as to be used in two tasks described in the subsections below: Task A (supervised framework) and Task B (weakly supervised framework). Participants could provide submissions for either one of the tasks, or both tasks. Both tasks required classification of tweet-target pairs into exactly one of three classes:

- Favor: We can infer from the tweet that the tweeter supports the target (e.g., directly or indirectly by supporting someone/something, by opposing or criticizing someone/something opposed to the target, or by echoing the stance of somebody else).
- Against: We can infer from the tweet that the tweeter is against the target (e.g., directly or indirectly by opposing or criticizing someone/something, by supporting someone/something opposed to the target, or by echoing the stance of somebody else).
- Neither: none of the above.

### 4.1 Task A: Supervised Framework

This task tested stance towards five targets: ‘Atheism’, ‘Climate Change is a Real Concern’, ‘Feminist Movement’, ‘Hillary Clinton’, and ‘Legalization of Abortion’. Participants were provided

| Target                    | # total | # train | % of instances in Train |         |         | % of instances in Test |       |         |
|---------------------------|---------|---------|-------------------------|---------|---------|------------------------|-------|---------|
|                           |         |         | favor                   | against | neither | # test                 | favor | against |
| <i>Data for Task A</i>    |         |         |                         |         |         |                        |       |         |
| Atheism                   | 733     | 513     | 17.9                    | 59.3    | 22.8    | 220                    | 14.5  | 72.7    |
| Climate Change is Concern | 564     | 395     | 53.7                    | 3.8     | 42.5    | 169                    | 72.8  | 6.5     |
| Feminist Movement         | 949     | 664     | 31.6                    | 49.4    | 19.0    | 285                    | 20.4  | 64.2    |
| Hillary Clinton           | 984     | 689     | 17.1                    | 57.0    | 25.8    | 295                    | 15.3  | 58.3    |
| Legalization of Abortion  | 933     | 653     | 18.5                    | 54.4    | 27.1    | 280                    | 16.4  | 67.5    |
| All                       | 4163    | 2914    | 25.8                    | 47.9    | 26.3    | 1249                   | 24.3  | 57.3    |
| <i>Data for Task B</i>    |         |         |                         |         |         |                        |       |         |
| Donald Trump              | 707     | 0       | -                       | -       | -       | 707                    | 20.93 | 42.29   |
|                           |         |         |                         |         |         |                        |       | 36.78   |

**Table 1:** Distribution of instances in the Stance Train and Test sets for Task A and Task B.

with 2,914 labeled training data instances for the five targets. The test data included 1,249 instances.

#### 4.2 Task B: Weakly Supervised Framework

This task tested stance towards one target ‘Donald Trump’ in 707 tweets. Participants were not provided with any training data for this target. They were given about 78,000 tweets associated with ‘Donald Trump’ to various degrees – the *domain corpus*, but these tweets were not labeled for stance. These tweets were gathered by polling Twitter for hashtags associated with Donald Trump.

#### 4.3 Common Evaluation Metric for Both Task A and Task B

We used the macro-average of the F1-score for ‘favor’ and the F1-score for ‘against’ as the bottom-line evaluation metric.

$$F_{avg} = \frac{F_{favor} + F_{against}}{2} \quad (1)$$

where  $F_{favor}$  and  $F_{against}$  are calculated as shown below:

$$F_{favor} = \frac{2P_{favor}R_{favor}}{P_{favor}+R_{favor}} \quad (2)$$

$$F_{against} = \frac{2P_{against}R_{against}}{P_{against}+R_{against}} \quad (3)$$

Note that the evaluation measure does not disregard the ‘neither’ class. By taking the average F-score for only the ‘favor’ and ‘against’ classes, we treat ‘neither’ as a class that is not of interest—or ‘negative’ class in Information Retrieval (IR) terms. Falsely labeling negative class instances still adversely affects the scores of this metric. If one uses simple accuracy as the evaluation metric, and if the negative class is

very dominant (as is the case in IR), then simply labeling every instance with the negative class will obtain very high scores.

If one randomly accesses tweets, then the probability that one can infer ‘favor’ or ‘against’ stance towards a pre-chosen target of interest is small. This has motivated the IR-like metric used in this competition, even though we worked hard to have marked amounts of ‘favor’ and ‘against’ data in our training and test sets. This metric is also similar to how sentiment prediction was evaluated in recent SemEval competitions.

This evaluation metric can be seen as a micro-average of F-scores across targets (F-microT). Alternatively, one could determine the mean of the  $F_{avg}$  scores for each of the targets—the macro average across targets (F-macroT). Even though not the official competition metric, the F-macroT can easily be determined from the per-target  $F_{avg}$  scores shown in the result tables of Section 5.

The participants were provided with an evaluation script so that they could check the format of their submission and determine performance when gold labels were available.

### 5 Systems and Results for Task A

We now discuss various baseline systems and the official submissions to Task A.

#### 5.1 Task A Baselines

Table 2 presents the results obtained with several baseline classifiers first presented in (Mohammad et al., 2016b). Since the baseline system was developed by some of the organizers of this task, it was

| Team                       |              | Overall       |              |              | Atheism      | Climate      | Feminism     | Hillary      | Abortion  |
|----------------------------|--------------|---------------|--------------|--------------|--------------|--------------|--------------|--------------|-----------|
|                            | $F_{favor}$  | $F_{against}$ | $F_{avg}$    | $F_{avg}$    | $F_{avg}$    | $F_{avg}$    | $F_{avg}$    | $F_{avg}$    | $F_{avg}$ |
| <i>Baselines</i>           |              |               |              |              |              |              |              |              |           |
| Majority class             | 52.01        | <b>78.44</b>  | 65.22        | 42.11        | 42.12        | 39.10        | 36.83        | 40.30        |           |
| SVM-unigrams               | 54.49        | 72.13         | 63.31        | 53.25        | 38.39        | 55.65        | 57.02        | 60.09        |           |
| SVM-ngrams                 | <b>62.98</b> | 74.98         | <b>68.98</b> | <b>65.19</b> | 42.35        | <b>57.46</b> | <b>58.63</b> | <b>66.42</b> |           |
| SVM-ngrams-comb            | 54.11        | 70.01         | 62.06        | 53.27        | <b>47.76</b> | 52.82        | 56.50        | 63.71        |           |
| <i>Participating Teams</i> |              |               |              |              |              |              |              |              |           |
| MITRE                      | 59.32        | <b>76.33</b>  | <b>67.82</b> | 61.47        | 41.63        | <b>62.09</b> | 57.67        | 57.28        |           |
| pkudblab                   | <b>61.98</b> | 72.67         | 67.33        | 63.34        | 52.69        | 51.33        | 64.41        | 61.09        |           |
| TakeLab                    | 60.93        | 72.73         | 66.83        | <b>67.25</b> | 41.25        | 53.01        | <b>67.12</b> | 61.38        |           |

**Table 2:** Results for Task A, reporting the official competition metric as ‘Overall  $F_{avg}$ ’, along with  $F_{favor}$  and  $F_{against}$  over all targets and  $F_{avg}$  for each individual target. The highest scores in each column among the baselines and among the participating systems are shown in bold.

not entered as part of the official competition.

#### Baselines:

1. *Majority class*: a classifier that simply labels every instance with the majority class (‘favor’ or ‘against’) for the corresponding target;
2. *SVM-unigrams*: five SVM classifiers (one per target) trained on the corresponding training set for the target using word unigram features;
3. *SVM-ngrams*: five SVM classifiers (one per target) trained on the corresponding training set for the target using word  $n$ -grams (1-, 2-, and 3-gram) and character  $n$ -grams (2-, 3-, 4-, and 5-gram) features;
4. *SVM-ngrams-comb*: one SVM classifier trained on the combined (all 5 targets) training set using word  $n$ -grams (1-, 2-, and 3-gram) and character  $n$ -grams (2-, 3-, 4-, and 5-gram) features.

The SVM parameters were tuned using 5-fold cross-validation on the training data. The first three columns of the table show the official competition metric (Overall  $F_{avg}$ ) along with the two components that are averaged to obtain it ( $F_{favor}$  and  $F_{against}$ ). The next five columns describe per-target results—the official metric as calculated over each of the targets individually.

Observe that the Overall  $F_{avg}$  for the Majority class baseline is very high. This is mostly due to the differences in the class distributions for the five targets: for most of the targets the majority of the instances are labeled as ‘against’ whereas for target ‘Climate Change is a Real Concern’ most of the data are labeled as ‘favor’. Therefore, the F-scores for the classes ‘favor’ and ‘against’ are more balanced over all targets than for just one target.

We can see that a supervised classifier using unigram features alone produces results markedly

| Team                       | Opinion Towards<br>Target | Opinion Towards<br>Other | All          |

**Table 3:** Results for Task A (the official competition metric  $F_{avg}$ ) on different subsets of the test data. The highest scores in each column among the baselines and among the participating systems are shown in bold.

above the majority baseline for most of the targets. Furthermore, employing higher-order  $n$ -gram features results in substantial improvements for all targets as well as for the Overall  $F_{avg}$ . Training separate classifiers for each target seems a better solution than training a single classifier for all targets even though the combined classifier has access to significantly more data. As expected, the words and concepts used in tweets corresponding to the stance categories do not generalize well across the targets. However, there is one exception: the results for ‘Climate Change’ improve by over 5% when the combined classifier has access to the training data for other targets. This is probably because it has access to more balanced dataset and more representative instances for ‘against’ class. Most teams chose to train separate classifiers for different targets.

## 5.2 Task A Participating Stance Systems

Nineteen teams competed in Task A on supervised stance detection. Table 2 shows each team’s performance, both in aggregate and in terms of individual targets. Teams are sorted in terms of their performance according to the official metric. The best results obtained by a participating system was an Overall  $F_{avg}$  of 67.82 by *MITRE*. Their approach employed two recurrent neural network (RNN) classifiers: the first was trained to predict task-relevant hashtags on a very large unlabeled Twitter corpus. This network was used to initialize a second RNN classifier, which was trained with the provided Task A data. However, this result is not higher than the SVM-ngrams baseline.

In general, per-target results are lower than the Overall  $F_{avg}$ . This is likely due to the fact that it is easier to balance ‘favor’ and ‘against’ classes over all targets than it is for exactly one target. That is, when dealing with all targets, one can use the natural abundance of tweets in favor of concern over climate change to balance against the fact that many of the other targets have a high proportion of tweets against them. Most systems were optimized for the competition metric, which allows cross-target balancing, and thus would naturally perform worse on per-target metrics. *IDI@NTNU* is an interesting exception, as their submission focused on the ‘Climate Change’ target, and they did succeed in producing the best result for that target.

We also calculated Task A results on two subsets of the test set: (1) a subset where opinion is expressed towards the target, (2) a subset where opinion is expressed towards some other entity. Table 3 shows these results. It also shows results on the complete test set (All), for easy reference. Observe that the stance task is markedly more difficult when stance is to be inferred from a tweet expressing opinion about some other entity (and not the target of interest). This is not surprising because it is a more challenging task, and because there has been very little work on this in the past.

## 5.3 Discussion

Most teams used standard text classification features such as  $n$ -grams and word embedding vectors, as well as standard sentiment analysis features such as

those drawn from sentiment lexicons (Kiritchenko et al., 2014b). Some teams polled Twitter for stance-bearing hashtags, creating additional noisy stance data. Three teams tried variants of this strategy: *MITRE*, *DeepStance* and *nldsucsc*. These teams are distributed somewhat evenly throughout the standings, and although *MITRE* did use extra data in its top-placing entry, *pkudblab* achieved nearly the same score with only the provided data.

Another possible differentiator would be the use of continuous word representations, derived either from extremely large sources such as Google News, directly from Twitter corpora, or as a by-product of training a neural network classifier. Nine of the nineteen entries used some form of word embedding, including the top three entries, but *PKULCWM*’s fourth place result shows that it is possible to do well with a more traditional approach that relies instead on Twitter-specific linguistic pre-processing. Along these lines, it is worth noting that both *MITRE* and *pkudblab* reflect knowledge-light approaches to the problem, each relying minimally on linguistic processing and external lexicons.

Seven of the nineteen submissions made extensive use of publicly-available sentiment and emotion lexicons such as the NRC Emotion Lexicon (Mohammad and Turney, 2010), Hu and Liu Lexicon (Hu and Liu, 2004), MPQA Subjectivity Lexicon (Wilson et al., 2005), and NRC Hashtag Lexicons (Kiritchenko et al., 2014b).

Recall that the SVM-ngrams baseline also performed very well, using only word and character  $n$ -grams in its classifiers. This helps emphasize the fact that for this young task, the community is still a long way from an established set of best practices.

## 6 Systems and Results for Task B

The sub-sections below discuss baselines and official submissions to Task B. Recall, that the test data for Task B is for the target ‘Donald Trump’, and no training data for this target was provided.

### 6.1 Task B Baselines

We calculated two baselines listed below:

1. *Majority class*: a classifier that simply labels every instance with the majority class (‘favor’ or ‘against’) for the corresponding target;

| Team                       | $F_{favor}$  | $F_{against}$ | $F_{avg}$    |
|----------------------------|--------------|---------------|--------------|
| <i>Baselines</i>           |              |               |              |
| Majority class             | 0.00         | 59.44         | 29.72        |
| SVM-ngrams-comb            | 18.42        | 38.45         | 28.43        |
| <i>Participating Teams</i> |              |               |              |
| pkudblab                   | <b>57.39</b> | 55.17         | <b>56.28</b> |
| LitisMind                  | 30.04        | <b>59.28</b>  | 44.66        |
| INF-UFRGS                  | 32.56        | 52.09         | 42.32        |
| UWB                        | 34.26        | 49.78         | 42.02        |
| ECNU                       | 17.96        | 50.20         | 34.08        |
| USFD                       | 10.93        | 54.46         | 32.70        |
| Thomson Reuters            | 14.39        | 50.39         | 32.39        |
| ltl.uni-due                | 46.56        | 05.71         | 26.14        |
| NEUSA                      | 16.59        | 34.87         | 25.73        |

**Table 4:** Results for Task B, reporting the official competition metric as  $F_{avg}$ , along with  $F_{favor}$  and  $F_{against}$ . The highest score in each column is shown in bold.

2. *SVM-ngrams-comb*: one SVM classifier trained on the combined (all 5 targets) Task A training set, using word  $n$ -grams (1-, 2-, and 3-gram) and character  $n$ -grams (2-, 3-, 4-, and 5-gram) features.

The results are presented in Table 4. Note that the class distribution for the target ‘Donald Trump’ is more balanced. Therefore, the  $F_{avg}$  for the Majority baseline for this target is much lower than the corresponding values for other targets. Yet, the combined classifier trained on other targets could not beat the Majority baseline on this test set.

### 6.2 Task B Participating Stance Systems

Nine teams competed in Task B. Table 4 shows each team’s performance. Teams are sorted in terms of their performance according to the official metric. The best results obtained by a participating system was an  $F_{avg}$  of 56.28 by *pkudblab*. They used a rule-based annotation of the domain corpus to train a deep convolutional neural network to differentiate ‘favour’ from ‘against’ instances. At test time, they combined their network’s output with rules to produce predictions that include the ‘neither’ class.

In general, results for Task B are lower than those for Task A as one would expect, as we remove the benefit of direct supervision. However, they are perhaps not as low as we might have expected, with the best result of 56.28 actually beating the best result for the supervised ‘Climate Change’ task (54.86).

| Team                       | Opinion Towards |              | All          |
|----------------------------|-----------------|--------------|--------------|

| NEUSA                      | 28.86           | 18.35        | 25.73        |

**Table 5:** Results for Task B (the official competition metric  $F_{avg}$ ) on different subsets of the test data. The highest score in each column is shown in bold.

Table 5 shows results for Task B on subsets of the test set where opinion is expressed towards the target of interest and towards some other entity. Observe that here too results are markedly lower when stance is to be inferred from a tweet expressing opinion about some other entity (and not the target of interest).

### 6.3 Discussion

Some teams did very well detecting tweets in favor of Trump (*ltl.uni-due*), with most of the others performing best on tweets against Trump. This makes sense, as ‘against’ tweets made up the bulk of the Trump dataset. The top team, *pkudblab*, was the only one to successfully balance these two goals, achieving the best  $F_{favor}$  score and the second-best  $F_{against}$  score.

The Task B teams varied wildly in terms of approaches to this problem. The top three teams all took the approach of producing noisy labels, with *pkudblab* using keyword rules, *LitisMind* using hashtag rules on external data, and *INF-UFRGS* using a combination of rules and third-party sentiment classifiers. However, we were pleased to see other teams attempting to generalize the supervised data from Task A in interesting ways, either using rules or multi-stage classifiers to bridge the target gap. We are optimistic that there is much interesting follow-up work yet to come on this task.

Further details on the submissions can be found

in the system description papers published in the SemEval-2016 proceedings, including papers by El-fardy and Diab (2016) for *CU-GWU*, Dias and Becker (2016) for *INF-URGS*, Patra et al. (2016) for *JU\_NLP*, Wojatzki and Zesch (2016) for *ltl.uni-due*, Zarrella and Marsh (2016) for *MITRE*, Misra et al. (2016) for *nldsucsc*, Wei et al. (2016) for *pkudblab*, Tutek et al. (2016) for *TakeLab*, Yuki et al. (2016) for *Tohoku*, and Augenstein et al. (2016) for *USFD*.

## 7 Related Work

Past work on stance detection includes that by Somasundaran and Wiebe (2010), Anand et al. (2011), Faulkner (2014), Rajadesigan and Liu (2014), Djemili et al. (2014), Boltuzic and Šnajder (2014), Conrad et al. (2012), Sridhar et al. (2014), Rajadesigan and Liu (2014), and Sobhani et al. (2015). There is a vast amount of work in sentiment analysis of tweets, and we refer the reader to surveys (Pang and Lee, 2008; Liu and Zhang, 2012; Mohammad, 2015) and proceedings of recent shared task competitions (Wilson et al., 2013; Mohammad et al., 2013; Rosenthal et al., 2015). See Pontiki et al. (2014), Pontiki et al. (2015), and Kiritchenko et al. (2014a) for tasks and systems on aspect based sentiment analysis, where the goal is to determine sentiment towards aspects of a product such as speed of processor and screen resolution of a cell phone.

## 8 Conclusions and Future Work

We described a new shared task on detecting stance towards pre-chosen targets of interest from tweets. We formulated two tasks: a traditional supervised task where labeled training data for the test data targets is made available (Task A) and a more challenging formulation where no labeled data pertaining to the test data targets is available (Task B). We received 19 submissions for Task A and 9 for Task B, with systems utilizing a wide array of features and resources. Stance detection, especially as formulated for Task B, is still in its infancy, and we hope that the dataset made available as part of this task will foster further research not only on stance detection as proposed here, but also for related tasks such as exploring the different ways in which stance is conveyed, and how the distribution of stance towards a target changes over time.

## Acknowledgment

Annotations of the Stance Dataset were funded by the National Research Council of Canada.

## Abstract

We present a shared task on automatically determining sentiment intensity of a word or a phrase. The words and phrases are taken from three domains: general English, English Twitter, and Arabic Twitter. The phrases include those composed of negators, modals, and degree adverbs as well as phrases formed by words with opposing polarities. For each of the three domains, we assembled the datasets that include multi-word phrases and their constituent words, both manually annotated for real-valued sentiment intensity scores. The three datasets were presented as the test sets for three separate tasks (each focusing on a specific domain). Five teams submitted nine system outputs for the three tasks. All datasets created for this shared task are freely available to the research community.

## 1 Introduction

Words have prior associations with sentiment. For example, *honest* and *competent* are associated with positive sentiment, whereas *dishonest* and *dull* are associated with negative sentiment. Further, the degree of positivity (or negativity), also referred to as intensity, can vary. For example, most people will agree that *succeed* is more positive (or less negative) than *improve*, and *fail* is more negative (or less positive) than *setback*. We present a shared task where automatic systems are asked to predict a prior sentiment intensity score for a word or a phrase. The words and phrases are taken from three domains: general English, English Twitter, and Arabic Twitter.

For each domain, a separate task with its own development and test sets was set up. The phrases include those composed of negators (e.g., *nothing wrong*), modals (e.g., *might be fun*), and degree adverbs (e.g., *fairly important*) as well as phrases formed by words with opposing polarities (e.g., *lazy sundays*).

Lists of words and their associated sentiment are commonly referred to as *sentiment lexicons*. They are used in sentiment analysis. For example, a number of unsupervised classifiers rely primarily on sentiment lexicons to determine whether a piece of text is positive or negative. Supervised classifiers also often use features drawn from sentiment lexicons (Mohammad et al., 2013; Pontiki et al., 2014). Sentiment lexicons are also beneficial in stance detection (Mohammad et al., 2016a; Mohammad et al., 2016b), literary analysis (Hartner, 2013; Kleres, 2011; Mohammad, 2012), and for detecting personality traits (Minamikawa and Yokoyama, 2011; Mohammad and Kiritchenko, 2015).

Existing manually created sentiment lexicons tend to provide only lists of positive and negative words (Hu and Liu, 2004; Wilson et al., 2005; Mohammad and Turney, 2013). The coarse-grained distinctions may be less useful in downstream applications than having access to fine-grained (real-valued) sentiment association scores. Most of the existing sentiment resources are available only for English. Non-English resources are scarce and often based on automatic translation of the English lexicons (Abdul-Mageed and Diab, 2014; Eskander and Rambow, 2015). Manually created sentiment lexicons usually include only single words. Yet, the sentiment of a phrase can differ markedly from the

sentiment of its constituent words. Sentiment composition is the determining of sentiment of a multi-word linguistic unit, such as a phrase or a sentence, from its constituents. Lexicons that include sentiment associations for phrases and their constituents are useful in studying sentiment composition. We refer to them as *sentiment composition lexicons*.

Automatically created lexicons often have real-valued sentiment association scores, have a high coverage, can include longer phrases, and can easily be collected for a specific domain. However, due to the lack of manually annotated real-valued sentiment lexicons the quality of automatic lexicons are often assessed only extrinsically through their use in sentence-level sentiment prediction. In this shared task, we intrinsically evaluate automatic methods that estimate sentiment association scores for terms in English and Arabic. For this, we assembled three datasets of phrases and their constituent single words manually annotated for sentiment with real-valued scores (Kiritchenko and Mohammad, 2016a; Kiritchenko and Mohammad, 2016c).

We first introduced this task as part of the SemEval-2015 Task 10 ‘Sentiment Analysis in Twitter’ Subtask E (Rosenthal et al., 2015). The 2015 test set was restricted to English single words and simple two-word negated expressions commonly found in tweets. This year (2016), we broadened the scope of the task and included three different domains. Furthermore, we shifted the focus from single words to longer, more complex phrases to explore sentiment composition.

Five teams submitted nine system outputs for the three tasks. All submitted outputs correlated strongly with the gold term rankings (Kendall’s rank correlation above 0.35). The best results on all tasks were achieved with supervised methods by exploiting a variety of sentiment resources. The highest rank correlation was obtained by team *ECNU* on the General English test set ( $\tau = 0.7$ ). On the other two domains, the results were lower ( $\tau$  of 0.4-0.5).

All datasets created as part of this shared task are freely available through the task website.<sup>1</sup> For ease of exploration, we also created online interactive visualizations for the two English datasets.<sup>2</sup>

## 2 Task Description

The task is formulated as follows: given a list of terms (single words and multi-word phrases), an automatic system needs to provide a score between 0 and 1 that is indicative of the term’s strength of association with positive sentiment. A score of 1 indicates maximum association with positive sentiment (or least association with negative sentiment) and a score of 0 indicates least association with positive sentiment (or maximum association with negative sentiment). If a term is more positive than another, then it should have a higher score than the other.

There are three tasks, one for each of the three domains:

- **General English Sentiment Modifiers Set:** This dataset comprises English single words and multi-word phrases from the general domain. The phrases are formed by combining a word and a modifier, where a modifier is a negator, an auxiliary verb, a degree adverb, or a combination of those, for example, *would be very easy*, *did not harm*, and *would have been nice*. The single word terms are chosen from the set of words that are part of the multi-word phrases, for example, *easy*, *harm*, and *nice*.
- **English Twitter Mixed Polarity Set:** This dataset focuses on English phrases made up of opposing polarity terms, for example, phrases such as *lazy sundays*, *best winter break*, *happy accident* and *couldn’t stop smiling*. The dataset also includes single word terms (as separate entries). These terms are chosen from the set of words that are part of the multi-word phrases. The multi-word phrases and single-word terms are drawn from a corpus of tweets, and include a small number of hashtag words (e.g., *#wantit*) and creatively spelled words (e.g., *plssss*). However, a majority of the terms are those that one would use in everyday English.
- **Arabic Twitter Set:** This dataset includes single words and phrases commonly found in Arabic tweets. The phrases in this set are formed only by combining a negator and a word.

Teams could participate in any one, two, or all three tasks; however, only one submission was al-

| Task                                | Total | Development set |         |     | Test set |         |       |
|-------------------------------------|-------|-----------------|---------|-----|----------|---------|-------|
|                                     |       | words           | phrases | all | words    | phrases | all   |
| General English Sentiment Modifiers | 2,999 | 101             | 99      | 200 | 1,330    | 1,469   | 2,799 |
| English Twitter Mixed Polarity      | 1,269 | 60              | 140     | 200 | 358      | 711     | 1,069 |
| Arabic Twitter                      | 1,366 | 167             | 33      | 200 | 1,001    | 165     | 1,166 |

**Table 1:** The number of single-word and multi-word terms in the development and test sets.

lowed per task. For each task, the above description and a development set (200 terms) were provided to the participants in advance; there were no training sets. The three test sets, one for each task, were released at the start of the evaluation period. The test sets and the development sets have no terms in common. The participants were allowed to use the development sets in any way (for example, for tuning or training), and they were allowed to use any additional manually or automatically generated resources.

In 2015, the task was set up similarly (Rothenthal et al., 2015). Single words and multi-word phrases from English Twitter comprised the development and test sets (1,515 terms in total). The phrases were simple two-word negated expressions (e.g., *can't waitttt*). Participants were allowed to use these datasets for the development of their systems.

### 3 Datasets of English and Arabic Terms Annotated for Sentiment Intensity

The three datasets, General English Sentiment Modifiers Set, English Twitter Mixed Polarity Set, and Arabic Twitter Set, were created through manual annotation using an annotation scheme known as Best–Worst Scaling (described below in Section 3.1). The terms for each set (domain) were chosen as described in Sections 3.2, 3.3, and 3.4, respectively. Note that the exact sources of data and the term selection procedures were not known to the participants. The total number of words and phrases included in each of the datasets can be found in Table 1. Table 2 shows a few example entries from each set.

#### 3.1 Best–Worst Scaling Method of Annotation

Best–Worst Scaling (BWS), also sometimes referred to as Maximum Difference Scaling (MaxDiff), is an annotation scheme that exploits the comparative approach to annotation (Louviere and Woodworth,

| Dataset  | Sentiment score |

| لا امكان (not possible)                        | 0.300           |
| ارهاب (terrorism)                              | 0.056           |

**Table 2:** Examples of entries with real-valued sentiment scores from the three datasets.

1990; Cohen, 2003; Louviere et al., 2015). Annotators are given four items (4-tuple) and asked which item is the Best (highest in terms of the property of interest) and which is the Worst (least in terms of the property of interest). These annotations can then be easily converted into real-valued scores of association between the items and the property, which eventually allows for creating a ranked list of items as per their association with the property of interest. The Best–Worst Scaling method has been shown to produce reliable annotations of terms for sentiment (Kiritchenko and Mohammad, 2016a).

Given  $n$  terms to be annotated, the first step is to randomly sample this set (with replacement) to obtain sets of four terms each, *4-tuples*, that satisfy the following criteria:

1. no two 4-tuples have the same four terms;
2. no two terms within a 4-tuple are identical;

3. each term in the term list appears approximately in the same number of 4-tuples;
4. each pair of terms appears approximately in the same number of 4-tuples.

The terms for the three tasks were annotated separately. For each task,  $2 \times n$  4-tuples were generated, where  $n$  is the total number of terms in the task.

Next, the sets of 4-tuples were annotated through a crowdsourcing platform, CrowdFlower. The annotators were presented with four terms at a time, and asked which term is the most positive (or least negative) and which is the most negative (or least positive). Below is an example annotation question.<sup>3</sup> (The Arabic data was annotated through a similar questionnaire in Arabic.)

---

Focus terms:

1. shameless self promotion
2. happy tears
3. hug
4. major pain

Q1: Identify the term that is associated with the most amount of positive sentiment (or least amount of negative sentiment) – **the most positive term**:

1. shameless self promotion
2. happy tears
3. hug
4. major pain

Q2: Identify the term that is associated with the most amount of negative sentiment (or least amount of positive sentiment) – **the most negative term**:

1. shameless self promotion
  2. happy tears
  3. hug
  4. major pain
- 

Each 4-tuple was annotated by at least eight respondents. Let *majority answer* refer to the option most chosen for a question. For all three datasets, at least 80% of the responses matched the majority answer.

The responses were then translated into real-valued scores and also a ranking of terms by sentiment for all the terms through a simple counting procedure: For each term, its score is calculated as the percentage of times the term was chosen as the most positive minus the percentage of times the term was chosen as the most negative (Orme, 2009; Flynn

---

<sup>3</sup>The full sets of instructions for both English and Arabic datasets are available on the shared task website: <http://alt.qcri.org/semeval2016/task7/>

and Marley, 2014). For this competition, we converted the scores into the range from 0 (the least positive) to 1 (the most positive). The resulting rankings constituted the gold annotations for the three datasets. Finally, random samples of 200 terms from each dataset with the corresponding gold annotations were released to the participants as development sets for the three tasks. The rest of the terms were kept as test sets.

### 3.2 General English Sentiment Modifiers Dataset

The terms for this dataset were taken from the Sentiment Composition Lexicon for Negators, Modals, and Degree Adverbs (SCL-NMA) (Kiritchenko and Mohammad, 2016b).<sup>4</sup> SCL-NMA includes all 1,621 positive and negative words from Osgood’s seminal study on word meaning (Osgood et al., 1957) available in General Inquirer (Stone et al., 1966). In addition, it includes 1,586 high-frequency phrases formed by the Osgood words in combination with simple negators such as *no*, *don’t*, and *never*, modals such as *can*, *might*, and *should*, or degree adverbs such as *very* and *fairly*.<sup>5</sup> The eligible adverbs were chosen manually from adverbs that appeared in combination with an Osgood word at least ten times in the British National Corpus (BNC)<sup>6</sup>. Each phrase includes at least one modal, one negator, or one adverb; a phrase can include several modifiers (e.g., *would be very happy*). Sixty-four different (single or multi-word) modifiers were used in the dataset.

For this shared task, we removed terms that were used in the SemEval-2015 dataset. The final SemEval-2016 General English Sentiment Modifiers dataset contains 2,999 terms.

### 3.3 English Twitter Mixed Polarity Dataset

The terms for this dataset were taken in part from the *Sentiment Composition Lexicon for Opposing Polarity Phrases (SCL-OPP)* (Kiritchenko and Moham-

<sup>4</sup>[www.saifmohammad.com/WebPages/SCL.html#NMA](http://www.saifmohammad.com/WebPages/SCL.html#NMA)

<sup>5</sup>The complete lists of negators, modals, and degree adverbs used in this dataset are available on the task website: <http://alt.qcri.org/semeval2016/task7/>

<sup>6</sup>The British National Corpus, version 3 (BNC XML Edition). 2007. Distributed by Oxford University Computing Services on behalf of the BNC Consortium.  
URL: <http://www.natcorp.ox.ac.uk/>

mad, 2016c).<sup>7</sup> SCL-OPP was created as follows. We polled the Twitter API (from 2013 to 2015) to collect a corpus of tweets that contain emoticons: ‘:)’ or ‘:(’. From this corpus, we selected bigrams and trigrams that had at least one positive word and at least one negative word. The polarity labels (positive or negative) of the words were determined by simple look-up in existing sentiment lexicons: Hu and Liu lexicon (Hu and Liu, 2004), NRC Emotion lexicon (Mohammad and Turney, 2013), MPQA lexicon (Wilson et al., 2005), and NRC’s Twitter-specific lexicon (Kiritchenko et al., 2014).<sup>8</sup> Apart from the requirement of having at least one positive and at least one negative word, an  $n$ -gram must satisfy the following criteria:

- the  $n$ -gram must have a clear meaning on its own, (for example, the  $n$ -gram should not start or end with ‘or’, ‘and’, etc.);
- the  $n$ -gram should not include a named entity;
- the  $n$ -gram should not include obscene language.

In addition, we ensured that there was a good variety of phrases—for example, even though there were a large number of bigrams of the form *super w*, where *w* is a negative adjective, only a small number of such bigrams were included. Finally, we aimed to achieve a good spread in terms of degree of sentiment association (from very negative terms to very positive terms, and all the degrees of polarity in between). For this, we estimated the sentiment score of each phrase using an automatic PMI-based method described in (Kiritchenko et al., 2014). Then, the full range of sentiment values was divided into 5 bins, and approximately the same number of terms were selected from each bin.<sup>9</sup>

In total, 851  $n$ -grams (bigrams and trigrams) were selected. We also chose for annotation all unigrams

---

<sup>7</sup>[www.saifmohammad.com/WebPages/SCL.html#OPP](http://www.saifmohammad.com/WebPages/SCL.html#OPP)

<sup>8</sup>If a word was marked with conflicting polarity in two lexicons, then that word was not considered as positive or negative. For example, the word *defeat* is marked as positive in Hu and Liu lexicon and marked as negative in MPQA; therefore, we did not select any phrases with this word.

<sup>9</sup>Fewer terms were selected from the middle bin that contained phrases with very weak association to sentiment (e.g., phrases like *cancer foundation*, *fair game*, and *a long nap*).

that appeared in the selected set of bigrams and trigrams. There were 810 such unigrams.

When selecting the terms, we used sentiment associations obtained from both manual and automatic lexicons. As a result, some unigrams had erroneous sentiment associations. After manually annotating the full set of 1,661 terms (that include unigrams, bigrams, and trigrams), we found that 114 bigrams and 161 trigrams had all their comprising unigrams of the same polarity. These 275  $n$ -grams were discarded from SCL-OPP but are included in this task dataset. Further, for this task we removed terms that were used in the SemEval-2015 dataset or in the General English set. The final SemEval-2016 English Twitter Mixed Polarity dataset contains 1,269 terms.

### 3.4 Arabic Twitter Dataset

Mohammad et al. (2015) automatically generated three high-coverage sentiment lexicons from Arabic tweets using hashtags and emoticons: Arabic Emoticon Lexicon, Arabic Hashtag Lexicon, and Dialectal Arabic Hashtag Lexicon.<sup>10</sup> In addition to Modern Standard Arabic (MSA), these three lexicons comprise terms in Dialectal Arabic as well as hashtagged compound words, e.g., #السعادة\_ الزوجية (#MaritalHappiness), which do not usually appear in manually created lexicons. Apart from unigrams, they also include entries for bigrams. From these lexicons, we selected single words as well as bigrams representing negated expressions in the form of ‘negator *w*’, where *negator* is a negation trigger from a list of 16 common Arabic negation words.<sup>11</sup> Words used in negated expressions, but missing from the original list were also included. The selected terms satisfied the following criteria:

- the terms must occur frequently in tweets;
- the terms should not be highly ambiguous.

We also wanted the set of terms as a whole to have these properties:

- the set should have a good spread in terms of degree of sentiment association (from very

negative terms to very positive terms, and all the degrees of polarity in between);

- the set should include both standard and dialectal Arabic, Romanized words, misspellings, hashtags, and other categories frequently used in Twitter. (We chose not to include URLs, user mentions, named entities, and obscene terms.)

The final SemEval-2016 Arabic Twitter dataset contains 1,366 terms.

#### 4 Evaluation

Sentiment association scores are most meaningful when compared to each other; they indicate which term is more positive than the other. Therefore, the automatic systems were evaluated in terms of their abilities to correctly *rank* the terms by the degree of sentiment association.

For each task, the predicted sentiment intensity scores submitted by the participated systems were evaluated by first ranking the terms according to the proposed sentiment scores and then comparing this ranked list to the gold rankings. We used Kendall’s rank correlation coefficient (Kendall’s  $\tau$ ) as the official evaluation metric to determine the similarity between the ranked lists (Kendall, 1938):

$$\tau = \frac{c - d}{n(n - 1)/2}$$

where  $c$  is the number of concordant pairs, i.e., pairs of terms  $w_i$  and  $w_j$  for which both the gold ranked list and the predicted ranked list agree (either both lists rank  $w_i$  higher than  $w_j$  or both lists rank  $w_i$  lower than  $w_j$ );  $d$  is the number of discordant pairs, i.e., pairs of terms  $w_i$  and  $w_j$  for which the gold ranked list and the predicted ranked list disagree (one list ranks  $w_i$  higher than  $w_j$  and the other list ranks  $w_i$  lower than  $w_j$ ); and  $n$  is the total number

of terms. If any list ranks two terms  $w_i$  and  $w_j$  the same, this pair of terms is considered neither concordant nor discordant. The values of Kendall’s  $\tau$  range from -1 to 1.

We also calculated scores for Spearman’s rank correlation (Spearman, 1904), as an additional (unofficial) metric.

#### 5 Participated Systems

There were nine submissions from five teams—three submissions for each task. The team affiliations are shown in Table 3.

Tables 4 and 5 summarize the approaches and resources used by the participants in the (two) English and (one) Arabic tasks, respectively. Most teams applied supervised approaches and trained regression classifiers using a variety of features. Team *ECNU* treated the task as a rank prediction task instead of regression and trained a pair-wise ranking model with the Random Forest algorithm.

The development data available for each task was used as the training data by some teams. However, these data were limited (200 instances per task); therefore, other manually labeled resources were also explored. One commonly used resource was the LabMT lexicon—a set of over 100,000 frequent single words from 10 languages, including English and Arabic (about 10,000 words in each language), manually annotated for happiness through Mechanical Turk (Dodds et al., 2011; Dodds et al., 2015). For the Arabic task, two teams took advantage of the Arabic Twitter corpus collected by Refaee and Rieser (2014). The features employed include sentiment scores obtained from different sentiment lexicons, general and sentiment-specific word embeddings, pointwise mutual information (PMI) scores between terms (single words and multi-word phrases) and sentiment classes, as well as lists of negators, intensifiers, and diminishers.

**Table 5:** Summary of the approaches for the Arabic-language task.

Only one team, *LSIS*, employed an unsupervised approach to all three tasks. To predict a sentiment intensity score for a term, they used the following three sources: existing sentiment lexicons, PMI scores between terms and sentiment classes computed on sentiment-annotated corpora, and PMI scores between terms and words *poor* and *excellent* computed on Google search results.

All teams heavily relied on existing sentiment lexicons: AFINN (Nielsen, 2011), ArabSenti (Abdul-Mageed et al., 2011), Hu and Liu (Hu and Liu, 2004), Dialectal Arabic Lexicon (Refaee and Rieser, 2014), JRC (Steinberger et al., 2012), MPQA (Wilson et al., 2005), NRC Emoticon (a.k.a. Senti-ment140) (Kiritchenko et al., 2014), NRC Emotion (Mohammad and Turney, 2013), NileULex (El-Beltagy, 2016b), and SentiWordNet (Esuli and Sebastiani, 2006). (Note that even though the NRC Emotion Lexicon was created for English terms, its translations in close to 40 languages, including Arabic, are available.<sup>12</sup>)

<sup>12</sup><http://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm>

## 6 Results

The results for the three tasks are presented in Tables 6, 7, and 8. Team *ECNU* showed the best performance in both English-language tasks. In the Arabic task, the best performing system was developed by *iLab-Edinburgh*.

A few observations can be made from the results:

- On all three datasets, the team rankings based on the two metrics, Kendall’s  $\tau$  and Spearman’s  $\rho$ , are the same.
- For most of the teams, the results obtained on the General English Sentiment Modifiers set are markedly higher than the results obtained on the other datasets.
- The English Twitter Mixed Polarity set proved to be a challenging task for all teams. We have further analyzed regularities present in different kinds of mixed polarity phrases and concluded that for most phrases the sentiment of the phrase cannot be reliably predicted only from the parts of speech and polarities of their

**Table 8:** Results for **Arabic Twitter** test set. The systems are ordered by their overall Kendall's  $\tau$  score, which was the official competition metric. The highest score is shown in bold.

constituent words (Kiritchenko and Mohammad, 2016d). For example, a positive adjective and a negative noun can form either a positive phrase (e.g., *happy tears*) or a negative phrase (e.g., *great loss*).

- The results achieved on the Arabic Twitter test set are substantially lower than the results achieved on a similar English Twitter data used in the 2015 competition.
- For most teams, the results obtained on single words are noticeably higher than the corresponding results on multi-word phrases. This is especially apparent on the Arabic Twitter data. The possible reason for this outcome is the lack of sufficient training data for phrases; none of the existing manually created English or Arabic real-valued sentiment lexicons provide annotations for multi-word phrases.

Overall, we observe strong correlations between the predicted and gold term rankings for terms in the general English domain as well as for single words in the other two domains. However, for multi-word phrases in the English Mixed Polarity set and Ara-

bic Twitter set the correlations are markedly weaker, especially for the Arabic language. We hope that the availability of these datasets will foster further research towards automatic methods for sentiment composition in English and other languages.

## 7 Conclusions

We have created three sentiment composition lexicons that provide real-valued sentiment association scores for multi-word phrases and their constituent single words in three domains: the General English Sentiment Modifiers Set, the English Twitter Mixed Polarity Set, and the Arabic Twitter Set. The terms were annotated manually using the Best–Worst Scaling method of annotation. We included phrases composed of negators, modals, and degree adverbs—categories known to be challenging for sentiment analysis. Furthermore, we included phrases formed by words with opposing polarities. As future work, we would like to extend the task to cover more domains (e.g., biomedical, legal) and more languages. All datasets are freely available to the research community.

## Abstract

In this paper we describe a deep learning system that has been built for SemEval 2016 Task4 (Subtask A and B). In this work we trained a Gated Recurrent Unit (GRU) neural network model on top of two sets of word embeddings: (a) general word embeddings generated from unsupervised neural language model; and (b) task specific word embeddings generated from supervised neural language model that was trained to classify tweets into positive and negative categories. We also added a method for analyzing and splitting multi-words hashtags and appending them to the tweet body before feeding it to our model. Our models achieved 0.58 F1-measure for Subtask A (ranked 12/34) and 0.679 Recall for Subtask B (ranked 12/19).

## 1 Introduction

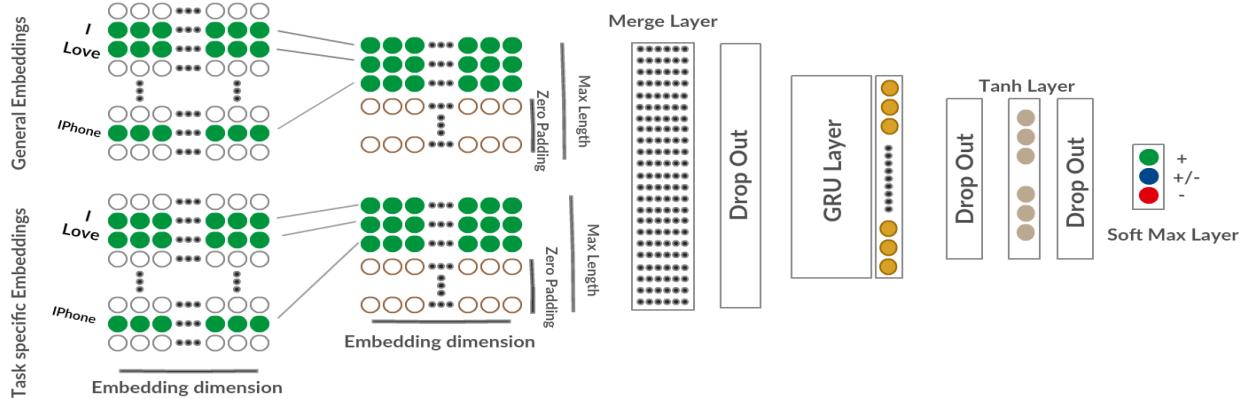

Twitter is a huge microblogging service with more than 500 million tweets per day<sup>1</sup> from different locations in the world and in different languages. This large, continuous, and dynamically updated content is considered a valuable resource for researchers. However many issues should be taken into account while dealing with tweets, namely: (1) informal language used by the users; (2) spelling errors; (3) text in the tweet may be referring to images, videos, or external URLs; (4) emoticons; (5) hashtags used (combining more than one word as a single word); (6) usernames used to call or notify other users; (7)

spam or irrelevant tweets; and (8) character limit for a tweet to 140 characters. This poses many challenges when analyzing tweets for natural language processing tasks. In this paper we describe our system used for SemEval 2016 (Nakov et al., 2016b) Subtasks A and B. Subtask A (Message Polarity Classification) requires classifying a tweet’s sentiment as positive; negative; or neutral,. Subtask B (Tweet classification according to a two-point scale) requires classifying a tweet’s sentiment given a topic as positive or negative. Our system uses a GRU neural network model (Bahdanau et al., 2014) with one hidden layer on top of two sets of word embeddings that are slightly fine-tuned on each training set (see Fig. 1). The first set of word embeddings is considered as general purpose embeddings and was obtained by training *word2vec* (Mikolov et al., 2013) on 20.5 million tweets that we crawled for this purpose. The second set of word embeddings is considered as task specific set, and was obtained by training on a supervised sentiment analysis dataset using another GRU model. We also added a method for analyzing multi-words hashtags by splitting them and appending them to the body of the tweet before feeding it to the GRU model. In our experiments we tried both keeping the word embeddings static during the training or fine-tuning them and reported the result for each experiment. We achieved 0.58 F1-measure for Subtask A (ranked 12/34) and 0.679 Recall for Subtask B (ranked 12/19).

## 2 Related Work

A considerable amount of research has been done to address the problem of sentiment analysis for

<sup>1</sup>[http://internetlivestats.com/  
twitter-statistics/](http://internetlivestats.com/twitter-statistics/)

**Figure 1:** The architecture of the GRU deep Learning model

social content. Nevertheless, most of the state-of-the-art systems still extensively depends on feature engineering, hand coded features, and linguistic resources. Recently, deep learning model gained much attention in sentence text classification inspired from computer vision and speech recognition tasks. Indeed, two of the top four performing systems from SemEval 2015 used deep learning models. (Severyn and Moschitti, 2015) used a Convolution Neural Network (CNN) on top of skip-gram model word embeddings trained on 50 million unsupervised tweets. In (Astudillo et al., 2015) the author built a model that uses skip-gram word embeddings trained on 52 million unsupervised tweets then they project these embeddings into a small subspace, finally they used a non-linear model that maps the embedding subspace to the classification space. In (Kim, 2014) the author presented a series of CNN experiments for sentence classification where static and fine-tuned word embeddings were used. Also the author proposed an architecture modification that allow the use of both task-specific and static vectors. In (Lai et al., 2015) the author proposed a recurrent convolutional neural network for text classification. Finally regarding feature engineering methods, (Büchner and Stein, 2015) the top performing team in SemEval 2015, used an ensemble learning approach that averages the confidence scores of four classifiers. The model uses a large set of linguistic resources and hand coded features.

### 3 System Description

Fig 1 shows the architecture of our deep learning model. The core of our network is a GRU layer, which we chose because (1) it is more computational efficient than Convolutional Neural Network (CNN) models (Lai et al., 2015) that we experimented with but were much slower; (2) it can capture long semantic patterns without tuning the model parameter, unlike CNN models where the model depends on the length of the convolutional feature maps for capturing long patterns; (3) it achieved superior performance to CNNs in our experiments.

Our network architecture is composed of a word embeddings layer, a merge layer, dropout layers, a GRU layer, a hyperbolic tangent *tanh* layer, and a soft-max classification layer. In the following we give a brief description of the main components of the architecture.

#### 3.1 Embedding Layer

This is the first layer in the network where each tweet is treated as a sequence of words  $w_1, w_2 \dots w_S$  of length  $S$ , where  $S$  is the maximum tweet length. We set  $S$  to 40 as the length of any tweet is limited to 140 character. We used zero padding while dealing with short tweets. Each word  $w_i$  is represented by two embedding vectors  $w_{i1}, w_{i2} \in R^d$  where  $d$  is the embedding dimension, and according to (Astudillo et al., 2015) setting  $d$  to 200 is a good choice with respect to the performance and the computation efficiency.  $w_{i1}$  is considered a general-purpose embedding vector while  $w_{i2}$  is considered a task-

specific embedding vector. We performed the following steps to initialize both types of word embeddings:

1. For the general word embeddings we collected about 40M tweets using twitter streaming API over a period of two month (Dec. 2015 and Jan. 2016). We used three criteria while collecting the tweets: (a) they contain at least one emoticon in a set of happy and sad emoticons like ':)' ,':(, ':D' ... etc. (Go et al., 2009); (b) hash tags collected from SemEval 2016 data set; (c) hash tags collected from SemEval 2013 data set. After preparing the tweets as described in Section 4 and removing retweets we ended up with about 19 million tweet. We also appended 1.5 million tweets from *Sentiment140* (Go et al., 2009) corpus after preparation so we end up with about 20.5 million tweet. To train the general embeddings we used *word2vec* (Mikolov et al., 2013) neural language model skipgram model with window size 5, negative sampling and filtered out words with frequency less than 5.
2. For the task specific word embeddings we used semi-supervised 1.5 million tweets from *sentiment140* corpus, where each tweet is tagged either positive or negative according to the tweet's sentiment . Then we applied another GRU model similar to Fig 1 with a modification to the soft-max layer for the purpose of the two classes classification and with random initialized embeddings that are fine-tuned during the training. We used the resulting fine-tuned embeddings as task-specific since they contain contextual semantic meaning from the training process.

### 3.2 Merge Layer

The purpose of this layer is to concatenate the two types of word embeddings used in the previous layer in order to form a sequence of length  $2S$  that can be used in the following GRU layer.

### 3.3 Dropout Layers

The purpose of this layer is to prevent the previous layer from overfitting (Srivastava et al., 2014) where

some units are randomly dropped during training so the regularization of these units is improved.

### 3.4 GRU Layer

This is the core layer in our model which takes an input sequence of length  $2S$  words each having dimension  $d$  (i.e. input dimension is  $2Sd$ ) . The gated recurrent network proposed in (Bahdanau et al., 2014) is a recurrent neural network (a neural network with feedback connection, see (Atiya and Parlos, 2000)) where the activation  $h_t^j$  of the neural unit  $j$  at time  $t$  is a linear interpolation between the previous activation  $h_{t-1}^j$  at time  $t - 1$  and the candidate activation  $\tilde{h}_t^j$  (Chung et al., 2014):

$$h_t^j = (1-z_t^j)h_{t-1}^j + z_t^j\tilde{h}_t^j$$

where  $z_t^j$  is the *update gate* that determines how much the unit updates its content, and  $\tilde{h}_t^j$  is the newly computed candidate state.

### 3.5 Tanh Layer

The purpose of this layer is to allow the neural network to make complex decisions by learning non-linear classification boundaries. Although the *tanh* function takes more training time than the Rectified Linear Units (ReLU), *tanh* gives more accurate results in our experiments.

### 3.6 Soft-Max Layer

This is last layer in our network where the output of the tanh layer is fed to a fully connected soft-max layer. This layer calculates the classes probability distribution.

$$P(y=c|x,b) = \frac{\exp(w_c^T x + b_c)}{\sum_{k=1}^K \exp(w_k^T x + b_k)}$$

where  $c$  is the target class,  $x$  is the output from the previous layer,  $w_k$  and  $b_k$  are the weight and the bias of class  $k$ , and  $K$  is the total number of classes. The difference between the architecture used for Subtask A and Subtask B is in this layer, where for Subtask A three neurons were used (i.e.  $K = 3$ ) while for Subtask B only two neurons were used (i.e.  $K = 2$ ).

## 4 Data Preparation

All the data used either for training the word embeddings or for training the sentiment classification model undergoes the following preprocessing steps:

| Pattern                | Examples       | Normalization |
|------------------------|----------------|---------------|
| Usernames              | @user1,@user2  | _UserName_    |
| Happy emotions         | :), :-), :=)   | :)            |
| Sad emotions           | :(, :-(, :=(   | :(            |
| Laugh emotions         | :D, :-D, :=D   | :D            |
| Kiss emotions          | :-*, :*, :-)*  | _KISS_        |
| Surprise emotions      | :O, :-o        | :o            |
| Tongue emotions        | :P, :p         | :p            |
| Numbers                | 123            | _NUM_         |
| URLs                   | www.google.com | _URL_         |
| Topic (Subtask B only) | Microsoft      | _Entity_      |

**Table 1:** Normalization Patterns

1. Using NLTK twitter tokenizer<sup>2</sup> to tokenize each tweet.
2. Using hand-coded tokenization regex to split the following suffixes: 's, 've, 't, 're, 'd, 'll.
3. Using the patterns described in Table 1 to normalize each tweet.
4. Adding \_StartToken\_ and \_EndToken\_ at the beginning and the ending of each tweet.
5. Splitting multi-word hashtags as explained below.

Consider the following tweet “Thinking of reverting back to 8.1 or 7. #Windows10Fail”. The sentiment of the tweet is clearly negative and the simplest way to give the correct tag is by looking at the word “Fail” in the hashtag “#Windows10Fail”. For this reason we added a depth first search dictionary method in order to infer the location of spaces inside each hashtag in the tweet and append the result tokens to the tweet’s end. We used 125k words dictionary<sup>3</sup> collected from Wikipedia. In the given example, we first lower the hashtag case, remove numbers and underscores from the hashtag then we apply our method to split the hashtag this results in two tokens “windows” and “fail”. Hence, we append these two tokens to the end of the tweet and the normal preparation steps continue. After the preparation the tweet will look like “\_StartToken\_ Thinking of reverting back to \_NUM\_ or \_NUM\_. #Windows10Fail. windows fail \_EndToken\_”.

| dev-A   | 3222  | 1395 | 462  | 1365  |
| train-B | 6324  | 5059 | 1265 | -     |
| dev-B   | 1265  | 1059 | 206  | -     |

**Table 2:** Tweets distribution for Subtask A and B

| Dataset                        | Subtask A    | Subtask B    |
|--------------------------------|--------------|--------------|
| GRU-static                     | 0.635        | 0.826        |
| GRU-fine-tuned                 | 0.639        | 0.829        |
| GRU-fine-tuned + Split Hashtag | <b>0.642</b> | <b>0.830</b> |

**Table 3:** Development results for Subtask A and B. **Note:** average F1-mesure for positive and negative classes is used for Subtask A, while the average recall is used for Subtask B.

## 5 Experiments

In order to train and test our model for Subtask A, we used the dataset provided for SemEval-2016 Task 4 and SemEval-2013 Task 2. We obtained 8,978 from the first dataset and 7,130 from the second, the remaining tweets were not available. So, we ended up with a dataset of 16,108 tweets. Regarding Subtask B we obtained 6,324 from SemEval-2016 provided dataset. We partitioned both datasets into train and development portions of ratio 8:2. Table 2 shows the distribution of tweets for both Subtasks.

For optimizing our network weights we used Adam (Kingma and Ba, 2014), a new and computationally efficient stochastic optimization method. All the experiments have been developed using Keras<sup>4</sup> deep learning library with Theano<sup>5</sup> backend and with CUDA enabled. The model was trained using the default parameters for Adam optimizer, and we tried either to keep the weights of embedding layer static or slightly fine-tune them by using a dropout probability equal to 0.9. Table 3 shows our results on the development part of the data set for Subtask A and B where we report the official performance measure for both subtasks (Nakov et al., 2016a). From 3 the results it is shown that fine-tuning word embeddings with hashtags splitting gives the best results on the development set. All our experiments were performed on a machine with Intel Core i7-4770 CPU @ 3.40GHz (8 cores), 16GB

**Table 4:** Results for Subtask A on different SemEval datasets.

| Dataset    | Baseline | Recall (Old) | Recall (New) |
|------------|----------|--------------|--------------|
| Tweet-2016 | 0.389    | 0.679        | 0.767        |

**Table 5:** Result for Subtask B on SemEval 2016 dataset.

of RAM and GeForce GT 640 GPU. Table 4 shows our individual results on different SemEval datasets. Table 5 shows our results for Subtask B. From the results and our rank in both Subtasks, we noticed that our system was not satisfactory compared to other teams this was due to the following reasons:

1. We used the development set to validate our model in order to find the best learning parameters, However we mistakenly used the learning accuracy to find the optimal learning parameters especially the number of the training epochs. This significantly affected our rank based on the official performance measure. Table 4 and Table 5 show the old and the new results after fixing this bug.
2. Most of the participating teams in this year competition used deep learning models and they used huge datasets (more than 50M tweets) to train and refine word embeddings according to the emotions of the tweet. However, we only used 1.5M from *sentiment140* corpus to generate task-specific embeddings.
3. The model used for generating the task-specific embeddings for Subtask A should be trained on three classes not only two (positive, negative, and neutral) where if the tweet contains positive emotions like “:)” should be positive, if it contains negative emotions like “:(“ should be negative, and if it contains both or none it should be neutral.

## 6 Conclusion

In this paper, we presented our deep learning model used for SemEval2016 Task4 (Subtasks A and B).

The model uses a gated recurrent layer as a core layer on top of two types of word embeddings (general-purpose and task-specific). Also we described our steps in generating both types word embeddings and how we prepared the dataset used especially when dealing with multi-words hashtags. The system ranked 12th on Subtask A and 12th for Subtask B.

## Abstract

We describe the systems we have used for participating in Subtasks D (binary quantification) and E (ordinal quantification) of SemEval-2016 Task 4 “Sentiment Analysis in Twitter”. The binary quantification system uses a “Probabilistic Classify and Count” (PCC) approach that leverages the calibrated probabilities obtained from the output of an SVM. The ordinal quantification approach uses an ordinal tree of PCC binary quantifiers, where the tree is generated via a splitting criterion that minimizes the ordinal quantification loss.

## 1 Introduction

This document describes the systems we have used for participating in Subtasks D (binary quantification) and E (ordinal quantification) of SemEval-2016 Task 4 “Sentiment Analysis in Twitter”. In the runs we have submitted no training data was used other than the officially provided ones (indeed, the only “external” data used were the sentiment lexicons mentioned in Section 2).

Like a classification system, a system for performing quantification consists of two main components: (i) an algorithm for converting the objects of interest (tweets, in our case) into vectorial representations that can be interpreted both by the learning algorithm and, once it has been trained, by the quantifier itself, and (ii) an algorithm for training quantifiers from vectorial representations of training ob-

jects. Section 2 will be devoted to discussing component (i), while Sections 3 and 4 will be devoted to discussing the two learning algorithms we have deployed for the two tasks.

## 2 Features for detecting tweet sentiment

As in (Gao and Sebastiani, 2015; Gao and Sebastiani, 2016), for building vectorial representations of tweets we have followed the approach discussed in (Kiritchenko et al., 2014, Section 5.2.1), since the representations presented therein are those used in the systems that performed best at both the SemEval 2013 (Mohammad et al., 2013) and SemEval 2014 (Zhu et al., 2014) tweet sentiment classification shared tasks.

The text is preprocessed by normalizing URLs and mentions of users to the constants `http://someurl` and `@someuser`, resp., after which tokenisation and POS tagging is performed. The binary features used (i.e., features denoting presence or absence in the tweet) include word  $n$ -grams, for  $n \in \{1, 2, 3, 4\}$ , and character  $n$ -grams, for  $n \in \{3, 4, 5\}$ , whether the last token contains an exclamation and/or a question mark, whether the last token is a positive or a negative emoticon and, for each of the 1000 word clusters produced with the CMU Twitter NLP tool<sup>1</sup>, whether any token from the cluster is present. Integer-valued features include the number of all-caps tokens, the number of tokens for each POS tag, the number of hashtags, the number of negated contexts, the number of sequences of exclamation and/or question marks, and the number of elongated words (e.g., `coooooool`).

\*Fabrizio Sebastiani is currently on leave from Consiglio Nazionale delle Ricerche, Italy.

<sup>1</sup><http://www.ark.cs.cmu.edu/TweetNLP/>

A key addition to the above is represented by features derived from both automatically generated and manually generated sentiment lexicons; for these features, we use the same sentiment lexicons as used in (Kiritchenko et al., 2014), which are all publicly available. We omit further details concerning our vectorial representations (and, in particular, how the sentiment lexicons contribute to them), both for brevity reasons and because these vectorial representations are not the central focus of this paper; the interested reader is invited to consult (Kiritchenko et al., 2014, Section 5.2.1) for details.

### 3 Subtask D: Tweet quantification according to a two-point scale

For the binary quantification task, we have performed a thorough set of preliminary experiments using 8 quantification methods from the literature, i.e., Classify and Count (CC), Probabilistic Classify and Count (PCC) (Bella et al., 2010), Adjusted Classify and Count (ACC) (Gart and Buck, 1966), Probabilistic Adjusted Classify and Count (PACC) (Bella et al., 2010), Expectation Maximization for Quantification (EMQ) (Saerens et al., 2002), SVMs optimized for  $KLD$  (SVM( $KLD$ )) (Esuli and Sebastiani, 2015), SVMs optimized for  $NKLD$  (SVM( $NKLD$ )) (Esuli and Sebastiani, 2014), and SVMs optimized for  $Q$  (SVM( $Q$ )) (Barranquero et al., 2015).

All 8 methods are described in detail in (Gao and Sebastiani, 2016), where we test them on a ternary<sup>2</sup> tweet sentiment quantification task using 11 datasets and 6 evaluation measures. The aim of (Gao and Sebastiani, 2016) was to test whether the conclusions drawn from a previous experiment (Esuli and Sebastiani, 2015), where quantification was according to topic and where texts were significantly longer than tweets, were confirmed also in a context in which quantification is according to sentiment and the items are significantly shorter.

The preliminary experiments we performed for the present work were carried out by training our models on TRAIN+DEV and testing on DEVTEST. For the first 5 methods mentioned at the beginning of this section we make use of a standard SVM with a

<sup>2</sup>Differently from the present task, the datasets we used in (Gao and Sebastiani, 2016) also used the Neutral class.

linear kernel, in the implementation made available in the LIBSVM system<sup>3</sup> (Chang and Lin, 2011). For the other 3 methods we make use of an SVM for structured output prediction, in the implementation made available in the SVM-perf system<sup>4</sup> (Joachims, 2005). For all 8 methods we optimize the  $C$  parameter (which sets the tradeoff between the training error and the margin) directly on DEVTEST by performing a grid search on all values of type  $10^x$  with  $x \in \{-6, \dots, 7\}$ ; we instead leave the other parameters at their default value. The PCC, PACC, EMQ methods require the classifier to also generate posterior probabilities; since SVMs do not natively generate posterior probabilities, for these three methods we use the  $-b$  option of LIBSVM, which converts the scores originally generated by SVMs into posterior probabilities according to the algorithm of (Wu et al., 2004).

The results of these preliminary experiments, which are reported in Table 1, indicated PCC as the best performer. These experiments by and large confirmed the results of (Gao and Sebastiani, 2016), where PCC was the best performer for 34 of the 66 combinations of 11 datasets  $\times$  6 evaluation measures. Instead, for none of the 66 combinations SVM( $KLD$ ), which had been the best performer in the experiments of (Esuli and Sebastiani, 2015) (where it also outperformed PCC), was the best performer. In (Gao and Sebastiani, 2016) we conjectured that this difference may be due to the fact that in quantification by sentiment, class prevalences tend to be fairly high ( $> .10$ ), and that the experiments of (Esuli and Sebastiani, 2015) mostly concerned classes with low prevalence ( $< .10$ ) or very low prevalence ( $< .01$ ), which tend to be the norm in classification by topic.

As a result of all this, in this work we decided to use PCC; Section 3.1 describes the PCC method in detail.

<sup>3</sup>LIBSVM is available from <http://www.csie.ntu.edu.tw/~cjlin/libsvm/>

<sup>4</sup>SVM-perf is available from [http://svmlight.joachims.org/svm\\_struct.html](http://svmlight.joachims.org/svm_struct.html). The modules that customize it to  $KLD$  and  $NKLD$  were made available by Andrea Esuli, while the module that customizes it to  $Q$  was made available by José Barranquero.

**Table 1:** Results of our preliminary experiments for 8 quantification methods. The 2nd column indicates accuracy as measured via  $KLD$  (lower values are better), while the 3rd column indicates the value of the  $C$  parameter used, and which had proved optimal when training on TRAIN+DEV and testing on DEVTEST; **boldface** indicates the best performer.

|           | $KLD$            | $C$      |
|-----------|------------------|----------|
| CC        | 0.0528275        | 0.00001  |
| PCC       | <b>0.0278864</b> | 0.000001 |

| SVM(Q)    | 0.0989133        | 0.1      |

### 3.1 Probabilistic Classify and Count (PCC)

The PCC method, originally introduced in (Bella et al., 2010), consists in generating a classifier from  $Tr$ , classifying the objects in  $Te$ , and computing  $p_{Te}(c)$  as the *expected* fraction of objects predicted to belong to  $c$ . If by  $p(c|\mathbf{x})$  we indicate the posterior probability, i.e., the probability of membership in  $c$  of test object  $\mathbf{x}$  as estimated by the classifier, and by  $E[x]$  we indicate the expected value of  $x$ , this corresponds to computing

$$\begin{aligned}\hat{p}_{Te}^{PCC}(c) &= E[p_{Te}(\hat{c})] \\ &= \frac{1}{|Te|} \sum_{\mathbf{x} \in Te} p(c|\mathbf{x})\end{aligned}\quad (1)$$

where  $\hat{p}_S^M(c)$  indicates the prevalence of class  $c$  in set  $S$  as estimated via method  $M$  (the “hat” symbol indicates estimation). The rationale of PCC is that posterior probabilities contain richer information than binary decisions, which are usually obtained from posterior probabilities by thresholding.

For our final run, we have retrained the system on TRAIN+DEV+DEVTEST, using the parameter values which had performed best on DEVTEST in the preliminary experiments. On the official test set (Nakov et al., 2016) we obtained a  $KLD$  score of 0.055, and thus ranked 5th in a set of 14 participating teams.

### 4 Subtask E: Tweet quantification according to a five-point scale

Our goal in tackling the ordinal quantification task has been to devise a new learning algorithm for or-

dinal quantification. We decided to aim for an algorithm that (a) leverages the information inherent in the class ordering, and (b) performs quantification according to the *Probabilistic Classify and Count* (PCC) method ((Bella et al., 2010) – see also (Gao and Sebastiani, 2016, §4.2)), since this has proven the best-performing method in the tweet quantification experiments of (Gao and Sebastiani, 2016).

Ordinal quantification will be tackled by arranging the classes in the totally ordered set  $\mathcal{C} = \{c_1, \dots, c_{|\mathcal{C}|}\}$  into a binary tree. Given any  $j \in \{1, \dots, (|\mathcal{C}| - 1)\}$ ,  $\underline{\mathcal{C}}_j = \{c_1, \dots, c_j\}$  will be called a *prefix* of  $\mathcal{C}$ , and  $\overline{\mathcal{C}}_j = \{c_{j+1}, \dots, c_{|\mathcal{C}|}\}$  will be called a *suffix* of  $\mathcal{C}$ . Given any  $j \in \{1, \dots, (|\mathcal{C}| - 1)\}$  and a set  $S$  of items labeled according to  $\mathcal{C}$ , by  $\underline{S}_j$  we denote the set of items in  $S$  whose class is in  $\underline{\mathcal{C}}_j$ , and by  $\overline{S}_j$  we denote the set of items in  $S$  whose class is in  $\overline{\mathcal{C}}_j$ .

### 4.1 Generating a quantification tree

The algorithm for training a quantification tree is described in concise form as Algorithm 1, and goes as follows. Assume we have a training set  $Tr$  and a held-out validation set  $Va$  of items labelled according to  $\mathcal{C}$ .

The first step (Line 3) consists in training  $(|\mathcal{C}| - 1)$  binary classifiers  $h_j$ , for  $j \in \{1, \dots, (|\mathcal{C}| - 1)\}$ . Each of these classifiers must discriminate between  $\underline{\mathcal{C}}_j$  and  $\overline{\mathcal{C}}_j$ ; for training  $h_j$  we will take the items in  $\underline{Tr}_j$  as the negative training examples and the items in  $\overline{Tr}_j$  as the positive training examples. We require that these classifiers, aside from taking binary decisions (i.e., predicting if a test item is in  $\underline{\mathcal{C}}_j$  or in  $\overline{\mathcal{C}}_j$ ), also output posterior probabilities, i.e., probabilities  $p(\underline{\mathcal{C}}_j|\mathbf{x})$  and  $p(\overline{\mathcal{C}}_j|\mathbf{x}) = (1 - p(\underline{\mathcal{C}}_j|\mathbf{x}))$ , where  $p(c|\mathbf{x})$  indicates the probability of membership in  $c$  of test object  $\mathbf{x}$  as estimated by the classifier<sup>5</sup>.

The second step (Line 5) is building the ordinal quantification (binary) tree. In order to do this,

<sup>5</sup>If the classifier only returns confidence scores that are not probabilities (as is the case with many non-probabilistic classifiers), the former must be converted into true probabilities. If the score is a monotonically increasing function of the classifier’s confidence in the fact that the object belongs to the class, the conversion may be obtained by applying a logistic function. *Well-calibrated* probabilities (defined as the probabilities such that the prevalence  $p_S(c)$  of a class  $c$  in a set  $S$  is equal to  $\sum_{\mathbf{x} \in S} p(c|\mathbf{x})$ ) may be obtained by using a *generalized* logistic function; see e.g., (Berardi et al., 2015, Section 4.4) for details.

```

1 Function GenerateTree ( $\mathcal{C}, Tr, Va$ );
/* Generates the quantification tree
*/
Input : Ordered set  $\mathcal{C} = \{c_1, \dots, c_{|\mathcal{C}|}\}$ ;
        Set  $Tr$  of labelled items;
        Set  $Va$  of labelled items;
Output: Quantification tree  $T_C$ .
2 for  $j \in \{1, \dots, (|\mathcal{C}| - 1)\}$  do
3   | Train classifier  $h_j$  from  $Tr_j$  and  $\overline{Tr}_j$ ;
4 end
5  $T_C \leftarrow \text{Tree}(\mathcal{C}, \{h_j\}, Va)$ ;
6 return  $T_C$ ;

7 Function Tree ( $\mathcal{C}, \mathcal{H}_{\mathcal{C}}, Va$ );
/* Recursive subroutine for
generating the quantification tree
*/
Input : Ordered set  $\mathcal{C} = \{c_1, \dots, c_{|\mathcal{C}|}\}$  of classes;
        Set of classifiers  $\mathcal{H}_{\mathcal{C}} = \{h_1, \dots, h_{(|\mathcal{C}| - 1)}\}$ ;
Output: Quantification tree  $T_C$ .
8 if  $\mathcal{C} = \{c\}$  then
9   | Generate a leaf node  $T_c$ ;
10  | return  $T_c$ ;
11 else
12   |  $h_t \leftarrow \arg \min_{h_j \in \mathcal{H}_{\mathcal{C}}} KLD(p, \hat{p}, h_j, Va)$ ;
13   | Generate a node  $T_C$  and associate  $h_t$  to it;
14   |  $\mathcal{H}'_{\mathcal{C}} \leftarrow \{h_1, \dots, h_{(t-1)}\}$ ;
15   |  $\mathcal{H}''_{\mathcal{C}} \leftarrow \{h_{(t+1)}, \dots, h_{(|\mathcal{C}| - 1)}\}$ ;
16   |  $LChild(T_C) \leftarrow \text{Tree}(\mathcal{C}_t, \mathcal{H}'_{\mathcal{C}}, Va)$ ;
17   |  $RChild(T_C) \leftarrow \text{Tree}(\overline{\mathcal{C}}_t, \mathcal{H}''_{\mathcal{C}}, Va)$ ;
18   | return  $T_C$ ;
19 end

```

**Algorithm 1:** Function `GenerateTree` for generating an ordinal quantification tree.

among the classifiers  $h_j$  we pick the one (let us assume it is  $h_t$ ) that displays the highest quantification accuracy (Line 12) on the validation set  $Va$ , and we place it at the root of the binary tree. We then repeat the process recursively on the left and on the right branches of the binary tree (Lines 14 to 17), thus building a fully grown quantification tree. Quantification is performed according to the PCC method described in Section 3.1. We measure the quantification accuracy of classifier  $h_j$  via *Kullback-Leibler Divergence* ( $KLD$ ), defined as

$$KLD(p, \hat{p}, h_j, S) = \sum_{c \in \mathcal{C}} p_S(c) \log \frac{p_S(c)}{\hat{p}_S(c)} \quad (2)$$

where  $\hat{p}$  is the distribution estimated via PCC using the posterior probabilities generated by  $h_j$ .

## 4.2 Estimating class prevalences via an ordinal quantification tree

The algorithm for estimating class prevalences by using an ordinal quantification tree is described in concise form as Algorithm 2, and goes as follows. Essentially, for each item  $\mathbf{x} \in Te$  and for each class  $c \in \mathcal{C}$ , we compute (Line 6) the posterior probability  $p(c|\mathbf{x})$ ; the estimate  $\hat{p}_{Te}(c)$  is computed as the average, across all  $\mathbf{x} \in Te$ , of  $p(c|\mathbf{x})$ . The posterior probability  $p(c|\mathbf{x})$  is computed in a recursive, hierarchical way (Lines 13 to 18), i.e., as the probability that the binary classifiers that lie on the path from the root to leaf  $c$ , would classify item  $\mathbf{x}$  exactly in leaf  $c$  (i.e., that they would route  $\mathbf{x}$  exactly to leaf  $c$ ). This probability is computed as the product of the posterior probabilities returned by the classifiers that lie on the path from the root to leaf  $c$ .

An example quantification tree for a set of  $|\mathcal{C}| = 6$  classes is displayed in Figure 1; for brevity, classes are represented by natural numbers, the total order defined on them is the order defined on the natural numbers, and sets of classes are represented by sequences of natural numbers. Note that, as exemplified in Figure 1, our algorithm generates trees for which (a) there is a 1-to-1 correspondence between classes and leaves of the tree, (b) leaves are ordered left to right in the same order of the classes in  $\mathcal{C}$ , and (c) each internal node represents a decision between a suffix and a prefix of  $\mathcal{C}$ .

Point (c) is interesting, and deserves some discussion. Indeed, internal node “1234 vs. 56” is trained by using items labelled as 1, or 2, or 3, or 4 as negative examples and items labelled as 5, or 6 as positive examples; however, by looking at Figure 1, it would seem intuitive that items labelled as 6 should *not* be used, since the node is root to a subtree where class 6 is not an option anymore. The reason why we do use items labelled as 6 (which is the reason the node is labelled “1234 vs. 56” and not “1234 vs. 5”) is that, during the classification stage, the classifier associated with the node might be asked to classify an item whose true label is 6, and which has thus been misclassified up higher in the tree. In this case, it would be important that this item be classified as 5, since this minimizes the contribution of this item to misclassification error; and the likelihood that this happens is increased if the classifier is trained to choose

```

1 Function QuantifyViaHierarchicalPCC ( $T_e, T_c$ );
  /* Estimates class prevalences on  $T_e$ 
   using the quantification tree */
Input : Unlabelled set  $T_e$ ;
         Quantification tree  $T_c$ ;
Output: Estimates  $\hat{p}(c)$  for all  $c \in \mathcal{C}$ ;
2 for  $c \in \mathcal{C}$  do
3    $\hat{p}(c) \leftarrow 0$ 
4 end
5 for  $x \in T_e$  do
6   CPost( $x, T_c, 1$ ); /* Compute the  $\{p(c|x)\}$ 
    */
7   for  $c \in \mathcal{C}$  do
8      $\hat{p}(c) \leftarrow \hat{p}(c) + \frac{p(c|x)}{|T_e|}$ ;
9 end
10 end
11 return  $\{\hat{p}(c)\}$ 

12 Procedure CPost ( $x, T_c, SubP$ );
  /* Recursive subroutine for computing
   all the posteriors  $\{p(c|x)\}$  */
Input : Unlabelled item  $x$ ;
         Quantification tree  $T_c$ ;
         Probability  $SubP$  of current subtree;
Output: Posteriors  $\{p(c|x)\}$ ;
13 if  $T_c = \{c\}$  then
  /*  $T_c$  is a leaf, labelled by class
    $c$  */
14    $p(c|x) \leftarrow SubP$ ;
15 else
16   CPost( $x, LChild(T_c), p(\mathcal{C}_t|x) \cdot SubP$ );
17   CPost( $x, RChild(T_c), p(\bar{\mathcal{C}}_t|x) \cdot SubP$ );
  /*  $p(\mathcal{C}_t|x)$  and  $p(\bar{\mathcal{C}}_t|x)$  are the
   posteriors returned by the
   classifier associated with the
   root of  $T_c$  */
18 end

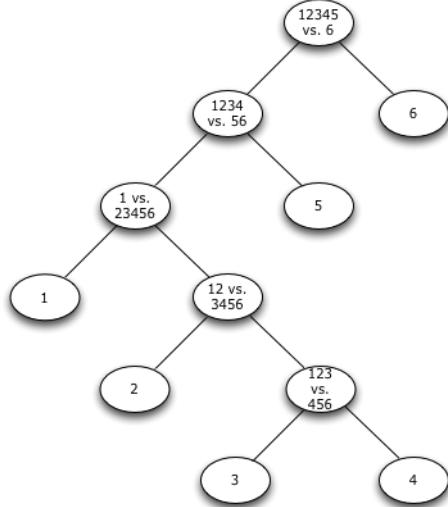

```

**Algorithm 2:** Function QuantifyViaHierarchicalPCC for estimating prevalences via an ordinal quantification tree.

between 1234 and 56, rather than between 1234 and 5.

Note also that this is one aspect for which our algorithm is a true *ordinal* classification algorithm; if there were no order defined on the classes this policy would make no sense.

A second reason why our algorithm is an inherently ordinal quantification algorithm is that the groups of classes (such as 1234 and 56) between which a binary classifier needs to discriminate are

**Figure 1:** An example ordinal quantification tree.

groups of classes that are *contiguous* in the order defined on  $\mathcal{C}$ . It is because of this contiguity that the structure of the trees we generate makes sense: if, say, classes  $\{1, \dots, 6\}$  represent degrees of positivity of product reviews, with 1 representing most negative and 6 representing most positive, the group 56 may be taken to represent the positive reviews (to different degrees), while 1234 may be taken to represent the reviews that are not positive; a group such as, say, 256, would instead be very hard to interpret, since it is formed of non-contiguous classes that have little in common with each other.

Finally, we remark that our ordinal quantification algorithm does not depend on the fact that PCC is the chosen quantification method, and could be adapted to work with other such methods, such as e.g., SVM(KLD). Indeed, if SVM(KLD) is the chosen quantification method, in Algorithm 1 we only need to change the learning method we use (Line 3), and change the recursive subroutine CPost (Lines 12 to 17) in such a way that, by recursively making binary choices down the tree, it picks exactly one out of the  $|\mathcal{C}|$  leaf classes instead of computing the posterior probabilities for all of them<sup>6</sup>.

---

<sup>6</sup>The code that implements the PCC method for binary quantification, and our method for ordinal quantification, is available from <http://alt.qcri.org/tools/quantification/>

#### 4.2.1 Our run

In our preliminary run over the DEVTEST set, our system obtained an *EMD* value of 0.210; for obtaining this, the optimization of the  $C$  parameter (see Section 3.1) was carried out using *EMD* as a criterion, i.e., the parameter that yielded the best *EMD* value on DEVTEST was chosen. For comparison, we also run on DEVTEST a baseline multiclass PCC system, i.e, one which performs quantification according to the PCC method and does not take the order on the classes into account; the baseline system, after parameter optimization, obtained an *EMD* value of 0.222, with a 5.64% deterioration over our system. As a result, we decided to tackle the unlabelled set with our system as described in Sections 4.1 and 4.2. Note that, unlike for Subtask D, in Subtask E we did not have a range of other datasets to perform preliminary experiments with; as a result, the only choice that could make sense here was using the system which had performed best on DEVTEST.

On the official test set (Nakov et al., 2016) we obtained an *EMD* score of 0.243, ranking 1st in a set of 10 participating systems, with a high margin over the other ones (systems from rank 2 to rank 8 obtained *EMD* scores between 0.316 and 0.366).

## Abstract

This paper describes our approach to the SemEval 2016 task 4, “Sentiment Analysis in Twitter”, where we participated in subtask A. Our system relies on AlchemyAPI and SentiWordNet to create 43 features based on which we select a feature subset as final representation. Active Learning then filters out noisy tweets from the provided training set, leaving a smaller set of only 900 tweets which we use for training a Multinomial Naive Bayes classifier to predict the labels of the test set with an F1 score of 0.478.

## 1 Introduction

Gaining an overview of opinions on recent events or trends is an appealing feature of Twitter. For example, receiving real-time feedback from the public about a politician’s speech provides insights to media for the latest polls, analysts and interested individuals including the politician herself. However, detecting tweet sentiment still poses a challenge due to the frequent use of informal language, acronyms, neologisms which constantly change, and the shortness of tweets, which are limited to 140 characters.

SemEval’s subtask 4A (Nakov et al., 2016) deals with the sentiment classification of single tweets into one of the classes “positive”, “neutral” or “negative”. Concretely a training set of 5481 tweets and a development set comprising 1799 tweets was given, and the sentiment of 32009 tweets in a test set had to be predicted and was evaluated using F1-score. The distribution of labels for the given datasets is depicted in Table 1. Tweets with positive polarity

outnumber the other two classes and the least number of instances is available for negative tweets. Initially, the organizers provided 6000 tweets for the training set and 2000 tweets for the development set, but only the tweet IDs were released to abide by the Twitter terms of agreement. By the time we downloaded the data, around 10% of the tweets (519 in the training set, 201 in the test set) were not available anymore. For further details about the labeling process and the datasets see (Nakov et al., 2016).

Lexicon-based approaches have done very well in this competition over the past years, i.e, the winners of the years 2013-2015 (Mohammad et al., 2013; Miura et al., 2014; Hagen et al., 2015) relied heavily on them. Our goal is to explore alternatives and to complement lexicon-based strategies. The SteM system performs preprocessing, including canonicalization of tweets, and based on that we extract 43 features as our representation, some features are based on AlchemyAPI<sup>1</sup> and SentiWordNet (Esuli and Sebastiani, 2006). We choose 28 of the features as final representation and learn three classifiers based on different subsets of these 28 features. We refer to the latter as *feature subspaces* or *subspaces* hereafter. However, independently of the subspace we use, we face the fact that tweet datasets inherently contain noise and all subspaces will - to a greater or lesser extend- be affected by this noise. To alleviate this problem, we propose to concentrate on only few of the labeled tweets, those likely to be most discriminative. To this purpose, we use Active Learning (AL) (Settles, 2012), as explained in Section 6. For AL, we set up a ”budget”, translating

<sup>1</sup><http://www.alchemyapi.com>

| Dataset | Total | Pos  | Neu  | Neg |
|---------|-------|------|------|-----|
| Train   | 5481  | 2817 | 1882 | 782 |
| Dev     | 1799  | 755  | 685  | 359 |

**Table 1:** Distribution of sentiment labels in the datasets.

to the maximum number of tweets, for which labels are requested. The term "budget" is motivated by the fact that labeling is a costly human activity. In our study, this budget is set to 900. On those 900 tweet we learn a classifier for each of the three feature subspaces to predict the labels of the test set.

The remainder of this paper is organized according to the pipeline of the SteM system. Section 2 explains preprocessing steps, Section 3 describes our features, Section 4 describes how we select our feature subset for the final representation, Section 5 gives details about learning the classifiers on the different subsets, Section 6 describes our Active Learning component, and Section 7 outlines the experiments we performed to select the best model for the competition.

## 2 Preprocessing

We note that while preprocessing tweets, we also extract related features. These features are described in the next section.

*Removing URLs, mentions and replacing slang, abbreviations:* we first remove Twitter handles (@username) and URLs. We remove dates and numbers with regular expressions and canonicalize common abbreviations, slang and negations using a lexicon we assembled from online resources.<sup>2</sup> Our list of negations encompasses: don't, mustn't, shouldn't, isn't, aren't, wasn't, weren't, not, couldn't, won't, can't, wouldn't. We replace these with the respective formal forms and we do the same for their apostrophe-free forms (e.g., 'cant'), which are more likely to occur in hashtags. In total we use 114 abbreviations, some are shown in Table 2.

*Spelling correction:* the remaining unknown words are replaced by the most likely alternative according to the PyEnchant dictionary.<sup>3</sup>

*Splitting hashtags into words:* instead of remov-

|                    |         |       |          |
|--------------------|---------|-------|----------|
| <b>Slang</b>       | c'mon   | l8r   | FB       |
| <b>Replacement</b> | come on | later | Facebook |

**Table 2:** Exemplary slang words to be replaced by our lexicon.

ing hashtags, we chunk them as follows. If a hashtag is comprised of a single word that exists in our dictionary, we only remove the hashtag symbol. In case of camel case hashtags (#HelloWorld), we split the words on the respective transitions from upper to lower case or vice versa. Otherwise we try to recover the multiple words in the following manner. If a hashtag contains less than 22 characters, we apply an exhaustive search to find a combination of words that all exist in a dictionary. For hashtags longer than 22 characters the exhaustive approach takes too long (about 10s), hence we opt for a greedy algorithm instead: we start at the end of the hashtag and traverse to the front trying to find the longest words that are found in a dictionary. In case not all parts can be resolved, we only keep the existing words and discard the remainder. Furthermore we remove emoticons and replace elongated characters by a single occurrence, e.g., woooooow → wow.

*Determine POS tags:* on the resulting canonicalized text, we determine part-of-speech (POS) tags using the Stanford POS tagger (Manning et al., 2014). Finally we eliminate any punctuation.

*Discard unbiased polarity words:* since some of the words in the training corpus are uniformly distributed across the three labels, encountering such words in any tweet does not allow us to learn anything about the overall tweet sentiment. Hence, we compile a list of these words and exclude them when calculating tweet polarities. We detect such words with the help of categorical proportional difference (CPD) (Simeon and Hilderman, 2008) which describes how much a word  $w$  contributes to distinguishing the different classes. It is calculated as  $CPD_w = |A - B|/(A + B)$ , where  $A$  corresponds to the occurrences of the word w.r.t. one of the three classes, while  $B$  denotes the number of occurrences of the word in the remaining two classes. After computing this value for all three classes separately, the maximum value is chosen as a result. High values close to 1 indicate a strong bias towards one of the classes, while a value close to 0 signals that  $w$  is almost uniformly distributed. If this value is below

<sup>2</sup><http://searchcrm.techtarget.com/definition/Twitter-chat-and-text-messaging-abbreviations>

<sup>3</sup><https://pypi.python.org/pypi/pyenchant>

a fixed threshold of 0.6 we exclude the word from sentiment computation. Large CPD values indicate that a word occurs frequently with a specific class, while low values signal no particular association of the word with any class. Note that we consider only the absolute value of the enumerator in our equation, similar to (O’Keefe and Koprinska, 2009), while this is not the case in the original paper. The reason is that the direction of the association of a word with a class is not important to us.

### 3 Extracted features

In this section we describe the extracted features and motivate our choice. Table 3 presents an overview of the 43 extracted features. Column ‘Used’ lists the features that comprise our final representation after feature subset selection which is described in Section 4. We explain our reasoning for the different feature subspaces (column ‘Subspace’) in Section 5.

Since emoticons correlate with sentiment, we exploit this knowledge in our features. To do so, we create a lexicon encompassing 81 common positive and negative emoticons based on Wikipedia. We manually labeled these emoticons as either expressing positive or negative sentiment. While preprocessing we extract the respective emoticon features 1 – 2. We assign features 3 – 4 into the same category, as all four of them are easy to identify in a tweet. Hashtags share a similar relationship with sentiment like emoticons, i.e., they correlate with the overall tweet sentiment (Mohammad, 2012). Thus, we extract the features 6 – 16 describing the sentiment of hashtags. Exclamation marks also hint at amplified overall tweet sentiment which is covered by feature 17. The length of a tweet affects whether it contains sentiment: if tweets are longer, it is more likely they contain mixed polarity and hence it is more difficult to label them. Features 18 – 20 deal with this issue. We expect that sentiment bearing tweets contain a different sentence parts composition which is reflected in the features 21 – 24.

We query AlchemyAPI about sentiment to benefit from a system that is known to yield accurate results, for example for the task of extracting entity-level sentiment (Saif et al., 2012). Moreover, AlchemyAPI allows to retrieve sentiment on different levels of granularity for documents, e.g., for a whole

tweet or for single entities within a tweet. Features 25 – 32 describe the relevant sentiment information from this online resource. The remaining features 33 – 43 address sentiment on the whole tweet.

Note that we normalize the features 6 – 8, 27, 33 – 35 by taking their absolute values and limiting them to the interval [0 . . . 1]. For extracting tweet and hashtag sentiment, we consider negations, diminishers (“a little”) and intensifiers (“very”) when summing up the polarity scores of the separate words. To account for the correlation of emoticons with the overall tweet sentiment, we eventually multiply the respective positive or negative overall tweet sentiment by 1.5 if emoticons are present. The resulting value is multiplied by 1.5 \* the number of multiple exclamation marks if multiple exclamation marks exist in a sentence. We query SentiWordNet to determine word polarities in order to obtain a triple of positive, neutral and negative sentiment scores per word. This allows us to define positive/neutral/negative words according to its prevalent sentiment. Similarly, we express the overall tweet sentiment with a triple representing positive, neutral and negative polarity. Values close to 0 indicate that only little sentiment is contained in a tweet, while larger ones imply stronger sentiment. In case of negations, we employ a simple sliding windows approach to switch positive and negative sentiment of the four succeeding words. If tweets end with “not”, e.g., “I like you - not”, we also switch their overall sentiment as this is a common pattern in tweets indicating sarcasm. The sentiment of capitalized and elongated words is amplified. We consider a word elongated if the same letter occurs more than twice consecutively. In case of intensifiers and diminishers, the sentiment of the four succeeding words is increased in the former case by multiplying it by 1.5, and decreased in the latter one by multiplying the term by 0.5. However, if “a bit” is encountered, also the sentiment of the four preceding words is updated, e.g., “I like you a bit”.

### 4 Selecting a feature subset

We first use Weka (Hall et al., 2009) to find an initially promising subset of features. For this purpose, we employ the WrapperSubsetEval method. That means, Multinomial Naive Bayes (MNB) is used

| ID | Name             | Description  | Subspace  | Used |
|----|------------------|--|-----------|------|
| 1  | Pos_emo          | Number of positive emoticons                         | emoticons | yes  |
| 2  | Neg_emo          | Number of negative emoticons                         | emoticons | yes  |
| 3  | Elongated        | Number of elongated words                            | emoticons | no   |
| 4  | Upper            | Number of CAPITALIZED words                          | emoticons | no   |
| 5  | has_ht           | Does the tweet contain at least one hashtag?         | hashtag   | yes  |
| 6  | neg_ht           | Negative sentiment of hashtag                        | hashtag   | no   |
| 7  | neu_ht           | Neutral sentiment of hashtag                         | hashtag   | no   |
| 8  | pos_ht           | Positive sentiment of hashtag                        | hashtag   | yes  |
| 9  | neg_words_ht     | Number of negative words in hashtag                  | hashtag   | yes  |
| 10 | neu_words_ht     | Number of neutral words in hashtag                   | hashtag   | yes  |
| 11 | pos_words_ht     | Number of positive words in hashtag                  | hashtag   | yes  |
| 12 | pol_words_ht     | Number of polarity words in hashtag                  | hashtag   | yes  |
| 13 | negat_words_ht   | Number of negation words in hashtag                  | hashtag   | yes  |
| 14 | neu_words_ht_sum | Sum of negative sentiment in hashtag                 | hashtag   | no   |
| 15 | pos_words_ht_sum | Sum of neutral sentiment in hashtag                  | hashtag   | yes  |
| 16 | pol_words_ht_sum | Sum of positive sentiment in hashtag                 | hashtag   | yes  |
| 17 | punct            | Number of occurrences of '!', '??', '!?', '?!'       | default   | yes  |
| 18 | start_len        | Number of words before preprocessing                 | default   | yes  |
| 19 | end_len          | Number of words after preprocessing                  | default   | no   |
| 20 | avg_len          | Average number of words per sentence                 | default   | no   |
| 21 | adj_frac         | Percentage of adjectives                             | default   | yes  |
| 22 | adv_frac         | Percentage of adverbs                                | default   | yes  |
| 23 | v_frac           | Percentage of verbs                                  | default   | no   |
| 24 | nn_frac          | Percentage of nouns                                  | default   | no   |
| 25 | al_t_pol         | Tweet polarity (AlchemyAPI)                          | default   | no   |
| 26 | al_t_type        | Tweet polarity type (AlchemyAPI)                     | default   | yes  |
| 27 | al_e_pol         | Average entity polarity (AlchemyAPI)                 | default   | no   |
| 28 | al_e_type        | Median entity polarity type (AlchemyAPI)             | default   | yes  |
| 29 | al_neg_e         | Number of negative named entities (AlchemyAPI)       | default   | yes  |
| 30 | al_neu_e         | Number of neutral named entities (AlchemyAPI)        | default   | yes  |
| 31 | al_pos_e         | Number of positive named entities (AlchemyAPI)       | default   | yes  |
| 32 | al_mixed         | Does the tweet contain mixed sentiment? (AlchemyAPI) | default   | yes  |
| 33 | neg              | Negative sentiment (SentiWordNet)                    | default   | yes  |
| 34 | neu              | Neutral sentiment (SentiWordNet)                     | default   | yes  |
| 35 | pos              | Positive sentiment (SentiWordNet)                    | default   | yes  |
| 36 | neg_words        | Number of negative words (SentiWordNet)              | default   | yes  |
| 37 | neu_words        | Number of neutral words (SentiWordNet)               | default   | no   |
| 38 | pos_words        | Number of positive words (SentiWordNet)              | default   | yes  |
| 39 | negat_words      | Number of negation words (SentiWordNet)              | default   | no   |
| 40 | pol_words        | Number of polarity words (SentiWordNet)              | default   | yes  |
| 41 | neg_words_sum    | Sum of negative sentiment (SentiWordNet)             | default   | no   |
| 42 | neu_words_sum    | Sum of neutral sentiment (SentiWordNet)              | default   | no   |
| 43 | pos_words_sum    | Sum of positive sentiment (SentiWordNet)             | default   | yes  |

Table 3: Overview of our extracted features.

to compute F1-scores and with the help of 10-fold cross-validation on the training set the merit of different feature subsets is determined. This leaves us with a feature subset comprising 10 features. But we must consider the fact that we are using different feature subspaces as opposed to a single one for which Weka selected the features. Hence, our approach might benefit from other features not selected by Weka as well as some currently selected features could affect the performance of our system negatively. To investigate this, we work with SteM and perform 10-fold cross-validation on the training set to monitor effects on the F1-scores. We first try to reduce the feature subset determined by Weka further by removing features separately. This yields a feature subset encompassing 7 features. Now we add all features that Weka discarded separately back into SteM and observe the effects on the F1-scores. Following this procedure, we added 21 more features to our subset leading to the final tweet representation with 28 features. The list of used features is found in Column 'Used' in Table 3.

## 5 Learning a model

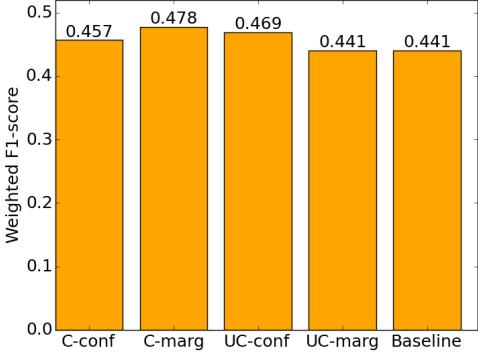

We employ Scikit-learn (Pedregosa et al., 2011) for building our classifiers. Since some of our features occur only in a small portion of the dataset, we build classifiers on different feature subspaces which we manually defined (column 'Subspace' in Table 3). Otherwise these underrepresented features would not be selected as informative features when removing noisy features during feature subset selection, although they actually help discriminate the different classes. For example, only 10-15% of the tweets in the training, development and test set contain hashtags. Likewise few tweets include emoticons. Hence, we consider *emoticons* and *hashtags* as separate feature subspaces. We learn in total three classifiers for three different subspaces: *default*, *default + emoticons*, *default + hashtags*. We choose MNB as our classifier as it is competitive with Logistic Regression and linear SVM and fast in learning models which allows us to carry out multiple experiments for quantifying the merit of different AL strategies, feature subsets, etc., as these experiments are time-consuming. With a similar reasoning we decide against ensemble methods for now as we first

want to obtain reliable results for single classifiers before studying ensembles.

## 6 Active learning

AL is motivated well in (Settles, 2010): "The key idea behind *active learning* is that a machine learning algorithm can achieve greater accuracy with fewer training labels if it is allowed to choose the data from which it learns." In (Martineau et al., 2014), the authors apply AL to detect misclassified samples and let experts relabel those instances to reduce noise. We utilize AL in a similar fashion, but instead of relabeling tweets, we discard them. We set a fixed budget for the AL strategy, which indicates for how many tweets the classifier can use the label for training, after starting from a small seed set of labeled tweets.

As AL strategies we pick uncertainty sampling (UC) and certainty sampling (C) and choose MNB as classifier. We calculate certainty/uncertainty according to two different criteria, namely margin and confidence (Li et al., 2012). In margin-based UC the tweet with the highest margin is selected for labeling, while in confidence-based UC the instance with the least confidence is chosen. Contrary to UC, C always selects the tweet about which the classifier is most confident in case of confidence, or the tweet with the lowest margin respectively. We initialize the seed set with approximately the same number of tweets from all three classes where the tweets are chosen randomly per class. Whenever an AL strategy selects a tweet to be labeled, we reveal its actual label. To identify a fixed budget for our AL strategies, we test different configurations of budgets and seed set sizes on the training set. For each run we perform 10-fold cross validation and average results over three executions to account for chance and then the labels of the development set are predicted. As a baseline method we choose random sampling which selects arbitrary tweets to be labeled. After conducting multiple experiments, we find that initializing the seed set with 500 tweets, setting the budget to 400 tweets and choosing confidence-based UC yields the highest weighted F1-scores with  $F1 = 0.48$ . Our experimental evaluation of different AL methods is visualized in Figure 1 using a seed set with 500 tweets

**Figure 1:** F1-scores on development set for different AL strategies with a seed set size of 500 tweets and a budget of 400 tweets.

and a budget of 400 tweets for which the strategies request the revealed labels. Although margin-based C seems to outperform confidence-based UC, we select the latter strategy. Tests on the development set using only the tweets selected by the respective AL strategies revealed that C achieved an F1-score of 0.30 while confidence-based UC achieved around 0.48. This inferiority of C on our data confirms reports from the literature, see e.g., (Kumar et al., 2010; Ambati et al., 2011).

## 7 Experiments

In this section we evaluate our approach on the development set as no labels for the test set are available. As AlchemyAPI is a full-fledged system, we use the 8 features extracted from it (Features 25 – 32 in Table 3) as a baseline in our experiments to compare it with SteM using a) the full training set and b) the reduced tweets after performing confidence-based UC as explained in the previous section. We then reapply the learning procedure described in Section 5 to obtain our F1-scores. The results are depicted in Table 4. Initially, our system achieves an F1-score of 0.454 using all training instances. After selecting the 900 most informative tweets using confidence-based UC from the previous section, the score increases to 0.473. We observe a similar trend for our baseline and note that it is outperformed by SteM, although the margin shrinks when reducing the number of tweets in the training set. When analyzing the corresponding confusion matrix of SteM

| Strategy | #Features | #Tweets | Dev          |
|----------|-----------|---------|--------------|
| BL       | 8         | 5481    | 0.444        |
| BL       | 8         | 900     | 0.466        |
| SteM     | 43        | 5481    | 0.454        |
| SteM     | 28        | 900     | <b>0.473</b> |

**Table 4:** Comparing F1-scores on development set using SteM and our baseline.

|       |     | Predicted |     |     |
|-------|-----|-----------|-----|-----|
|       |     | neg       | neu | pos |
| Truth | neg | 181       | 93  | 85  |
|       | neu | 206       | 181 | 298 |
|       | pos | 116       | 124 | 515 |

**Table 5:** Confusion matrix of SteM with 900 training instances.

with 900 tweets in Table 5, it becomes obvious that it fails to distinguish neutral sentiment from the remaining ones properly.

## 8 Conclusion and future work

In this paper we proposed SteM to predict tweet sentiment. After preprocessing, it extracts 43 features from tweets, selects 28 of these features as an appropriate subset to represent tweets for Multinomial Naive Bayes. One such classifier is trained for each of our three overlapping feature subspaces. To predict the labels of unknown instances, they are passed to the classifier that was trained on the respective feature subspace. Due to the noisy nature of labels in sentiment analysis, we select only few tweets for our training set by applying Active Learning. Despite utilizing only 26.3% (900 out of 5481) of the provided tweets for training, SteM outperforms an identical system trained on the full training set. Overall, our approach looks promising, but has room for improvement. Firstly, we plan to test our approach with ensembles and secondly, identify tweets with neutral sentiment more accurately. To this purpose, we plan to incorporate more features.

## Abstract

In this work, we apply classifier fusion to tweet polarity identification problem. The task is to predict whether the emotion hidden in a tweet is positive, neutral, or negative. An asymmetric SIMPLS (ASIMPLS) based classifier, which was proved to be able to identify the minority class well in imbalanced classification problems, is implemented. Word embedding is also employed as a new feature. For each word, we obtain three word embedding vectors on positive, neutral, and negative tweet sets respectively. These vectors are used as features in the ASIMPLS classifier. Another three state-of-the-art systems are implemented also, and these four systems are fused together to further boost the performance. The fusion system achieved 59.63% accuracy on the 2016 test set of SemEval2016 Task 4, Subtask A.

## 1 Introduction

The I2RNTU system works on the Subtask A: Message Polarity Classification in Twitter of SemEval-2016 Task 4: the Sentiment Analysis in Twitter (Nakov et al., 2016). The task is to predict whether a tweet is of positive, neutral, or negative sentiment. This task can be formulated as a multi-class classification problem, i.e., to classify a tweet into one of the three classes. We use the one-vs-rest strategy to solve the three-class classification problem. Given a tweet, a classifier generates three confidence scores about the tweet belonging to the three classes respectively. The predicted label is chosen based on the highest confidence score. Four classifiers are implemented in our work, and classifier

fusion is used to improve the system performance.

Classifier fusion has been proved to be very powerful in classification problems. In SemEval-2015, a system named Webis won the first place in the message polarity classification subtask, which is subtask B of SemEval-2015 task 10 “Sentiment Analysis in Twitter” (Hagen et al., 2015). The authors reproduced four state-of-the-art twitter polarity prediction algorithms. Each algorithm generates three confidence scores for a tweet. The fusion system averages the scores generated by the four classifiers, and then predicts a label according to the highest average score. In the Speaker State Challenge of INTER-SPEECH 2011, the method of fusing Asymmetric SIMPLS (ASIMPLS) and Support Vector Machines (SVMs) won the sleepiness sub-challenge (Huang et al., 2011). The asymmetric SIMPLS based classifier is shown to be able to generate a higher prediction accuracy for the class with small number of instances in the imbalanced classification problem, while SVMs are strong at predicting the class with majority number of instances. The fusion of these two types of methods could achieve a balance between favouring the majority class and the minority class. In the Music Information Retrieval Evaluation eXchange (MIREX 2013), the method of fusing SIMPLS and SuperFlux won the 3rd place on Audio Onset Detection subtask (Zhang et al., 2013). In the Emotion Recognition in the Wild Challenge (EmotiW2014), which aims to automatically classify the emotions acted by human subjects in video clips under real-world environment, the fusion of kernel SVM, logistic regression, and partial least squares (PLS) with different Riemannian ker-

nels won the first place of the competition (Liu et al., 2014). In this paper, we will take advantage of the classifier fusion again. We introduce the asymmetric SIMPLS based classifier to the tweet polarity classification problem, and combine it with other three of state-of-the-art classifiers. The fusion method is same with (Hagen et al., 2015).

The most popular features used in the tweet polarity classification problem are derived from sentiment lexicons (Rosenthal et al., 2015). Word embedding represents a word using a low dimensional vector which contains the syntactic and semantic meaning of the word. If we can enhance the sentiment information hidden in the vector, it may be a good feature for the task. Word embedding has been used in tweet sentiment analysis in (Zhang et al., 2015). The authors used the vectors with dimensionality of 300 trained by word2vec, which is publicly available on-line<sup>1</sup>. However, the vectors are trained using Google News. No emotional info was considered during the training. Also, the news articles are written in formal language. Many words appearing frequently in tweets such as ‘goood’ may not be included in the data set. In this paper, we train the word embedding on downloaded tweet data sets. Furthermore, we separate the tweet data set into three subsets named positive, neutral, and negative subsets respectively. For each word, three vectors are obtained. These vectors are used as features for the ASIMPLS classifier.

The papers of task description of Se-mEval (Rosenthal et al., 2015; Rosenthal et al., 2014; Nakov et al., 2013) may be the best material of understanding the related work of sentiment analysis in twitter. The classifiers used include SVM, maximum entropy, Conditional Random Fields (CRFs), deep neural networks, and linear regression etc. The most popular features are derived from sentiment lexicons. Bag-of-words, hashtags, and punctuations etc. are also used widely.

We will introduce the asymmetric SIMPLS classifier and the proposed word embedding feature in Section 2. The three state-of-the-art systems and the fusion method are described in Section 3. The experimental results are shown in Section 4. We conclude

our work in Section 5.

## 2 The Asymmetric SIMPLS (ASIMPLS) based classifier

### 2.1 The ASIMPLS algorithm

Partial Least Squares (PLS) has been introduced into classification problems in (Huang et al., 2011). SIMPLS is an efficient algorithm for PLS regression that calculates the PLS factors as linear combinations of the original variables (De Jong, 1993). Given two matrices  $\mathbf{X} \in \mathbb{R}^{N \times M}$  with  $N$  samples and  $M$  dimensional features, and a label matrix  $\mathbf{Y} \in \mathbb{R}^{N \times K}$ . The SIMPLS algorithm aims to find a linear projection (De Jong, 1993)

$$\hat{\mathbf{Y}} = \mathbf{XB} \quad (1)$$

For the bianry classification problems,  $K = 1$ . The solution is to extract the orthogonal factors of  $\mathbf{X}$  and  $\mathbf{Y}$  sequentially,

$$\mathbf{t}_a = \mathbf{X}_0 \mathbf{r}_a \quad (2)$$

and

$$\mathbf{u}_a = \mathbf{Y}_0 \mathbf{q}_a, a = 1, 2, \dots, A \quad (3)$$

where  $\mathbf{X}_0 = \mathbf{X} - \text{mean}(\mathbf{X})$ ,  $\mathbf{Y}_0 = \mathbf{Y} - \text{mean}(\mathbf{Y})$ , and  $A \leq M$ . The algorithm of extracting the parameters is shown in Algorithm 1 (De Jong, 1993; Huang et al., 2011; Zhang et al., 2013). It can be seen as the training algorithm of the ASIMPLS based classifier.

In the SIMPLS algorithm, a constrain is added that the scores  $\mathbf{t}_i$  are orthogonal to each other, i.e.,  $\mathbf{t}'_b \mathbf{t}_a = 0$  for  $a > b$ . Also  $\mathbf{t}_a$  is normalized by  $\mathbf{t}_a = \mathbf{t}_a / \sqrt{\mathbf{t}'_a * \mathbf{t}_a}$ . Then we have  $\mathbf{T}'\mathbf{T} = \mathbf{I}$  where  $\mathbf{T} = [\mathbf{t}_1, \dots, \mathbf{t}_A]$ . Hence,

$$\hat{\mathbf{Y}}_0 = \mathbf{T}\mathbf{T}'\mathbf{Y}_0 = \mathbf{X}_0 \mathbf{R} \mathbf{R}' \mathbf{X}'_0 \mathbf{Y}_0 = \mathbf{X}_0 \mathbf{R} \mathbf{R}' \mathbf{S}_0 \quad (4)$$

We can write  $\mathbf{B}$  in (1) as:

$$\mathbf{B} = \mathbf{R}(\mathbf{R}'\mathbf{S}_0) = \mathbf{R}(\mathbf{T}'\mathbf{Y}_0) = \mathbf{R}\mathbf{Q}' \quad (5)$$

For a new feature matrix  $\mathbf{X}^*$ , the new projected matrix

$$\hat{\mathbf{Y}}^* = \mathbf{X}_0^* \mathbf{B} \quad (6)$$

where  $\mathbf{X}_0^* = \mathbf{X}^* - \text{mean}(\mathbf{X}^*)$ . The prediction can be written in another format (De Jong, 1993):

$$\mathbf{Y} = \sum_{i=1}^A \mathbf{b}_i \mathbf{t}_i^* \mathbf{q}_i' \quad (7)$$

---

**Algorithm 1** Training procedure of SIMPLS

---

**Input:** Feature set  $\mathbf{X}$ , Label  $y$ , and Number of components  $A$

**Variables:** Projection matrix  $\mathbf{R}$ ,  
score vectors  $\mathbf{T}$  and  $\mathbf{U}$ ,  
loading  $\mathbf{P}$  and  $\mathbf{Q}$

$\mathbf{R} = []$ ;  $\mathbf{V} = []$ ;  $\mathbf{Q} = []$ ;  $\mathbf{T} = []$ ;  $\mathbf{U} = []$ ;  
 $\mathbf{y} = [y_1, y_2, \dots, y_N]'$ ;  $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N]'$ ;  
 $\mathbf{y}_0 = \mathbf{y} - \text{mean}(\mathbf{y})$ ;  $\mathbf{X}_0 = \mathbf{X} - \text{mean}(\mathbf{X})$ ;  
 $\mathbf{S} = \mathbf{X}_0' \mathbf{y}_0$

**for**  $i = 1$  to  $A$  **do**

- $\mathbf{q}_i$  = dominant eigenvectors of  $\mathbf{S}'\mathbf{S}$
- $\mathbf{r}_i = \mathbf{S} * \mathbf{q}_i$
- $\mathbf{t}_i = \mathbf{X}_0 * \mathbf{r}_i$
- $\text{normt}_i = \text{SQRT}(\mathbf{t}_i' \mathbf{t}_i)$
- $\mathbf{t}_i = \mathbf{t}_i / \text{normt}_i$
- $\mathbf{r}_i = \mathbf{r}_i / \text{normt}_i$
- $\mathbf{p}_i = \mathbf{X}_0' * \mathbf{t}_i$
- $\mathbf{q}_i = \mathbf{y}_0^T * \mathbf{t}_i$
- $\mathbf{u}_i = \mathbf{y}_0 * \mathbf{q}_i$
- $\mathbf{v}_i = \mathbf{p}_i$
- if**  $i > 1$  **then**

  - $\mathbf{v}_i = \mathbf{v}_i - \mathbf{V} * (\mathbf{V}' * \mathbf{p}_i)$
  - $\mathbf{u}_i = \mathbf{u}_i - \mathbf{T} * (\mathbf{T}' * \mathbf{u}_i)$

- end if**
- $\mathbf{v}_i = \mathbf{v}_i / \text{SQRT}(\mathbf{v}_i' * \mathbf{v}_i)$
- $\mathbf{S} = \mathbf{S} - \mathbf{v}_i * (\mathbf{v}_i' * \mathbf{S})$
- $\mathbf{r}_i, \mathbf{t}_i, \mathbf{p}_i, \mathbf{q}_i, \mathbf{u}_i$ , and  $\mathbf{v}_i$  into  $\mathbf{R}, \mathbf{T}, \mathbf{P}, \mathbf{Q}, \mathbf{U}$ , and  $\mathbf{V}$ , respectively.

**end for**

$\mathbf{B} = \mathbf{R} * \mathbf{Q}'$

---

---

**Algorithm 2** To obtain new  $\mathbf{T}$  in testing

---

**Input:** New feature matrix  $\mathbf{X}$ ; projection matrix  $\mathbf{R}$ .

**Output:** New  $\mathbf{T} = [\mathbf{t}_1^*, \mathbf{t}_2^*, \dots, \mathbf{t}_A^*]$

$\mathbf{X}_0 = \mathbf{X} - \text{mean}(\mathbf{X})$

**for**  $i = 1$  to  $A$  **do**

- $\mathbf{t}_i^* = \mathbf{X}_{i-1} \mathbf{r}_i$ ;
- $\mathbf{X}_i = \mathbf{X}_{i-1} - \mathbf{t}_i^* (\mathbf{t}_i^{*'} \mathbf{X}_{i-1}) / (\mathbf{t}_i^{*'} \mathbf{t}_i^*)$ ;

**end for**

---

where  $\mathbf{b}_a = \mathbf{u}_a' \mathbf{t}_a / (\mathbf{t}_a' \mathbf{t}_a)$ . The new  $\mathbf{t}^*$  is calculated by Algorithm 2. For the classification problems, we need to predict the label of a sample

$$\hat{\mathbf{Y}} = \text{sign}\left(\sum_{i=1}^A \mathbf{b}_i \mathbf{t}_i^* \mathbf{q}_i'\right) \quad (8)$$

$$= \text{sign}\left(\sum_{i=1}^A \mathbf{m}_i \mathbf{t}_i^*\right) \quad (9)$$

$$= \text{sign}(\mathbf{m} \cdot \mathbf{t}^*) \quad (10)$$

It can be observed that the label  $\hat{\mathbf{Y}}$  is a function of the score vectors  $\mathbf{t}^*$ . If  $\hat{\mathbf{Y}}$  and  $\mathbf{t}$  were on a plane, the boundary would be a line passes the original point  $(0, 0)$ . Suppose the original point is the center of the whole data set, which can be achieved by subtracting the mean of the data. When the number of instances of a class is much less than the other one, the original point will be far away from the center of the minority class, while near the center of the majority class. Hence, the line will pass cross the majority class. That is the reason that PLS based classifiers can detect the minority class well. However, the accuracy of majority class will decrease because the line cuts the majority class into two parts. The Asymmetric PLS classifier tries to move the line towards to the center of the minority class to make the boundary in the middle of the two classes (Huang et al., 2014). The distance moved is calculated on the first dimension of  $\mathbf{T}$ . The center points and the radii of positive and negative classes are estimated as in (11). Let the minority class be the positive class, and  $\text{index\_positive}$  denotes the index of positive items in  $\mathbf{Y}$ . We use  $\mathbf{t}_p = \mathbf{t}_1[\text{index\_positive}]$ . Similarly,  $\mathbf{t}_n = \mathbf{t}_1[\text{index\_negative}]$ . The center points and the radii of the two classes are estimated by

$$\begin{aligned} rad_p &= \text{std}(\mathbf{t}_p) \\ rad_n &= \text{std}(\mathbf{t}_n) \\ cp_p &= \text{mean}(\mathbf{t}_p) \\ cp_n &= \text{mean}(\mathbf{t}_n) \end{aligned} \quad (11)$$

Then the distance should be moved is

$$\text{distance} = cp_p - (cp_p - cp_n) * \frac{rad_p}{rad_p + rad_n}$$

We move the line on the plane of  $t$

$$\hat{\mathbf{Y}} = \text{sign}\left(\sum_{i=1}^A \mathbf{m}_i \mathbf{t}_i^*\right) - \mathbf{m}_1 * \text{distance} \quad (12)$$

## 2.2 Features used in the ASIMPLS classifier

The features used in the ASIMPLS system are mainly adopted from the NRC-Canada (Mohammad et al., 2013) system. We will describe the features in detail in Section 3.1. In addition, we propose a type of word embedding based feature named emotional word embedding.

We assume that vectors obtained on pure positive/negative tweets are different from those obtained on the general text because the distribution of words are different. Hence, we collected three tweet sets on-line: positive, neutral, and negative. The twitter4j library <sup>2</sup> is used to collect the tweets. We collected a set of happy emoticons such as :), :D, : -, :o), :], :c), =], 8), =), :}, as well as a set of unhappy emoticons like :(, :-(), :c, :c, :[, :[], :{. We use them as keywords, and search tweets containing these emoticons. The tweets containing a happy emoticon are put into the positive set. Similarly, a tweet containing an unhappy emoticon is put into the negative set. For the neutral tweets, we search those containing keywords like sports, news, etc. This is a very simple rule to collect data sets. Noise will be introduced, and more filtering work shall be done in the future. Finally, we collect about 69 million positive tweets, 19 million neutral tweets, and 19 million negative tweets. The tweets are pre-processed by the CMU tweet NLP tools (Gimpel et al., 2011). We remove the @somebody tags and the hyper-links in the tweets. Three vectors are trained on the three data sets respectively for each word. The vectors are obtained using the open-source toolkit word2vec with negative sampler 10, window width 5, and vector dimension 100. The feature of a tweet is the mean value of the vectors of every word. These 300 dimensional features are put together with the other features to train the ASIMPLS classifier.

## 3 Reproduced Systems

With reference to the state-of-the-art system designed by team Webis (Hagen et al., 2015), we had

---

<sup>2</sup><http://twitter4j.org/en/index.html>

also incorporated three models out of four (those developed by team NRC-Canada, team GU-MLT-LT and team KLUE) into our own system. As proved by the outstanding performance of team Webis in SemEval-2015, each of the three systems employed a unique set of features that could complement each other and would help enhance the performance in the three-point scale tweets sentiment classification. Thus, we decide to keep most of the same set of features for each reimplemented model and use the same classifier, L2-regularized logistic regression, for the three reimplemented systems. In detail, we use the weka.classifiers.functions.LibLINEAR class. The SVM Type is set to be 0, and the Cost is set to be 0.05. The other parameters use default values. The preprocessing steps for all three implementations are similar, which involves converting all letters to lower case and removing all the URLs and user names. Each system is described shortly in the following subsections.

### 3.1 NRC-Canada

In the reimplementation of the model developed by team NRC-Canada (Mohammad et al., 2013), all preprocessed tweets are tokenized and POS-tagged with the Twitter NLP tool developed by Carnegie Mellon University (Gimpel et al., 2011). The model leverages a rich set of features. We had kept all the features. Firstly, **word N-grams** and **character N-grams** are used. Word N-grams include the existence of one to four contiguous sequences of tokens and non-contiguous ones. Character N-grams include the existence of three, four and five consecutive sequences of characters. Secondly, the number of words with **all capitalized letters** and the number of **hashtags** are included in the feature set. Thirdly, the feature set contains the number of times each **part-of-speech tag** occurred. Next, **punctuation marks** and **emoticons** are also part of the features, because the number of consecutive sequences of exclamation/question marks and the polarity of an emoticon in the tweets would help determine the overall sentiment. In addition, the number of **elongated words**, such as “youuuuu”, and the number of **negations** are employed. As specified in (Pang et al., 2002), the negated context is part of a tweet that begins with a negation word, such as “not”, and ends with a punctuation mark. With negation, the

sentiment expressed by a token will be reversed. We attach each token in a negated context with a suffix “NEG”. Furthermore, with the Brown clustering method (Brown et al., 1992), 56,345,753 tweets by Owoputi (Owoputi et al., 2013) have been clustered into 1000 clusters. If the tokens belonging to these clusters were present in the tweets, these clusters would be included in the feature set. Lastly, three manually crafted and two automatically generated polarity dictionaries are used, i.e., the **NRC Emotion Lexicon** (Mohammad and Turney, 2010; Mohammad and Turney, 2013), the **MPQA Lexicon** (Wilson et al., 2005), the **Bing Liu Lexicon** (Hu and Liu, 2004), **Hashtag Sentiment Lexicon** and **sentiment140 Lexicon**.

### 3.2 GU-MLT-LT

For the system designed by team GU-MLT-LT (Günther and Furrer, 2013), the tokenization process is slightly different from that of NRC-Canada system. Besides tokenizing the original raw tweets, the letters of tweets are lowercased and these normalized tweets are tokenized. In addition, for all the elongated words shown in the aforementioned normalized tweets, such as “youuu”, repetitions of letters after the first one are removed. A new version of further normalized tweets are obtained and then tokenized. Team GU-MLT-LT employed a smaller set of features as compared to that of team NRC-Canada. Our team keeps some of the features original used by GU-MLT-LT in our reimplementation. Firstly, **unigrams and bigrams** are used. For bigrams, stop word tokens, such as “the”, and punctuation tokens, such as “.”, are removed. In addition, following the Porter stemmer algorithm (Porter, 1980), **the word stems** of the normalized tokens are included in the feature set. Moreover, the polarity dictionary used is **the Senti-WordNet** (Baccianella et al., 2010). Similar to that of team NRC-Canada, **clustering and negation** are also employed in the feature set.

### 3.3 KLUE

The tokenization process in the reimplementation of system designed by team KLUE (Proisl et al., 2013) is similar to that of team NRC-Canada. The features used by KLUE are quite different from those used by the other two teams. In order to complement

the features of the other two systems, we keep most of the features used by team KLUE in our reimplementation. Firstly, **unigram and bigrams** are considered and their frequencies of occurrence serve as feature weights. In order to be counted as part of the feature set, the unigrams and bigrams should be present in at least five tweets. Secondly, **the total number of tokens per tweet** is also incorporated in the feature set. Furthermore, the polarity dictionary chosen is **AFINN-111 lexicon** (Nielsen, 2011) which contains a variety of words of degree from -5(very negative) to +5(very positive). The dictionary is used to extract features including **the frequencies of occurrence of positive and negative tokens, the total number of tokens that expressed one sentiment as well as the arithmetic mean of total sentiment scores per tweet**. Moreover, for **emoticons**, we adopt the manually crafted dictionary and its polarity scoring from Webis team and apply them in this reimplementation. Lastly, **negation** is considered for up to next three tokens or less for the case that the tweet ends within three tokens after the negated word and the sentiment scores for tokens up to a distance of at most 4 following the negated marker are reversed.

### 3.4 The fusion method

The four classifiers generate three confident scores  $s_{pos}^i, s_{neu}^i, s_{neg}^i, i = 1, 2, 3, 4$  for each tweet respectively. We fuse the systems by summing these scores with a same weight. The final scores are  $[\frac{1}{4} \sum_{i=1}^4 s_{pos}^i, \frac{1}{4} \sum_{i=1}^4 s_{neu}^i, \frac{1}{4} \sum_{i=1}^4 s_{neg}^i]$ . The predicted label is the index with the maximum score value.

We find that ASIMPLS does not perform well if the dimension of the features is much larger than the number of training samples. Unfortunately the features used in this task have more than 200 thousand dimensions, while we only have about 16 thousands training samples. Hence, the classifier fusion is used again. We split the features into 5 parts, e.g., the first 40 thousand dimensions of the features are used to train a ASIMPLS classifier. The second 40 thousand dimensions are used to train another one etc. The confidence scores of the 5 ASIMPLS classifiers are averaged to generate a new set of confidence scores. These scores are the output of the ASIMPLS system. We combine them with scores generated by other

|                     | Training Set | Testing Set |
|---------------------|--------------|-------------|
| 2013                | 11338        | 3813        |
| 2014                | 0            | 1853        |
| 2016                | 5348         | 1704+1781   |
| Total               | 16686        | 9151        |
| After Preprocessing | 16682        | 9146        |
| Positive            | 6956         | 4153        |
| Neutral             | 7166         | 3579        |
| Negative            | 2560         | 1414        |

**Table 1:** Training and testing sets.

three systems as discussed above. For the ASIMPLS classifier, feature selection is an alternative way of improving system performance instead of classifier fusion, which will be tried in future work.

## 4 Experimental Results

Our training set is composed by the training and development set of SemEval-2013 as well as the training set of SemEval-2016. The testing set includes the development-test set of 2013 and 2014, as well as the development and development-test sets of 2016. The numbers of tweets in all data sets are shown in Table 1. We remove the tweets that only have @somebody or hyper-links. Hence, we have a total of 16682 tweets for training and 9146 tweets for testing after preprocessing. In both training and testing sets, there are much less number of negative tweets comparing to positive and neutral tweets. ASIMPLS may help improve the accuracy of negative tweets.

The experimental results are shown in Table 2. We list all the results of individual systems and the fusion results. In the table, the “Score” is the value obtained using the evaluation method of SemEval2016 Task 4 (Nakov et al., 2016). “Positive” means the accuracy of positive samples in the testing, i.e.  $\text{Positive} = \frac{\text{number of correct positive samples}}{\text{number of all positive samples}}$ . Similarly, “Negative” and “Neutral” denote the accuracies of negative as well as neutral samples respectively. “All Accuracy” means  $\frac{\text{number of all correct samples}}{\text{number of all testing samples}}$ . The results demonstrated that classifier fusion is able to generate better scores than individual classifiers. Fusing all systems obtained the best score 63.78. It is marginally higher than the score of fusing the first three systems 63.72. The score of the PLS system is worse than the other three systems. The reason may

be that the dimension of the features (more than 200 thousands) is even bigger than the number of training samples (about 16 thousands). The ASIMPLS classifier is not good at handling this type of data even we have used 5 subsystems to alleviate the influence of high dimensional features. Nonetheless, it obtained the highest accuracy of negative samples and the second-best accuracy of neutral samples. The positive accuracy is much worse than the other three classifiers. It indicates that the bias should be further adjusted in the future. The results of our submission are shown in Table 3. We obtained a score of 59.63 on the 2016 Tweet submission.

## 5 Conclusion

In this paper, we have applied classifier fusion to the sentiment analysis in twitter task. An ASIMPLS based classifier has been implemented, and has been combined with other three state-of-the-art methods. A new feature named emotional word embedding has been introduced, and has been used in the ASIMPLS based method. Experimental results demonstrated that the fusion is able to improve the system performance because it can combine the strengths of different classifiers. The ASIMPLS obtained a good minority class accuracy and a bad accuracy for the majority class. How to adjust the bias to improve the balance between these two classes is the future work.

## Abstract

In this paper we describe our deep learning approach for solving both two-, three- and five-class tweet polarity classification, and two- and five-class quantification. We first trained a convolutional neural network using pretrained Twitter word embeddings, so that we could extract the hidden activation values from the hidden layers once some input had been fed to the network. These values were then used as features for a support vector machine in both the classification and quantification subtasks, together with additional linguistic information in the former scenario. The results obtained for the classification subtasks show that this approach performs better than a single convolutional network, and for the quantification part it also yields good results. Official rankings locate us: 2nd (practically tied with 1st) for the binary classification task, 2nd for binary quantification and 4th (practically tied with 3rd) for the five-class polarity classification challenge.

## 1 Introduction

Opinion mining has become an important mechanism to monitor what people are saying about a variety of topics (Cambria et al., 2013). As an example, Thelwall et al. (2011) use SentiStrength to

\*This research is supported by the Ministerio de Economía y Competitividad (FFI2014-51978-C2). David Vilares is funded by the Ministerio de Educación, Cultura y Deporte (FPU13/01180). monitor popular events on Twitter (e.g. the Oscars, the SuperBowl), showing how these resonate among the public. In a similar line, Vilares et al. (2015) also use Twitter to measure the level of popularity of the main Spanish political leaders, proving that the results obtained by their systems are similar to the ones obtained by traditional polls.

Opinion mining on Twitter actually involves two different challenges: (1) analyzing the characteristics of individual tweets and (2) quantifying a given set of tweets so that useful statistics can be extracted. This paper describes our different models to overcome such challenges, using the SemEval 2016:Task 4 as the evaluation framework.

## 2 Sentiment Analysis in Twitter

The SemEval organization proposed two different types of challenges in its 2016 edition: (1) classification into two, three and five classes and (2) quantification into two and five categories. A detailed explanation of the task can be found in the description paper (Nakov et al., 2016). For all subtasks, three official splits are provided: training, development and development test sets. In this paper, we use the training and development sets for training, and the development test set for evaluation.<sup>1</sup>

### 2.1 Convolutional Neural Network

As a starting point, we train a deep neural network (DNN), in particular a convolutional neural network (CNN), following a similar configuration to the one

<sup>1</sup>For classification into 3 polarities, we include the training set of SemEval 2013 as part of our training set and its development set as a part of our collection for tuning.

used by Severyn and Moschitti (2015). Figure 1 illustrates the topology of the CNN from where we will extract the hidden activation values.

### 2.1.1 Embeddings layer

Let  $w$  be a token of a vocabulary  $V$ , a word embedding is a distributed representation of that token as a low dimensional vector  $v \in \mathbb{R}^n$ . In that way, it is possible to create a matrix of embeddings,  $E \in \mathbb{R}^{|V| \times n}$ , to act as the input layer to the CNN. Particularly, we rely on a collection of Twitter word embeddings pretrained with Glove<sup>2</sup> (Pennington et al., 2014) with  $|V| \approx 10^6$  and  $n=100$ .

Thus, given a tweet  $t=[w_1, w_2, \dots, w_t]$ , after running our input layer we will obtain a matrix  $T \in \mathbb{R}^{|t| \times n}$  that will serve as the input to the convolutional layer. Since tweets might have variable length,  $|t|$  is set to 100, padding with zeros if the tweet is shorter and taking the first 100 words if it is longer. We have realized after the evaluation that this value might be not the best option for short texts, such as tweets, and we plan to optimize this parameter empirically. To avoid overfitting, we first apply dropout (Srivastava et al., 2014), which randomly sets to zero the activation values of  $x\%$  of the neurons in a given layer (in this paper,  $x = 50$ ).

### 2.1.2 Convolutional Layer

A convolutional layer exploits local correlations in the input data. In the case of text as input, this translates into extracting correlations between groups of word or character n-grams in a sentence. To do so, each hidden unit of the CNN will only respond (activate) to a specific continuous slice of the input text. This is implemented on <http://keras.io> using convolutional operations with  $m$  convolutional filters of width  $f$  separately applied to the input, obtaining  $m$  representations of this input usually known as feature maps.

Formally, let  $T \in \mathbb{R}^{|t| \times n}$  be the matrix embedding for the tweet  $t$  and let  $F \in \mathbb{R}^{f \times n}$  be a filter, the output of a wide convolution is a matrix  $C \in \mathbb{R}^{m \times (|t|+f-1)}$ , where each  $c_i \in \mathbb{R}^{|t|+f-1}$  is defined as:

$$C_i = \sum_{j,k} T_{[i-f+1:i,:]} \otimes F \quad (1)$$

---

<sup>2</sup><http://nlp.stanford.edu/data/glove.twitter.27B.zip>

and where  $\otimes$  is the element-wise multiplication,  $1 < i < m$ ; and  $j$  and  $k$  are the rows and columns of the matrix  $T_{[i-f+1:i,:]} \otimes F \in \mathbb{R}^{f \times n}$ . The non valid rows of  $T$  ( $T_{(i,:)}$  with  $i < 0$ ) are set to zero.

Following Severyn and Moschitti (2015), in this paper we chose  $f = 5$  and  $m = 300$ . We also rely on  $ReLU(x) = \max(0, x)$  as the non-linear activation function. To avoid overfitting we incorporate a L2 regularization of 0.0001. After that, a max pooling layer selects  $\max(ReLU(c_i))$  for each feature map.

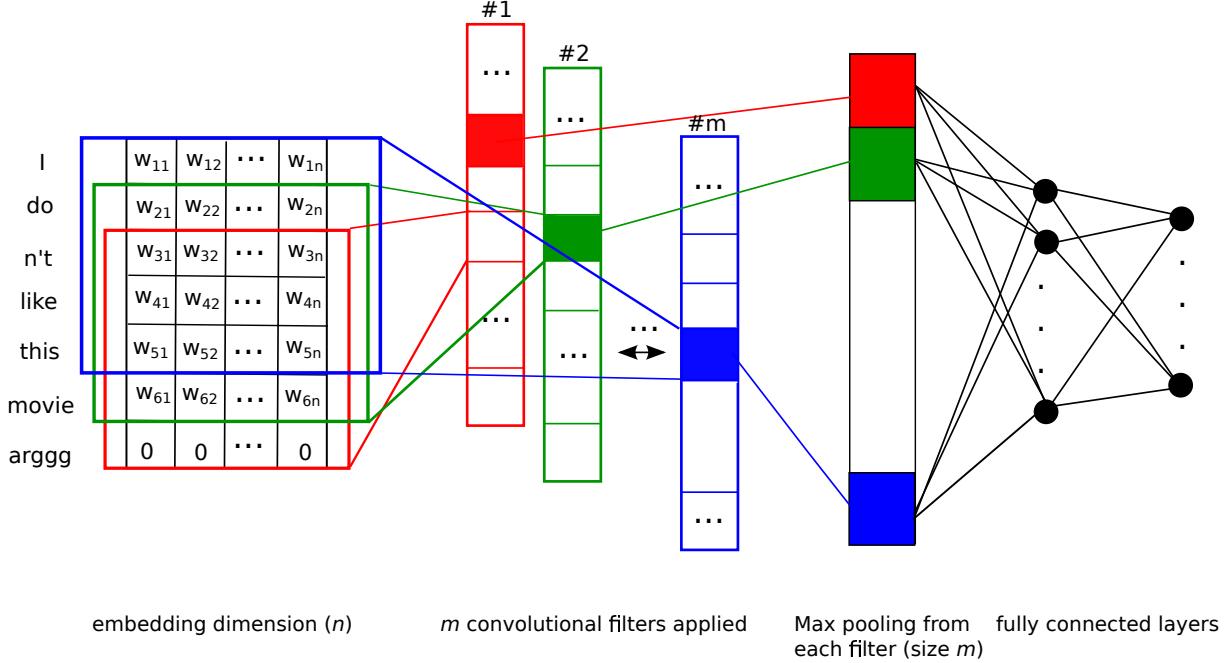

### 2.1.3 Output layer

The output of the pooling layer is then passed to a fully connected layer ( $\mathbb{R}^{100}$ ). We add again dropout (50%) and a ReLU as the activation function. Finally, an additional fully connected layer reduces the dimensionality of the input to fit the output (number of classes) and as the final step we apply a softmax function to make the final prediction.

### 2.1.4 Current limitations

Obtaining an accurate deep neural network can be a very slow process. Hyper-parameter engineering is often needed, but training a single DNN with its hyper-parameters can be painfully slow without enough computational resources. Additionally, *distant supervision* is also recommended to pretrain the network (Go et al., 2009; Severyn and Moschitti, 2015). These two issues act as limitations that we could not overcome at the moment. We did try pre-training, but at the moment, we did not achieve improvements over the CNN without pretraining. A preliminary analysis suggests that: (1) we need more tweets to exploit distant supervision, (2) fine hyper-parameter engineering needs to be explored to ensure that the fine-tuning on the labeled data does not completely overwrite what the network has already learned and (3), it is easy to collect tweets for analysis into 2 classes, but downloading non-noisy tweets for analysis into 3 and 5 classes is a more challenging issue.

In the following section we show how to exploit the hidden activation values of our deep learning model as part of a supervised system (Poria et al., 2015), when pretraining and fast hyper-parameter engineering are not feasible options.

**Figure 1:** Topology of our CNN from where we will extract the neural activation values

## 2.2 Classification

Let  $S = \{s_1, \dots, s_n\}$  be a set of tweets and let  $L = \{l_1, \dots, l_n\}$  be a set of labels, the classification subtask can be defined as designing a hypothesis function  $h_\Theta : S \rightarrow L$ , where  $\Theta$  denotes a set of features representing the texts. We build functions to solve classification into five (strong positive (P+), positive (P), neutral (NEU), negative (N) and strong negative (N+)), three (P, NEU and N) and two (P and N) classes. We rely on a support vector machine (SVM), in particular on a LibLinear (Fan et al., 2008) implementation with L2-regularization, to train our supervised model.<sup>3</sup> As features, we started testing some of those from our last SemEval system (Vilares et al., 2014), using the total occurrence as the weighting factor. Information gain (IG) is used in all cases. Thus, before training our classifier we run an information gain algorithm to remove all irrelevant features, i.e. those where  $IG=0$ :

- *Words (w)*: Each single word is considered as a feature to feed the supervised classifier.
- *Psychometric properties (P)*: Features extracted from psychological properties coming from LIWC (Pennebaker et al., 2001) that relate

terms with psychometric properties (e.g. *anger* or *anxiety*) or topics (e.g. *family* or *religion*).

- *Part-of-speech tags (T)*.

Additionally, this year we have included:

- *The last word of the tweet (LW)*: The last term of each tweet is used as a separate feature.
- *The psychometric properties of the last word of the tweet (LP)*.
- *Hidden activation values from the CNN (HV)*: We take the hidden activation values of the last hidden layer.
- *Features extracted from sentiment dictionaries*: We extract the total, maximum, minimum and last sentiment score of a tweet from the Sentiment140 (Mohammad et al., 2013), Hu and Liu (2004) and Taboada et al. (2011) subjective lexica.

### 2.2.1 Experimental results

Table 1 shows the experimental results for classification into two classes obtained using the SVM with different feature sets and the CNN. The neural network outperforms most of the SVM approaches. Only when we combine a number of linguistic features with the hidden activation values and we

<sup>3</sup>We used Weka (Hall et al., 2009) to build the models.

| Features         | Recall-P | Recall-N | Macro avg. R |

| CNN              | 0.802    | 0.671    | 0.737        |

**Table 1:** Classification into two classes using the development test set 2016. We include feature models that include hidden activation values (HV), words (w), psychometric (P), sentiment dictionaries (D), last word of the tweet (LW) and last psychometric properties (LP). The dot indicates a model that combines those features. \* indicates a model where the class weights have been tuned. We compared them against our CNN.

weight the classes, we obtain an improvement over the CNN. We believe that by applying fine hyper-parameter tuning on the CNN we will be able to further improve these results. Similar conclusions can be extracted from the classification into three classes, whose results are shown in Table 2. Finally, Table 3 details the results for the five categories classification subtask. In this case, the neural network does not perform as good as in previous scenarios.

| Features         | F1-P  | F1-Neu | F1-N  | Macro avg. F1 |
|------------------|-------|--------|-------|---------------|
| HV.P.FT.D.LW.LP* | 0.676 | 0.520  | 0.538 | 0.598         |

**Table 3:** Classification into five classes using the development test set 2016. Macro-averaged absolute error (MAE) is used to rank the models. F1-measure is used to show the performance over each class.

With respect to SVM-specific parameter optimiza-

tion, cost parameter (C) and class weights (w):

- 2 classes: C=0.005, w<sub>negative</sub>=2.25 and w<sub>positive</sub>=0.25.
- 3 classes: C=0.0001, w<sub>positive</sub>=0.5, w<sub>neutral</sub>=0.4 and w<sub>negative</sub>=2.
- 5 classes: C=1, w<sub>strong negative</sub>=5.5, w<sub>negative</sub>=1, w<sub>strong positive</sub>=1.5, w<sub>positive</sub>=0.25 and w<sub>neutral</sub>=0.5.

## 2.3 Quantification

For this task we are not interested in predicting the class of each individual instance of the dataset, as in classification tasks, but the relative frequency of each class in whole groups of instances; this is, the *class distribution*. In this context, models trained using loss functions well suited for classification are not necessarily good enough for quantification, as the loss function we need to optimize for has changed just in the same way as the aim of the task, in relation to a classification task (Barranquero et al., 2015).

The most simple approach to tackle this problem would be *Classify and Count* (CC) (Forman, 2008), which estimates the class frequencies counting the positive results of a classifier for each class over the total amount of input instances. Nevertheless, more specialized methods exist, such as the use of an SVM learning algorithm paired with a nonlinear loss function such as the *Kullback-Leibler Divergence* (KLD) (Esuli and Sebastiani, 2015), which we have used in this work thanks to the tool *SVMperf* (Joachims, 2005) patched to work with KLD.<sup>4</sup>

The different feature sets tested for our quantification system were automatically obtained as the activation values from different layers of the convolutional network used in the classification subtasks of this workshop. The SVM model was trained with a linear kernel and no regularization bias, optimizing the KLD over the entire training dataset.

Finally, as our system deals specifically with binary quantification, we took a one-vs-all approach and trained multiple models to generalize the quantification process for  $n$  classes rather than just two

<sup>4</sup><http://hlt.isti.cnr.it/quantification/>.

| (#) CNN layer     | 2 classes (KLD) | 5 classes (EMD) |
|-------------------|-----------------|-----------------|
| (4th) Max pooling | 0.07            | 0.82            |

classes. The results obtained later by these models were normalized so that relative frequencies sum up to one.

### 2.3.1 Experimental results

Results obtained using neural activation values chosen from particular layers of our convolutional network as features for the SVM can be found in Table 4. As our baseline, we performed a CC on the results obtained from the best classifiers from the classification subtasks.

## 3 Results on the gold test set

Table 5 shows the scores and rankings of our systems for each subtask, according to the official metrics used for each challenge. A detailed report of the results for all participants can be found at Nakov et al. (2016) and the official website.<sup>5</sup>

## 4 Conclusions

We have described our approach to tackle the classification and quantification challenges proposed at

<sup>5</sup><http://alt.qcri.org/semeval2016/task4/index.php?id=results>

Task 4 of SemEval 2016: Sentiment Analysis in Twitter. Official rankings locate us in top positions for binary classification and quantification and also for the 5-class polarity classification challenge.

We first trained a convolutional neural network to address the classification challenge. Additionally, we used its hidden activation values as features to train support vector machines, both for classification and quantification tasks. In light of the results obtained, we can state that our convolutional network seems to be a good feature extractor for both of these tasks.

As future work, we plan to exploit new distributed representations of the input to improve the performance of our current model. For the quantification task, we are planning on extending our experiments to other machine learning architectures, such as quantification trees (Milli et al., 2013) and different types of neural networks, and further exploring the feature domain using both handcrafted features and other continuous representation methods such as *doc2vec* (Le and Mikolov, 2014).

# TwiSE at SemEval-2016 Task 4: Twitter Sentiment Classification

**Georgios Balikas and Massih-Reza Amini**

University of Grenoble-Alpes

`firstname.lastname@imag.fr`

## Abstract

This paper describes the participation of the team “TwiSE” in the SemEval 2016 challenge. Specifically, we participated in Task 4, namely “Sentiment Analysis in Twitter” for which we implemented sentiment classification systems for subtasks A, B, C and D. Our approach consists of two steps. In the first step, we generate and validate diverse feature sets for twitter sentiment evaluation, inspired by the work of participants of previous editions of such challenges. In the second step, we focus on the optimization of the evaluation measures of the different subtasks. To this end, we examine different learning strategies by validating them on the data provided by the task organisers. For our final submissions we used an ensemble learning approach (stacked generalization) for Subtask A and single linear models for the rest of the subtasks. In the official leaderboard we were ranked 9/35, 8/19, 1/11 and 2/14 for subtasks A, B, C and D respectively. The code can be found at [https://github.com/balikasg/SemEval2016-Twitter\\_Sentiment\\_Evaluation](https://github.com/balikasg/SemEval2016-Twitter_Sentiment_Evaluation).

## 1 Introduction

During the last decade, short-text communication forms, such as Twitter microblogging, have been widely adopted and have become ubiquitous. Using such forms of communication, users share a variety of information. However, information concerning one’s sentiment on the world around her has attracted a lot of research interest (Nakov et al., 2016; Rosenthal et al., 2015).

Working with such short, informal text spans poses a number of different challenges to the Natural Language Processing (NLP) and Machine Learning (ML) communities. Those challenges arise from the vocabulary used (slang, abbreviations, emojis) (Maas et al., 2011), the short size, and the complex linguistic phenomena such as sarcasm (Rajadesingan et al., 2015) that often occur.

We present, here, our participation in Task 4 of SemEval 2016 (Nakov et al., 2016), namely Sentiment Analysis in Twitter. Task 4 comprised five different subtasks: Subtask A: Message Polarity Classification, Subtask B: Tweet classification according to a two-point scale, Subtask C: Tweet classification according to a five-point scale, Subtask D: Tweet quantification according to a two-point scale, and Subtask E: Tweet quantification according to a five-point scale. We participated in the first four subtasks under the team name “TwiSE” ([Twitter Sentiment Evaluation](#)). Our work consists of two steps: the preprocessing and feature extraction step, where we implemented and tested different feature sets proposed by participants of the previous editions of SemEval challenges (Tang et al., 2014; Kiritchenko et al., 2014a), and the learning step, where we investigated and optimized the performance of different learning strategies for the SemEval subtasks. For Subtask A we submitted the output of a stacked generalization (Wolpert, 1992) ensemble learning approach using the probabilistic outputs of a set of linear models as base models, whereas for the rest of the subtasks we submitted the outputs of single models, such as Support Vector Machines and Logistic

Regression.<sup>1</sup>

The remainder of the paper is organised as follows: in Section 2 we describe the feature extraction and the feature transformations we used, in Section 3 we present the learning strategies we employed, in Section 4 we present a part of the in-house validation we performed to assess the models’ performance, and finally, we conclude in Section 5 with remarks on our future work.

## 2 Feature Engineering

We present the details of the feature extraction and transformation mechanisms we used. Our approach is based on the traditional  $N$ -gram extraction and on the use of sentiment lexicons describing the sentiment polarity of unigrams and/or bigrams. For the data pre-processing, cleaning and tokenization<sup>2</sup> as well as for most of the learning steps, we used Python’s Scikit-Learn (Pedregosa et al., 2011) and NLTK (Bird et al., 2009).

### 2.1 Feature Extraction

Similar to (Kiritchenko et al., 2014b) we extracted features based on the lexical content of each tweet and we also used sentiment-specific lexicons. The features extracted for each tweet include:

- $N$ -grams with  $N \in [1, 4]$ , character grams of dimension  $M \in [3, 5]$ ,
- # of exclamation marks, # of question marks, # of both exclamation and question marks,
- # of capitalized words and # of elongated words,
- # of negated contexts; negation also affected the  $N$ -grams features by transforming a word  $w$  in a negated context to  $w\_NEG$ ,
- # of positive emoticons, # of negative emoticons and a binary feature indicating if emoticons exist in a given tweet, and

<sup>1</sup>To enable replicability we make the code we used available at [https://github.com/balikasg/SemEval2016-Twitter\\_Sentiment\\_Evaluation](https://github.com/balikasg/SemEval2016-Twitter_Sentiment_Evaluation).

<sup>2</sup>We adapted the tokenizer provided at <http://sentiment.christopherpotts.net/tokenizing.html>

- Part-of-speech (POS) tags (Gimpel et al., 2011) and their occurrences partitioned regarding the positive and negative contexts.

With regard to the sentiment lexicons, we used:

- manual sentiment lexicons: the Bing Liu’s lexicon (Hu and Liu, 2004), the NRC emotion lexicon (Mohammad and Turney, 2010), and the MPQA lexicon (Wilson et al., 2005),
- # of words in positive and negative context belonging to the word clusters provided by the CMU Twitter NLP tool<sup>3</sup>
- positional sentiment lexicons: sentiment 140 lexicon (Go et al., 2009) and the Hashtag Sentiment Lexicon (Kiritchenko et al., 2014b)

We make, here, more explicit the way we used the sentiment lexicons, using the Bing Liu’s lexicon as an example. We treated the rest of the lexicons similarly. For each tweet, using the Bing Liu’s lexicon we obtain a 104-dimensional vector. After tokenizing the tweet, we count how many words (i) in positive/negative contexts belong to the positive/negative lexicons (4 features) and we repeat the process for the hashtags (4 features). To this point we have 8 features. We generate those 8 features for the lowercase words and the uppercase words. Finally, for each of the 24 POS tags the (Gimpel et al., 2011) tagger generates, we count how many words in positive/negative contexts belong to the positive/negative lexicon. As a result, this generates  $2 \times 8 + 24 \times 4 = 104$  features in total for each tweet.

For each tweet we also used the distributed representations provided by (Tang et al., 2014) using the min, max and average composition functions on the vector representations of the words of each tweet.

### 2.2 Feature Representation and Transformation

We describe the different representations of the extracted  $N$ -grams and character-grams we compared when optimizing our performance on each of the classification subtasks we participated. In the rest of this subsection we refer to both  $N$ -grams and

<sup>3</sup><http://www.cs.cmu.edu/~ark/TweetNLP/>

character-grams as words, in the general sense of letter strings. We evaluated two ways of representing such features: (i) a bag-of-words representation, that is for each tweet a sparse vector of dimension  $|V|$  is generated, where  $|V|$  is the vocabulary size, and (ii) a hashing function, that is a fast and space-efficient way of vectorizing features, i.e. turning arbitrary features into indices in a vector (Weinberger et al., 2009). We found that the performance using hashing representations was better. Hence, we opted for such representations and we tuned the size of the feature space for each subtask.

Concerning the transformation of the features of words, we compared the tf-idf weighing scheme and the  $\alpha$ -power transformation. The latter, transforms each vector  $x = (x_1, x_2, \dots, x_d)$  to  $x' = (x_1^\alpha, x_2^\alpha, \dots, x_d^\alpha)$  (Jegou et al., 2012). The main intuition behind the  $\alpha$ -power transformation is that it reduces the effect of the most common words. Note that this is also the rationale behind the *idf* weighting scheme. However, we obtained better results using the  $\alpha$ -power transformation. Hence, we tuned  $\alpha$  separately for each of the subtasks.

### 3 The Learning Step

Having the features extracted we experimented with several families of classifiers such as linear models, maximum-margin models, nearest neighbours approaches and trees. We evaluated their performance using the data provided by the organisers, which were already split in training, validation and testing parts. Table 1 shows information about the tweets we managed to download. From the early validation schemes, we found that the two most competitive models were Logistic Regression from the family of linear models, and Support Vector Machines (SVMs) from the family of maximum margin models. It is to be noted that this is in line with the previous research (Mohammad et al., 2013; Büchner and Stein, 2015).

#### 3.1 Subtask A

Subtask A concerns a multiclass classification problem, where the general polarity of tweets has to be classified in one among three classes: “Positive”, “Negative” and “Neutral”, each denoting the tweet’s overall polarity. The evaluation measure used for the

subtask is the Macro-F<sub>1</sub> measure, calculated only for the Positive and Negative classes (Nakov et al., 2016).

Inspired by the wining system of SemEval 2015 Task 10 (Büchner and Stein, 2015) we decided to employ an ensemble learning approach. Hence, our goal is twofold: (i) to generate a set of models that perform well as individual models, and (ii) to select a subset of models of (i) that generate diverse outputs and to combine them using an ensemble learning step that would result in lower generalization error.

We trained four such models as base models. Their details are presented in Table 2. In the stacked generalization approach we employed, we found that by training the second level classifier on the probabilistic outputs, instead of the predictions of the base models, yields better results. Logistic Regression generates probabilities as its outputs. In the case of SVMs, we transformed the confidence scores into probabilities using two methods, after adapting them to the multiclass setting: the Platt’s method (Platt and others, 1999) and the isotonic regression (Zadrozny and Elkan, 2002). To solve the optimization problems of SVMs we used the Liblinear solvers (Fan et al., 2008). For Logistic Regression we used either Liblinear or LBFGS, with the latter being a limited memory quasi Newton method for general unconstrained optimization problems (Yu et al., 2011). To attack the multiclass problem, we selected among the traditional one-vs-rest approach, the crammer-singer approach for SVMs (Crammer and Singer, 2002), or the multinomial approach for Logistic Regression (also known as MaxEnt classifier), where the multinomial loss is minimised across the entire probability distribution (Malouf, 2002).

For each of the four base models the tweets are represented by the complete feature set described in Section 2. For transforming the n-grams and character-grams, the value of  $\alpha \in \{0.2, 0.4, 0.6, 0.8, 1\}$ , the dimension of the space where the hashing function projects them, as well as the value of  $\lambda \in \{10^{-7}, \dots, 10^6\}$  that controls the importance of the regularization term in the SVM and Logistic regression optimization problems were selected by grid searching using 5-fold cross-validation on the training part of the provided data. We tuned each model independently before integrat-

|               | Train | Development | DevTest | Test   |
|---------------|-------|-------------|---------|--------|
| Subtask A     | 5,500 | 1,831       | 1,791   | 32,009 |
| Subtask B & D | 4,346 | 1,325       | 1,417   | 10,551 |
| Subtask C & E | 5,482 | 1,810       | 1,778   | 20,632 |

**Table 1:** Size of the data used for training and development purposes. We only relied on the SemEval 2016 datasets.

| Algorithm           | Multiclass approach       | Optimizer | Probabilistic Outputs |
|---------------------|---------------------------|-----------|-----------------------|
| SVMs                | crammer-singer            | Liblinear | isotonic regression   |
| SVMs                | crammer-singer            | Liblinear | Platt's               |
| Logistic Regression | one-vs-all                | Liblinear | native                |
| Logistic Regression | multinomial loss function | LBFGS     | native                |

**Table 2:** Description of the base learners used in the stacked generalization approach.

ing it in the stacked generalization.

Having the fine-tuned probability estimates for each of the instances of the test sets and for each of the base learners, we trained a second layer classifier using those fine-grained outputs. For this, we used SVMs, using the crammer-singer approach for the multi-class problem, which yielded the best performance in our validation schemes. Also, since the classification problem is unbalanced in the sense that the three classes are not equally represented in the training data, we assigned weights to make the problem balanced. Those weights were inversely proportional to the class frequencies in the input data for each class.

### 3.2 Subtask B

Subtask B is a binary classification problem where given a tweet known to be about a given topic, one has to classify whether the tweet conveys a positive or a negative sentiment towards the topic. The evaluation measure proposed by the organisers for this subtask is macro-averaged recall (MaR) over the positive and negative class.

Our participation is based on a single model. We used SVMs with a linear kernel and the Liblinear optimizer. We used the full feature set described in Section 2, after excluding the distributed embeddings because in our local validation experiments we found that they actually hurt the performance. Similarly to subtask A and due to the unbalanced nature of the problem, we use weights for the classes of the problem. Note that we do not consider the topic of the tweet and we classify the tweet's overall polarity.

Hence, we ignore the case where the tweet consists of more than one parts, each expressing different polarities about different parts.

### 3.3 Subtask C

Subtask C concerns an ordinal classification problem. In the framework of this subtask, given a tweet known to be about a given topic, one has to estimate the sentiment conveyed by the tweet towards the topic on a five-point scale. Ordinal classification differs from standard multiclass classification in that the classes are ordered and the error takes into account this ordering so that not all mistakes weigh equally. In the tweet classification problem for instance, a classifier that would assign the class “1” to an instance belonging to class “2” will be less penalized compared to a classifier that will assign “-1” as the class . To this direction, the evaluation measure proposed by the organisers is the macroaveraged mean absolute error.

Similarly to Subtask B, we submitted the results of a single model and we classified the tweets according to their overall polarity ignoring the given topics. Instead of using one of the ordinal classification methods proposed in the bibliography, we use a standard multiclass approach. For that we use a Logistic Regression that minimizes the multinomial loss across the classes. Again, we use weights to cope with the unbalanced nature of our data. The distributed embeddings are excluded by the feature sets.

We elaborate here on our choice to use a conventional multiclass classification approach instead

of an ordinal one. We evaluated a selection of methods described in (Pedregosa-Izquierdo, 2015) and in (Gutiérrez et al., 2015). In both cases, the results achieved with the multiclass methods were marginally better and for simplicity we opted for the multiclass methods. We believe that this is due to the nature of the problem: the feature sets and especially the fine-grained sentiment lexicons manage to encode the sentiment direction efficiently. Hence, assigning a class of completely opposite sentiment can only happen due to a complex linguistic phenomenon such as sarcasm. In the latter case, both methods may fail equally.

### 3.4 Subtask D

Subtask D is a binary quantification problem. In particular, given a set of tweets known to be about a given topic, one has to estimate the distribution of the tweets across the Positive and Negative classes. For instance, having 100 tweets about the new iPhone, one must estimate the fractions of the Positive and Negative tweets respectively. The organisers proposed a smoothed version of the Kullback-Leibler Divergence (KLD) as the subtask’s evaluation measure.

We apply a classify and count approach for this task (Bella et al., 2010; Forman, 2008), that is we first classify each of the tweets and we then count the instances that belong to each class. To this end, we compare two approaches both trained on the features sets of Section 2 excluding the distributed representations: the standard multiclass SVM and a structure learning SVM that directly optimizes KLD (Esuli and Sebastiani, 2015). Again, our final submission uses the standard SVM with weights to cope with the imbalance problem as the model to classify the tweets. That is because the method of (Gao and Sebastiani, 2015) although competitive was outperformed in most of our local validation schemes.

## 4 The evaluation framework

Before reporting the scores we obtained, we elaborate on our validation strategy and the steps we used when tuning our models. in each of the subtasks we only used the data that were realised for the 2016 edition of the challenge. Our validation had the following steps:

|           | DevTest | Test  | Rank |
|-----------|---------|-------|------|
| Subtask A | 56.01   | 58.61 | 9/35 |
| Subtask B | 0.748   | 0.748 | 8/18 |
| Subtask C | 0.8121  | 0.72  | 1/11 |
| Subtask D | 0.00018 | 0.053 | 2/14 |

**Table 3:** The performance obtained on the “devtest” data and the SemEval 2016 Task 4 test data.

1. Training using the released training data,
2. validation on the validation data,
3. validation again, in the union of the devtest and trial data (when applicable), after retraining on training and validation data.

For each parameter, we selected its value by averaging the optimal parameters with respect to the output of the above-listed steps (2) and (3). It is to be noted, that we strictly relied on the data released as part of the 2016 edition of SemEval; we didn’t use past data.

We now present the performance we achieved both in our local evaluation schemas and in the official results released by the challenge organisers. Table 3 presents the results we obtained in the “DevTest” part of the challenge dataset and the scores on the test data as they were released by the organisers. In the latter, we were ranked 9/35, 8/19, 1/11 and 2/14 for subtasks A, B, C and D respectively. Observe, that for subtasks A and B, using just the “devtest” part of the data as validation mechanism results in a quite accurate performance estimation.

## 5 Future Work

That was our first contact with the task of sentiment analysis and we achieved satisfactory results. We relied on features proposed in the framework of previous SemEval challenges and we investigated the performance of different classification algorithms.

In our future work we will investigate directions both in the feature engineering and in the algorithmic/learning part. Firstly, we aim to deal with tweets in a finer level of granularity. As discussed in Section 3, in each of the tasks we classified the overall polarity of the tweet, ignoring cases where the tweets were referring to two or more subjects. In the

same line, we plan to improve our mechanism for handling negation. We have used a simple mechanism where a negative context is defined as the group of words after a negative word until a punctuation symbol. However, our error analysis revealed that punctuation is rarely used in tweets. Finally, we plan to investigate ways to integrate more data in our approaches, since we only used this edition’s data.

The application of an ensemble learning approach, is a promising direction towards the short text sentiment evaluation. To this direction, we hope that an extensive error analysis process will help us identify better classification systems that when integrated in our ensemble (of subtask A) will reduce the generalization error.

## Acknowledgments

We would like to thank the organisers of the Task 4 of SemEval 2016, for providing the data, the guidelines and the infrastructure. We would also like to thank the anonymous reviewers for their insightful comments.

## Abstract

This paper details on the participation of ISTI-CNR to task 4 of Semeval 2016. Among the five subtasks, special attention has been paid to the five-point scale quantification subtask. The quantification method we propose is based on the observation that a standard document-by-document regression method usually has a bias towards assigning high prevalence labels. Our method models such bias with a linear model, in order to compensate it and to produce the quantification estimates.

## 1 Introduction

The participation of ISTI-CNR to task 4 of Semeval 2016 (Nakov et al., 2016) produced submissions for all the five proposed subtasks.

Submissions for subtasks A and B are based on a relatively typical machine learning pipeline, with B used as the base classification tool for subtask D, which uses a quantification via classification method. Subtask C uses an ordinal regression method, based on building a data-balanced tree of binary classifiers. The regression method of subtask C has been used as the base regression tool for the implementation of the quantification method for subtask E.

We propose a novel quantification method for subtask E, tweet quantification according to a five-point scale. The method stems from the intuition of measuring and compensating the bias a regression model may have for the labels with high prevalences.

All the code we produced for these tasks is mainly based on the scikit-learn python library (Pedregosa et al., 2011) and it is published under an open source license<sup>1</sup>.

The next sections detail on the data and methods adopted to produce the five submissions.

## 2 Training data

The labeled training dataset has been downloaded using the tool suggested by the organizers<sup>2</sup>. Table 1 summarizes the total number of tweets available for download at the time of crawling (November 2015). The final number of tweets used to train the classifiers, or quantifiers, is 6223 for subtasks A, C and E, and 4475 for subtasks B and D.

A small number of tweets in the dataset appeared multiple times, some with conflicting labels. In the “train” data parts, for example, 25 tweets appeared twice for subtasks A, C, and E, six of them with conflicting labels for subtask A, and 14 with conflicting labels for subtasks C and E<sup>3</sup>. For subtasks B, D, the number of tweets appearing twice in training is 13, one of them with conflicting labels. Duplicate tweets have been reduced to a single instance and those with conflicting labels have been excluded from the dataset and from any analysis performed in this work.

<sup>1</sup><https://github.com/aesuli/semeval2016-task4>

<sup>2</sup>[https://github.com/aritter/twitter\\_download](https://github.com/aritter/twitter_download)

<sup>3</sup>Subtask A uses a coarse-grained three-point scale, so it may happen that a conflicting ‘-1’/‘-2’ labeling of a tweet for subtasks C and E is reduced to a non-conflicting ‘negative’ labeling for subtask A.

| subtask | set        | labeled | downloaded |
|---------|------------|---------|------------|
| A       | train      | 6000    | 3804       |
| A       | dev        | 2000    | 1229       |
| A       | devtest    | 2000    | 1190       |
| A       | <i>all</i> | 10000   | 6223       |
| C,E     | train      | 6000    | 3804       |
| C, E    | dev        | 2000    | 1229       |
| C, E    | devtest    | 2000    | 1190       |
| C, E    | <i>all</i> | 10000   | 6223       |
| B, D    | train      | 4346    | 2764       |
| B, D    | dev        | 1325    | 836        |
| B, D    | devtest    | 1417    | 875        |
| B, D    | <i>all</i> | 7088    | 4475       |

**Table 1:** Number of tweets with labeling provided by the organizers and number of such tweets available for download at the time of crawling.

Training data for subtasks A and B has been enriched by adding 5331 positive and 5331 negative sentences extracted from movie reviews, which are part of the movie review dataset (Pang and Lee, 2005)<sup>4</sup>. Even though these sentences are domain-specific, they are deemed to contribute to the learning process by enriching the vocabulary of expressions used to denote positive and negative sentiments. The final training set for subtask A is thus composed of 16885 examples, and 15137 for subtask B.

## 2.1 Features

The transformation of each tweet into its vectorial representation uses a relatively simple processing. The text of each tweet is tokenized, stopwords are removed. Word bigrams and trigrams, and character fourgrams are added to representation. Regular expressions are used to detect mentions, hashtag, URLs, and emoticons, and metafeatures for each of these special type of information are added to the representation, e.g., if a tweet has two hashtags, the '\_hashtag' feature with frequency two is added to the representation of the tweet. The vectors are weighted by  $tf \cdot idf$ . Feature selection based on  $\chi^2$  is used to retain only the  $x$  most informative features, with  $x$  determined for each subtask with a

| method | $MAE^M$ |
|--------|---------|
| BBTOR  | 0.927   |
| DDAG   | 1.227   |
| SVORIM | 1.066   |

**Table 2:** Subtask C: comparison of ordinal regression methods, based on 10-fold cross-validation on training data.

cross-validation on training data.

## 3 Subtasks A and B: classification

A linear SVM has been used for both classification tasks: a simple binary classifier for subtask B, and three *one-vs-all* binary classifiers for subtask A. The value of the parameter  $C$  of the SVM has been determined with a cross-validation on training data.

## 4 Subtask C: regression

The *Balanced Binary Tree for Ordinal Regression* (BBTOR) method we designed for subtask C is based on building a tree of binary classifiers that recursively split the ordinal scale on the points of maximum balance in the number of training example assigned to the two sides of the binary classification problem.

For example, let's suppose to have a dataset with the following distribution of training examples:  $|c_1| = 20$ ,  $|c_2| = 10$ ,  $|c_3| = 20$ ,  $|c_4| = 30$ ,  $|c_5| = 50$ , where  $|c_i| = n$  means that label  $c_i$  has  $n$  training examples. The first binary classifier learns to separate  $\{c_1, c_2, c_3\}$  from  $\{c_4, c_5\}$ , given that the partition with 50 vs 80 training examples is the most balanced one<sup>5</sup>. Then two second-level binary classifiers are trained on the  $\{c_1, c_2\}$  vs  $\{c_3\}$  split and the  $\{c_4\}$  vs  $\{c_5\}$  split. The training is completed learning a  $\{c_1\}$  vs  $\{c_2\}$  classifier. A linear SVM is used to train the binary classifier, optimizing its  $C$  parameter with a cross-validation on training data.

This approach is in line with the proposal of *Data-Balanced Nested Dichotomies* of Dong et al. (2005) for multi-class problems, and extends it to consider the ordinal relations between labels. The method has been compared in cross-validation experiments on

<sup>5</sup>Note that also the  $\{c_1, c_2, c_3, c_4\}$  from  $\{c_5\}$  split produces an equivalent 80 vs 50 split. A second criterium is to prefer the splits in which also the number of labels is more balanced. In case of a tie also on the second criterium a random choice is made.

| method | <i>KLD</i> |
|--------|------------|
| CC     | 0.742      |
| ACC    | 0.756      |
| PCC    | 0.230      |
| PACC   | 0.319      |

| method | <i>EMD</i> |
|--------|------------|
| RC     | 0.547      |
| ARC    | 0.374      |

**Table 4:** Subtask E: comparison of ordinal regression quantification methods, based on leave-one-topic-out validation on training data.

training data against other regression methods, i.e., SVORIM (Chu and Keerthi, 2007), based on linear regression, and DDAG (Aioli et al., 2009), based on binary classifiers, and produced the best performance.

## 5 Subtask D: binary quantification

Four quantification methods based on classification have been compared, following the works of Forman (2008) and Bella et al. (2010). The four methods are: *classify and count* (CC), in which a classifier is applied to the test documents and the prevalences are determined by counting the documents assigned to each label; *adjusted classify and count* (ACC), in which the output of the CC method is corrected to take into account the bias in error towards one of the two labels the classifier may have; *probabilistic classify and count* (PCC) in which the contribution of each document to the counting is weighted on the confidence the classifier has on the assignment; *probabilistic adjusted classify and count* (PACC) which is the ACC method applied to the probabilistic model of PCC. From a cross validation on training data, in which each topic has been in turn used as test data and the remaining as training data, the PCC performed best and it was thus used for the final submission.

## 6 Subtask E: quantification on an ordinal scale

Two methods have been compared for subtask E. One is a simple *regress and count* (RC) method in which the BBTOR method used in subtask C is applied to documents of a topic and then the quantification values for the topic is determined by counting the number of documents assigned to each slot in the ordinal scale. We propose the *adjusted regress and count* (ARC) method, that is based on the intuition to measure, and compensate, the typical bias of regression methods to assign documents to the slots in the ordinal scale that have higher prevalences.

Let's denote the prevalences for a topic-label pair with  $p_j(c_i)$ , where  $j$  indicates a topic in the set of topics  $\{t_1, \dots, t_n\}$  and  $i$  a label in the set of ordered labels  $\{c_1, \dots, c_m\}$  that form the ordinal scale. On a given set of topics, the cumulative prevalence for each label is denoted as  $P(c_i) = \sum_{j=1}^n p_j(c_i)$ . Given a quantification method that produces estimations  $\hat{p}_j(c_i)$ , its cumulative prevalences are denoted as  $\hat{P}(c_i) = \sum_{j=1}^n \hat{p}_j(c_i)$ .

Under the hypothesis of a linear error model, knowing the estimate prevalences and the cumulative correct and estimate prevalences on a set of topics, the true prevalence for a topic can be determined as:

$$p_j(c_i) \simeq \frac{P(c_i)}{\hat{P}(c_i)} \hat{p}_j(c_i) = w_i \hat{p}_j(c_i) \quad (1)$$

Note that the model uses a different linear correction weight  $w_i = \frac{P(c_i)}{\hat{P}(c_i)}$  for each label  $c_i$ .

The correction value  $w_i$  cannot be determined on the test data, since  $P(c_i)$  is unknown. Following the ACC method for binary quantification (Forman, 2008) that estimates its correction parameter on the training set, also the  $w_i$  values can be approximated on the training data using cross-validation, substituting  $w_i$  with the  $w_i^{Tr} = \frac{P^{Tr}(c_i)}{\hat{P}^{Tr}(c_i)}$  value. In this way the ARC quantification estimate can be derived from the RC estimate using the formula :

$$\hat{p}_j^{\text{ARC}}(c_i) = \frac{1}{Z_j} w_i^{Tr \text{RC}} \hat{p}_j^{\text{RC}}(c_i) \quad (2)$$

where  $Z_j = \sum_{i=1}^m \hat{p}_j^{\text{ARC}}(c_i)$  is a normalization factor to guarantee that the prevalences for a topic sum up to one.

The ARC method produced a sensible improvement over RC on a leave-one-topic-out validation on training data as reported in Table 4.

## 7 Future work

The features extracted from text in these experiments are based on a traditional vector space model in which each distinct feature is represented by a dedicated dimension in the vector space. The limited amount of training data, and the variety of topics, produces an effect of data sparsity, in which there is little overlap between features from training and test data. We plan to repeat the experiments using semantically-richer features based on the use of language models, which should improve the vectorial representations by projecting onto similar vectorial representations the features with similar semantic properties, thus reducing the effect of data sparsity.

The participation to subtask E resulted in a bias correction method, ARC, that performed well. ARC sensibly improved on the baseline produced by the direct use of the original regression method, the one used to produce the submission for subtask C, without correction. Future work will explore the use of the bias correction method in combination with other ordinal regression methods, either based on classification or linear regression.

A strong assumption of the ARC method is that the error on each label has a linear relation with respect to the prevalence. This assumption can be considered to hold locally, i.e., when the variation of prevalence for a label across topics is limited, while it is harder to consider it valid when prevalences varies a lot across topics. Future work will explore the use of more complex models, e.g., fitting the differences observed between  $p_j(c_i)$  and  $\hat{p}_j(c_i)$  on the training set using a polynomial model, instead of a single  $w_i$  weight.

## Abstract

This paper describes the system with which we participated in SemEval-2016 Task 4 (Sentiment Analysis in Twitter) and specifically the Message Polarity Classification subtask. Our system is a weighted ensemble of two systems. The first one is based on a previous sentiment analysis system and uses manually crafted features. The second system of our ensemble uses features based on word embeddings. Our ensemble was ranked 5th among 34 teams. The source code of our system is publicly available.

## 1 Introduction

This paper describes the system with which we participated in SemEval-2016 Task 4 (Sentiment Analysis in Twitter) and specifically the Message Polarity Classification subtask (Nakov et al., 2016). In this subtask, each tweet is classified as expressing a positive, negative, or no opinion (neutral). Our system is a weighted ensemble of two systems. The first one is based on a previous sentiment analysis system (Karampatsis et al., 2014) and uses manually crafted features. The second system of our ensemble uses features based on word embeddings (Mikolov et al., 2013; Pennington et al., 2014). Our ensemble was ranked 5th among 34 teams.

Section 2 discusses the datasets we used to train and tune our ensemble. Sections 3 and 4 describe our ensemble and its performance respectively. Finally, Section 5 concludes and discusses future work.

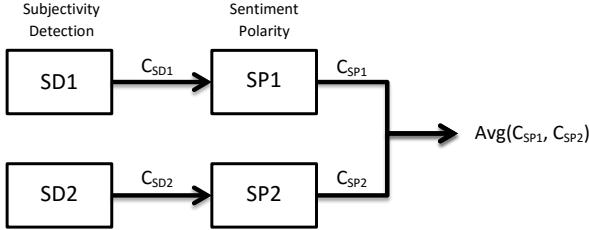

## 2 Data

For system training and tuning we used 19,305 tweets from the 2016 datasets provided by the organisers of SemEval-2016 Task 4, as well as data from SemEval-2013 Task 2. Specifically, the datasets were:

- $\text{TW}_{train16}$  : train data for SemEval-2016 Task 4,
- $\text{TW}_{dev16}$  : development data for SemEval-2016 Task 4,
- $\text{TW}_{devtest16}$  : dev-test data for SemEval-2016 Task 4,
- $\text{TW}_{train13}$  : train data for SemEval-2013 Task 2,
- $\text{TW}_{dev13}$  : development data for SemEval-2013 Task 2.

The organisers also provided 6,908 tweets from old SemEval data, to allow system evaluation during development. These data could not be used directly for training or tuning and were the following:

- $\text{TW}_{devtest13}$  : dev-test data for SemEval-2013 Task 2,
- $\text{TW}_{devtest14}$  : dev-test data for SemEval-2014 Task 9,
- $\text{TW}_{sarcasm14}$  : tweets containing sarcasm,
- $\text{SMS}_{13}$  : SMS messages from 2013,
- $\text{LJ}_{14}$  : messages from Live Journal.

**Figure 1:** Ensemble of two sentiment polarity classifiers, SP1 and SP2, which are influenced by two subjectivity detection classifiers, SD1 and SD2, respectively.

### 3 System Overview

The main objective of SemEval-2016 Task 4 is to detect sentiment polarity, i.e., to identify whether a message (tweet) expresses positive, negative or no sentiment at all. We used a weighted ensemble of two sentiment polarity classifiers, namely SP1 and SP2 (Figure 1), each influenced by a subjectivity detection classifier, SD1 and SD2, respectively.

A correlation analysis between the confidence scores of SP1 and SP2 ( $C_{SP1}$  and  $C_{SP2}$  respectively) revealed that the two systems make different mistakes, which motivated combining them in an ensemble. Given a message and the confidence scores of the two systems (i.e.,  $C_{SP1}$  and  $C_{SP2}$ ), the ensemble computes a new confidence score for every sentiment label ( $C_{pos}$ ,  $C_{neg}$  and  $C_{neu}$ ) as follows:

$$C_{pos} = C_{SP1@pos} \cdot w_{pos} + C_{SP2@pos} \cdot (1 - w_{pos})$$

$$C_{neg} = C_{SP1@neg} \cdot w_{neg} + C_{SP2@neg} \cdot (1 - w_{neg})$$

$$C_{neu} = C_{SP1@neu} \cdot w_{neu} + C_{SP2@neu} \cdot (1 - w_{neu})$$

where  $w_{pos}$ ,  $w_{neg}$ ,  $w_{neu}$  are weights tuned on the development data. The sentiment with the highest confidence score is assigned to each tweet.<sup>1</sup>

Below, we describe the two Sentiment Polarity classifiers, along with the two subjectivity detection classifiers that influence them.

#### 3.1 SP1 and SD1

First, each message is preprocessed by a Twitter specific tokeniser and part-of-speech (POS) tagger (Owoputi et al., 2013) to obtain the tokens and

<sup>1</sup>Tuning led to  $w_{pos} = w_{neg} = w_{neu} = 0.66$ .

the corresponding POS tags, which are necessary for some features.<sup>2</sup> Then, we extract features, which can be categorized as follows:<sup>3</sup>

- features based on morphology,
- POS based features,
- sentiment lexicon based features,
- negation based features,
- features based on clusters of tweets.

We used a linear SVM classifier (Vapnik, 1998; Cristianini and Shawe-Taylor, 2000; Joachims, 2002) trained on three labels, namely, positive, negative and neutral.<sup>4</sup>

As already mentioned, SP1 is influenced by a subjectivity detection classifier called SD1. That is, SP1 uses as a feature the confidence score of SD1. SD1 is also a linear SVM classifier, which is trained on data of two labels, neutral and subjective (i.e., positive or negative).<sup>5</sup> The higher the confidence score of SD1 the more likely it is for the message to express sentiment (positive or negative). Apart from the score of SD1 (which was used by SP1), SP1 and SD1 used the same features.

#### 3.2 SP2 and SD2

The second system of our ensemble uses word embeddings (Mikolov et al., 2013; Pennington et al., 2014). We use the centroid of the word embeddings of each tweet as the feature vector of the tweet. The centroid of a tweet (message)  $M$  is computed as follows:

$$\vec{M} = \frac{1}{|M|} \sum_{i=1}^{|M|} \vec{w}_i$$

<sup>2</sup>No lemmatization or stemming was used and tokens could be words, emoticons, hashtags, etc.

<sup>3</sup>All the features of SP1 are described in detail in a publicly available report, accompanying the source code of the system. The code and the report are available at <https://github.com/nlpaeub/aueb.twitter.sentiment>.

<sup>4</sup>We used the SVM implementation of Scikit Learn (Pedregosa et al., 2011; Fan et al., 2008). The same implementation was used for all our SVM classifiers. The optimal  $C$  value was found to be 0.00341, by using 5-fold cross validation on  $TW_{train16}$ .

<sup>5</sup>The optimal  $C$  value for SD1 was found to be 0.00195, by using 5-fold cross validation on  $TW_{train16}$ .

**Table 1:** Rankings of our system

|                 | Train data | Dev data | Tweet2016      |
|-----------------|------------|----------|----------------|
| Strict 2 stages | 62.60%     | 58.50%   | 54.83% (19/34) |
| SP1 (with SD1)  | 68.00%     | 64.70%   | 59.40% (7/34)  |
| SP2 (with SD2)  | 60.80%     | 59.00%   | 57.50% (15/34) |
| ENS             | 68.40%     | 65.80%   | 60.52% (5/34)  |

**Table 2:** Average F1 scores of SP1, SP2, ENS (our ensemble) and a strict two-stage system.

where  $|M|$  is the number of tokens in  $M$  and  $\bar{w}_i$  is the embedding of word  $w_i$ .<sup>6</sup> We used the 200-dimensional word vectors for Twitter produced by Glove (Pennington et al., 2014).<sup>7</sup>

As with SP1, SP2 incorporates the confidence score of SD2 as a feature. SD2 is a classifier trained on neutral and subjective data (positive or negative), again with centroid feature vectors. Given a message  $M$ , the confidence score of SD2 for  $M$  was added as a feature to its centroid and the resulting 201-dimension feature vector was used as input to SP2.<sup>8</sup> SP2 was then trained on the same three classes as SP1 (positive, negative, neutral).<sup>9</sup>

## 4 Experiments & Discussion

Our system was ranked 5th among 34 teams.<sup>10</sup> All teams were ranked by their score on the Twitter2016 Task 4 test dataset. Table 1 shows our rankings on each dataset. Below we discuss the results of our ensemble and we show how the subjectivity detection classifiers affect our system.

<sup>6</sup>We allow multiple word occurrences in a sentence, while we ignore words without embeddings.

<sup>7</sup>The word vectors were pre-trained on a 2 billion tweets corpus. See <http://nlp.stanford.edu/projects/glove/>.

<sup>8</sup>The confidence scores of SD1 and SD2 were exponentially normalized (Bishop, 2006).

<sup>9</sup>The optimal  $C$  values were found to be 1.40688 for SD2 and 7.39618 for SP2, by using 5-fold cross validation.

<sup>10</sup>[http://alt.qcri.org/semeval2016/task4/data/uploads/semeval2016\\_task4\\_results.pdf](http://alt.qcri.org/semeval2016/task4/data/uploads/semeval2016_task4_results.pdf)

A strict two-stage approach, like the one suggested by Karampatsis et al. (2014), discards messages the sentiment detection (SD) classifier (first stage) decides they do not express sentiment, and classifies the rest as positive or negative. However, errors of the first stage propagate to the second, thus, playing a significant role in overall performance. We extend their approach and attempt to use the results of a subjectivity detection stage in a less rigorous manner; i.e., as a confidence factor along with various other features. Recall that our SD1 is actually the first stage of the system of Karampatsis et al. (2014), and that we use the confidence of SD1 as feature of SP1. Table 2 shows that SP1 (with the confidence of SP1 as a feature) outperforms the strict two-stage approach by 4.57%, yielding an increase in the ranking by 12 positions. Another interesting observation is that SP2 (with the confidence of SD2 as a feature) achieves a score only 1.9% lower than SP1 (with SD1) yielding a ranking around the middle of the list. This is achieved by using only features based on word embeddings along with the confidence of SD2 and no sophisticated feature engineering at all. A final, and also very interesting observation is that when we use an ensemble of SP1 and SP2, the results improve yielding a 5th place in the ranking.

## 5 Conclusions and future work

In this paper we presented the system with which we participated in the Message Polarity Classification subtask of SemEval-2016 Task 4. We used a weighted ensemble of two systems each operating in two stages. In a first, subjectivity detection stage, each message is assigned a confidence score representing the probability that the message expresses an opinion. This probability is then used as a feature by a classifier that detects sentiment. We used two different systems, one based on previous work by Karampatsis et al. (2014) (SP1 with the confidences of SD1 as a feature) and a second system that represents the messages by the centroids of their word embeddings (SP2 with the confidence of SD2 as a feature). The two systems are then combined with a weighted linear ensemble scheme in order to get the final sentiment label. Our experiments show that using the confidence of the subjectivity detection stage as a feature instead of using a strict two-stage ap-

proach can lead to an improved performance. Also, the ensemble performs better than any of its two systems on their own.

Despite the encouraging results of our approach (5th among 34 participating teams), there is still much room for improvement. A better continuous space vector representation of the messages might improve SD2 and SP2. Much research has been conducted recently on obtaining better continuous space vector representations of sentences (Le and Mikolov, 2014; Kiros et al., 2015; Hill et al., 2016) instead of centroid vectors. Another direction for future work would be to investigate replacing the SVM classifiers by multilayer perceptrons, possibly on top of recurrent neural nets that would compute vector representations of sentences.

## Acknowledgments

This work was carried out during the BSc projects of the first two authors, which were co-supervised by the other three authors.

# thecerealkiller at SemEval-2016 Task 4: Deep Learning based System for Classifying Sentiment of Tweets on Two Point Scale

Vikrant Yadav

Amazon.in

Hyderabad, India

vikrantiitr1@gmail.com

## Abstract

In this paper, we propose a deep learning system for classification of tweets on a two-point scale. Our architecture consists of a multilayered recurrent neural network having gated recurrent units. The network is pre-trained with a weakly labeled dataset of tweets to learn the sentiment specific embeddings. Then it is fine tuned on the given training dataset of the task 4B in SemEval-2016. The network does very little pre-processing for raw tweets and no post-processing at all. The proposed system achieves 3rd rank on the leaderboard of task 4B.

## 1 Introduction

Task 4 of SemEval-2016 (Nakov et al., 2016) - Sentiment Analysis in Twitter- turned out to be the most popular task of SemEval-2016. Among its sub-tasks, sub-task B - Tweet classification according to a two-point scale - was the 2nd most popular sub-task. A total of 19 teams participated in it including ours.

In this paper, we propose a multilayered RNN architecture for classifying tweets on a two-point scale, namely, positive and negative. We first pre-train the network with a weakly labeled corpus of tweets, where labels are assigned based on the sentiment of the emoticon present in the tweets. It helps the network to learn sentiment specific embeddings of the words in the tweet. The network is then fine-tuned on the dataset of tweets provided as part of the sub-task 4B along with the training and development dataset of SemEval-2013 task 2.

In the second section, we describe our architecture. In third section, we explain our approach to train the network. After that, we describe the experimental setup and statistical properties of the data used. In the end, we discuss our results on the test dataset. We stood 3rd on the final leaderboard for sub-task 4B.

## 2 Proposed System

In this section, we elaborate our proposed architecture. The network is fed pre-processed tweets as input and it predicts the binary label of the tweets. It has 3 RNN layers each with gated recurrent units. Then a sum layer is added to sum the hidden states of the last recurrent layer over time. After that, a dense layer is present followed by a single sigmoid unit.

Now, we describe the components of our architecture in brief.

### 2.1 Pre-processing

The tweets are pre-processed to remove any punctuation if present. All URLs are encoded into a URL token. All the user accounts mentioned in a tweet are encoded as USER token. The tweet is converted to lower-case before feeding to the network. Note that we don't remove any stop-words as they define useful relationships between words and phrases. This amount of pre-processing turned out to be sufficient for the network to learn useful semantic and sentiment specific word-embeddings.

## 2.2 Embedding layer

The embedding layer maps a sequence of words present in the input tweet to the corresponding fixed length real valued vectors. The fixed length  $d$  is called the dimension of the embeddings. The embedding layer keeps track of the mapping so that the correct embeddings gets updated while doing back-propagation of the errors.

## 2.3 Recurrent layers

Recurrent neural networks are proved to be useful in handling variable length sequences. A stacking of recurrent layers on the top of each other allows the semantic composition of representations of words and phrases over time. We use the same intuition in our architecture.

The embedding layer passes the embedding matrix to the first recurrent layer. Each layer takes into input an embedding matrix which it processes i.e. updates its hidden state over time. The hidden states are stored after each time-step and fed to the next layer as input. Thus, the last layer outputs a matrix of hidden states.

We prefer GRU(Gated Recurrent Unit) (Cho et al., 2014) compared to a vanilla RNN unit. A classic RNN is difficult to train, because the gradients either tend to vanish or explode (Bengio et al., 1994). A GRU unit takes care of this problem and is able to cope with vanishing or exploding gradients while capturing the information for longer periods of time.

## 2.4 Sum over time

This layer receives the time-distributed hidden state matrix of the last recurrent layer as input where the  $n$ th column describes the hidden state at  $n$ th time-step. It outputs a vector where the  $k$ th element is sum of the  $k$ th row in the hidden state matrix. This helps to combine the sentiment specific representation of the phrases so as to yield an aggregate representation.

## 2.5 Dense layer and output layer

The output of the sum layer is fully connected with the dense layer consisting of rectified linear units. The dense layer in turn is connected with the output sigmoid units which predicts the probability of assigning a positive or negative label for the input tweet.

## 3 Approach to Train the Network

In this section, we describe our choice of training algorithm and the regularization method.

### 3.1 Training algorithm

We use mini-batch gradient descent algorithm as our choice of training algorithm. We utilized two Nvidia GK104 series GPU hardware to make matrix-matrix multiplications efficient. A mini-batch size of 128 is chosen for pre-training the network. We use rmsprop as an update rule for the parameters, an optimizer which divides the gradient by an exponential moving average of its squares.

### 3.2 Regularization

We use dropout (Srivastava, 2013) as the regularizer to prevent our network from overfitting. Dropout selects a fraction of the hidden units at random and sets their output to zero and thus, prevents co-adaptation of the features. However, it is tricky to be applied in the RNN as it is capable of unsettling the recurrent connections and thus, interfere with our recurrent layer's ability of retaining information for longer periods of time.

We choose the approach proposed in (Zaremba et al., 2014) to apply dropout in our network where it is being applied between inter-layer connections instead of intra-layer connections. This doesn't interfere with the recurrent updates in a layer and helps prevent co-adaptation of the features at the same time.

### 3.3 Pre-training the network

The training dataset provided as part of sub-task 4B in Semeval-2016 contain very few samples to effectively train our deep architecture. Thus, we used a weakly labeled corpus of tweets, namely, Sentiment140 (Go et al., 2009), to pre-train our network so as to learn semantic and sentiment specific representation of words and phrases.

We take the learned weights of the trained network as it is and fine tune them on the provided training dataset of sub-task 4B along with training and development dataset of task 2 in SemEval-2013. The network uses validation scores as the metric to do an early-stop while training. Macro-averaged recall, the official scoring metric of sub-task 4B, was

| Type     | Dataset                    | Positives | Negatives |
|----------|----------------------------|-----------|-----------|
| Training | Twitter'16<br>+ Twitter'13 | 8250      | 2500      |
| Testing  | Twitter'16                 | 8212      | 2337      |

**Table 1:** Statistical information of training and testing datasets.

| Scoring-metric | Score        | Best-score   | Rank |
|----------------|--------------|--------------|------|
| AvgR           | <b>0.784</b> | <b>0.797</b> | 3    |
| AvgF1          | 0.762        | 0.799        | 5    |
| Accuracy       | 0.823        | 0.862        | 9    |

**Table 2:** Resulting scores on testing dataset. AvgR was the official scoring metric of the task 4B.

also used as the validation scoring metric.

## 4 Experiments

### 4.1 Experimental settings

The statistical properties of training and testing datasets are provided in Table 1.

For evaluation, we use official scoring metric of Semeval-2016 task 4B - macro-averaged recall - average of recalls for both positive and negative classes.

The chosen parameters of our network are as follows: the maximum input sequence length is set to 30, vocabulary size is 400000, dimensionality of word embedding ( $d$ ) is 100, recurrent units hidden state vector size is 128, number of recurrent layers is 3, number of hidden unit in dense layer is 256 with relu activation. We used a dropout of 50% after each layer while training.

### 4.2 Results

Results are shown in Table 2.

Our system produces a macro-averaged recall of 0.784, while the best system scored 0.797. Our system's performance with other scoring metrics is also good, achieving 5th and 9th rank for macro-averaged F1 and accuracy metric, respectively.

Our architecture uses very little pre-processing compared to the other systems of Semeval-2016. It is able to capture useful semantic relationships and sentiment specific embeddings of words and phrases using just the raw tweets. It can be improved by adding handcrafted features such as topics, number of positive-negative lexicons, etc. which we would like to try in future.

## 5 Conclusion

In this paper, we proposed a deep learning system for sentiment classification of tweets on a two-point scale. Our architecture was able to capture complex semantic relationships between words and phrases of the input tweets to decide their final sentiment. We show how to pre-train and fine-tune a deep network like ours well from end-to-end using weakly supervised dataset. Our system used very little pre-processing before feeding the raw tweets to the network. In future, we would like to use handcrafted features in addition to the raw tweets to see if they improve the overall score.

# NTNUSentEval at SemEval-2016 Task 4:<sup>\*</sup>

## Combining General Classifiers for Fast Twitter Sentiment Analysis

**Brage Ekroll Jahren      Valerij Fredriksen      Björn Gambäck      Lars Bungum**

Department of Computer and Information Science  
Norwegian University of Science and Technology (NTNU)

### Abstract

The paper describes experiments on sentiment classification of microblog messages using an architecture allowing general machine learning classifiers to be combined either sequentially to form a multi-step classifier, or in parallel, creating an ensemble classifier. The system achieved very competitive results in the shared task on sentiment analysis in Twitter, in particular on non-Twitter social media data, that is, input it was not specifically tailored to.

## 1 Introduction

As a growing platform for people to express themselves on a global scale, Twitter has become exceedingly attractive as an information source. In addition to text, a tweet comes with metadata such as the sender’s location and language, and hashtags, making it possible to quickly gather vast amounts of data regarding a specific product, person or event. With a working Twitter Sentiment Analysis system, companies could get a feel of what consumers think of their products, or politicians could estimate their popularity amongst Twitter users in specific regions.

However, tweets and other informal texts on social media are quite different from texts elsewhere. They are short in length and contain a lot of abbreviations, misspellings, Internet slang, and creative syntax. Although the relative occurrence of non-standard English syntax is fairly constant among many types of social media (Baldwin et al., 2013),

analysing such texts using traditional language processing systems can be problematic, primarily since the main common denominator of social media text is not that it is informal, but that it describes language in rapid change (Androutsopoulos, 2011; Eisenstein, 2013), so that resources targeted directly at social media language quickly become outdated.

Twitter Sentiment Analysis (TSA) has been a rapidly growing research area in recent years, and a typical approach to TSA has been identified, using a supervised machine learning strategy, consisting of three main steps: preprocessing, feature extraction and classifier training. Preprocessing is used in order to remove noise and standardize the tweet format, for example, by replacing or removing URLs. Desired features of the tweets are then extracted, such as sentiment scores using specific sentiment lexica or the occurrence of different emoticons. Finally, a classifier is trained on the extracted features.

Since the machine learning algorithms used commonly are supervised, sentiment-annotated data is a prerequisite for training — and the growth of the TSA research field can largely be attributed to the International Workshop on Semantic Evaluation (SemEval) having run shared tasks on this theme since 2013 (Wilson et al., 2013), annually producing new annotated data. The SemEval-2016 version (Task 4) of the TSA task and the data sets are described by Nakov et al. (2016). Here we will specifically address Subtask A, which is a 3-way sentiment polarity classification problem, attributing the labels ‘positive’, ‘negative’ or ‘neutral’ to tweets.

The rest of the paper is laid out as follows: Section 2 describes a general architecture for building

<sup>\*</sup>Thanks to Mikael Brevik, Jørgen Faret, Johan Reitan and Øyvind Selmer for their work on two previous NTNU systems.

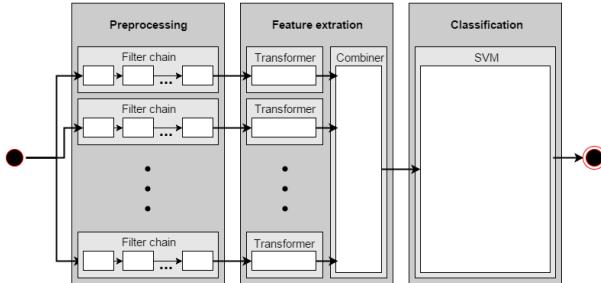

Figure 1: Overview of the core system architecture

Twitter sentiment classifiers, drawing on the experiences of developing two previous TSA systems (Selmer et al., 2013; Reitan et al., 2015). Section 3 reports the application of such a system ('NTNU-SentEval') to the SemEval data sets, while Section 4 points to ways that the results could be improved.

## 2 Sentiment Classifier Architecture

To solve the three-way sentiment classification task, a general multi-class classifier, *BaseClassifier*, was created. Utilizing a general methodology enables the combination of several BaseClassifiers in various ways, either sequentially to create a multi-step classifier, or in parallel, as a classifier ensemble.

The BaseClassifier consists of three steps: pre-processing, feature extraction, and then either classification or training. These are handled by a Pipeline object built in the Scikit-Learn Python machine learning library (Pedregosa et al., 2011). Scikit-Learn Transformer objects are used to extract or generate feature representations of the data. Figure 1 illustrates the overall architecture of the system. When creating a BaseClassifier instance, a set of parameters is specified, including the classification algorithm, the preprocessing functions to use, and options for each of the transformers. The preprocessing methods invoked depend on the transformers and the features they aim to extract.

## 2.1 Preprocessing

The preprocessing step modifies the raw tweets before they are passed to feature extraction: noise is filtered out and negation scope is detected. The filtering consists of a chain of simple methods using regular expressions. There are ten basic filters that can be invoked, six of which replace various twitter-specific objects with the empty string: emoticons, username

mentions, RT (retweet) tags, URLs, only hashtag signs (#), and hashtags (incl. the string following the sign). The other four filters transform uppercase characters to lowercase, remove non-alphabetic or space characters, limit the maximum repetitions of a single character to three, and perform tokenization using Pott's tweet tokenizer (Potts, 2011).

Negation detection uses a simple approach where  $n$  words appearing after a negation cue, but before the next punctuation mark, are marked as negated. The negation cues were adopted from Councill et al. (2010), supplemented by five common misspellings obtained by looking up each negation cue in TweetNLP’s Twitter word cluster (Owoputi et al., 2013): *anit*, *couldnt*, *dnt*, *does’nt*, and *wont*.

## 2.2 Feature Extraction

The feature extraction is implemented as a Scikit-Learn Feature Union, which is a collection of independent transformers (feature extractors), that build a feature matrix for the classifier. Each feature is represented by a transformer. Eight such transformers have been implemented: two extract the number of *punctuations* (repeated alphabetical and grammatical signs) and the number of happy and sad *emoticons* found in the tweet. Two other transformers extract TF-IDF values for *word n-grams* and *character n-grams* using a bag-of-words vectorizer implementation, which is an extension of Scikit-Learn’s default *TfidfVectorizer*.

A *part-of-speech* transformer uses the GATE TwitIE tagger (Derczynski et al., 2013) to assign part-of-speech tags to every token in the text; the tag occurrences are then counted and returned. A *word cluster* transformer counts the occurrences of different TweetNLP word clusters (Owoputi et al., 2013), that is, if a word in a tweet is a member of a cluster, a counter for that specific cluster is incremented.

The last two transformers are essentially lexical: the *VADER* transformer runs the lexicon-based social media sentiment analysis tool VADER (Hutto and Gilbert, 2014) and extracts its output. VADER (Valence Aware Dictionary and sEntiment Reasoner) goes beyond the bag-of-words model, taking into consideration word order and degree modifiers.

The *lexicon* transformer is a single transformer using a combination of six automatically and manually annotated prior polarity sentiment lexica. The

automatically annotated lexica used are NRC Sentiment140 and HashtagSentiment (Kiritchenko et al., 2014), that contain sentiment scores for both unigrams and bigrams, where some are in a negated context. Similarly, two manually annotated lexica, AFINN (Nielsen, 2011) and NRC Emoticon (Mohammad and Turney, 2010), give a sentiment score for each word (AFINN) or each emoticon (NRC Emoticon). However, two further manually annotated lexica, MPQA (Wilson et al., 2005) and Bing Liu (Ding et al., 2008), do not list sentiment scores for words, but only whether a word contains positive or negative sentiment. For those two lexica, negative and positive word sentiments were mapped to the scores  $-1$  or  $+1$ , respectively.

For all lexica, four different features were extracted from each tweet. Following Kiritchenko et al. (2014), the four features for manually annotated lexica are the sums of positive scores and of negative scores for words in both affirmative and negated contexts, while the four features for automatically annotated lexica comprise the number of unigrams or bigrams with sentiment score  $\neq 0$ , the sum of all sentiment scores, the highest sentiment score, and the score of the last unigram or bigram in the tweet.

### 2.3 Classification

After all desired features have been extracted, a BaseClassifier instance allows for the use of state-of-the-art classification algorithms such as Support Vector Machines (SVM), Naïve Bayes and Maximum Entropy (MaxEnt). Scikit-Learn includes a series of implementations of the SVM algorithm (Vapnik, 1995). The NTNUSentEval system uses the SVC variant, also known as C-Support SVM classifier since it is based on the idea of setting a constant  $C$  to penalize incorrectly classified instances. High  $C$  values create a narrower margin, enabling more elements to be correctly classified. However, this can lead to overfitting, so it is desirable to perform some kind of parameter optimization to find the best  $C$  value. For multi-class classification, Scikit-Learn uses a One-vs-One method with a run time complexity more than quadratic to the number of elements; however, this is not a problem for our relatively small (under 10,000 elements) datasets.

A single BaseClassifier acts as a one-step classifier, but by chaining BaseClassifiers sequentially,

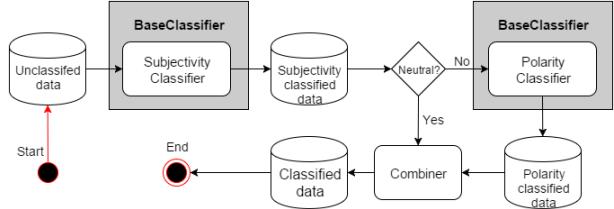

Figure 2: Data flow in the two-step classifier

a *multi-step classifier* can be created. Each classifier can be trained independently on different data, thereby learning a different classification function. Figure 2 illustrates how chaining two BaseClassifiers can create a two-step classifier. The first BaseClassifier is trained only on data labeled as subjective or objective, while the second BaseClassifier is trained only on subjective data, labeled positive or negative. When classifying, if the first BaseClassifier classifies an instance as subjective, the instance is forwarded to the second BaseClassifier to determine if it is positive or negative. The results from both classifiers are then combined and the final classification is returned.

By combining BaseClassifiers in parallel, an *ensemble of classifiers* can be created. Each of the classifiers is independent of the others and all classify the same instances. In the end, the classifiers vote to decide on the classification of an instance. Since the BaseClassifiers are so general, it is possible to create BaseClassifiers that extract different features, do different preprocessing, or use different classification algorithms — and then combine these to create an ensemble system.

### 2.4 Parameter Optimization

In order to find the optimal parameter values for the NTNUSentEval system, an extensive grid search was performed through the Scikit-Learn framework over all subsets of the training set (shuffled), using stratified 5-fold cross-validation and optimizing on  $F_1$ -score. During development we were able to find parameters that yielded better results on the complete test set than the parameters from the grid search. However, the optimal parameters are those that perform best on average, and using the parameters identified through development when presented with new data would most likely perform worse than using the parameters identified through grid search.

| Feature         | tokenize | lower_case | no_emoes | no_user | no_rt_tag | no_url | no_hashtag | limit.chars | limit_repeat |
|-----------------|----------|------------|----------|---------|-----------|--------|------------|-------------|--------------|

Table 1: Preprocessing used by feature extractors

| Parameter       | $n$ -grams |           |         |
|-----------------|------------|-----------|---------|
|                 | Word       | Character | Lexicon |
| $n$ -range      | (1, 5)     | (3, 6)    | N/A     |
| use_idf         | True       | True      | N/A     |
| min_df          | 0.0        | 0.0       | N/A     |
| max_df          | 0.5        | 0.5       | N/A     |
| negation_length | 4          | None      | -1      |

Table 2: Optimal parameter settings

As described in Section 2.2, a total of eight different feature extractors have been implemented, all of which can be enabled or disabled. Each feature extractor utilizes a specific preprocessor setting, as shown in Table 1. Further, there are three option settings for the SVM algorithm: type, kernel and  $C$ , which after grid search were set to SVC, Linear, and 0.1, respectively. In addition to the preprocessor options, there are eleven more feature extractor options, whose grid-searched optimal values are displayed in Table 2, where  $n$ -range gives the lower and upper  $n$ -gram sizes, use\_idf enables Inverse Document Frequency weighting, min\_df and max\_df give the proportions of lowest resp. highest document frequency occurring terms to be excluded from the final vocabulary, and negation\_length the maximum number of tokens inside a negation scope.

### 3 Experimental Results

The NTNUSentEval TSA system was trained on the Twitter training set (8,748 tweets), using the optimal parameters identified through grid search, and tested on the SemEval Twitter test sets from 2013 and 2014. The complete results on these test sets are shown in Table 4 below, while Nakov et al. (2016)

give the results on all test sets, including the unknown 2016 tweet set, in terms of the official evaluation metric,  $F_1^{PN}$ , which is the average of the F1-scores on the negative and the positive tweets.

Notably, our system performed extremely well on the out-of-domain test sets (i.e., the non-Twitter data), being the best of all 34 participating systems on the 2013-SMS set (with a 0.641  $F_1^{PN}$  score, compared to a 0.190  $F_1^{PN}$  baseline), the 3rd on the 2014-Live-journal set ( $F_1^{PN} = 0.719$ , with a 0.272 baseline), and overall tied for first on the out-of-domain data, supporting our claim that the approach taken in itself is quite general. However, the lack of domain fine-tuning of the system showed in comparison to the best systems on Twitter data, with the NTNUSentEval system consistently placing 11–13 on the different test sets, including 11th on the 2016 set ( $F_1^{PN} = 0.583$ , with baseline 0.255).

### 3.1 Ablation Study

In order to detect the overall importance or impact each feature has, a simple ablation study was conducted by removing each feature in turn and checking how the performance of the system was affected. The results of this study are shown in Table 3.

Evidently, the single most important feature is Sentiment Lexica. On the 2013-test set, system accuracy is reduced from 0.7227 to 0.6945 when the feature is removed, while the effect of removing it when testing on the 2014 set is not as apparent. A possible reason for this difference may be that most of the sentiment lexica used were created at the same time as the 2013-test set, and they might thus better reflect the language in that period of time. As noted in Section 1, the language of social media is rapidly changing, so that a lexicon created in 2013 might have reduced value already for data collected a year later. This effect is also noticeable when testing the system on the 2014-test set, where the VADER Sentiment feature is the most important one, reducing the accuracy from 0.6905 to 0.6793 when being removed. On the 2013-test set, the VADER Sentiment feature, which was created in 2014, does not have the same impact, again indicating a change in how the language is used and that VADER might better reflect the Twitter language of 2014.

The second most important contribution comes from the n-gram features. The removal of both char-

| Features                    | 2013-test | 2014-test |
|-----------------------------|-----------|-----------|
| All                         | .7227     | .6905     |
| - Word $n$ -grams           | .7136     | .6892     |
| - Character $n$ -grams      | .7085     | .6885     |
| - Both $n$ -grams           | .7017     | .6872     |
| - Automatic Lexica          | .7088     | .6799     |
| - Manual Lexica             | .7085     | .6938     |
| - All Sentiment Lexica      | .6945     | .6826     |
| - Word Clusters             | .7166     | .6872     |
| - Part-of-Speech tag counts | .7159     | .6865     |
| - Punctuation counts        | .7143     | .6932     |
| - Emoticons counts          | .7156     | .6918     |
| - All counts                | .7127     | .6925     |
| - VADER Sentiment           | .7114     | .6793     |

Table 3: Feature ablation study results ( $F_1$ -scores)

acter  $n$ -grams and word  $n$ -grams lead to a degradation in performance. On the 2013-test set the degradation in performance is quite significant, while on the 2014-test set the degradation is more subtle.

Another interesting result is the impact of the Emoticons and Punctuation count features. On the 2013-test set, removing them gives a slight reduction in performance, while on the 2014-test set we can observe a slight *increase* in performance. One possible reason for this could be that the way emoticons and punctuation are used in tweets changes over time, but the most likely cause is merely noise in the data. Although causing slightly increased or decreased performance, the individual count features do not significantly affect the overall results.

### 3.2 Architectural Experiments

Two instances of the BaseClassifier can be chained sequentially creating a 2-step classifier. Such a classifier was tested on the 2013 and 2014 test sets, as shown in Table 4. The 2-step classifier performs worse than the 1-step classifier on the 2013 set, while their performances on the 2014 set are comparable, so based on these results it is not clear that 1-step classification is better than 2-step.

The GATE TwitIE part-of-speech tagger uses an underlying model when tagging tweets. In addition to the standard best performing model, another high-speed model trading 2.5% token accuracy for half

| Data   | Precision | Recall | $F_1$ | Accuracy | Time   |
|--|-----------|--------|-------|----------|--------|
| <b>1-step classifier</b>                       |           |        |       |          |        |
| 2013   | .7370     | .6639  | .6848 | .7227    | 106.97 |
| 2014   | .7031     | .6619  | .6691 | .6905    | 53.01  |
| <b>2-step classifier</b>                       |           |        |       |          |        |
| 2013   | .7278     | .6526  | .6729 | .7172    | 118.36 |
| 2014   | .7079     | .6570  | .6676 | .6912    | 59.6   |
| <b>1-step classifier with fast PoS tagging</b> |           |        |       |          |        |
| 2013   | .7364     | .6639  | .6846 | .7221    | 80.13  |
| 2014   | .7032     | .6591  | .6673 | .6892    | 41.03  |

Table 4: Sentiment classifier performance

the tagging speed is available, and the results from testing BaseClassifier using the high-speed tagger model are also shown in Table 4. Although a slight reduction in performance can be observed compared to using the best tagger model, the high-speed model significantly reduced the total execution time, from 107 to 80 seconds on the 2013-test set and from 53 to 41 seconds on the 2014-test set.

## 4 Conclusion and Future Work

Drawing on the experiences from two previous Twitter Sentiment Analysis systems (Selmer et al., 2013; Reitan et al., 2015), a new TSA system was created using a simplified and generalised architecture, allowing for accurate and fast tweet classification.

As seen in the ablation study of Section 3.1, the Sentiment Lexica is the single most important feature, while also being one of the simplest: our implementation is based only on summing up the sentiment value of each word. A possible improvement would thus be to extract more information by considering the order of the words, part-of-speech tags, and degree modifiers, such as ‘very’, ‘really’ and ‘somewhat’, that can affect the sentiment value of the following word. These modifiers are currently not handled by the Sentiment Lexica extractor, yet they clearly carry a lot of sentiment weight.

Another interesting feature of lexicon-based systems is their good run-time performance, which is also confirmed in our system, where the lexicon feature extractor is one of the fastest feature extractors. This is a particularly important property for a TSA system to be useful in a real world setting, as the opinion mining accuracy confidence depends on the number of opinions examined.

## Abstract

We present an approach for tackling the tweet quantification problem in SemEval 2016. The approach is based on the creation of a co-occurrence graph per sentiment from the training dataset and a graph per topic from the test dataset with the aim of comparing each topic graph against the sentiment graphs and evaluate the similarity between them. A heuristic is applied on those similarities to calculate the percentage of positive and negative texts. The overall result obtained for the test dataset according to the proposed task score (KL divergence) is **0.261**, showing that the graph based representation and heuristic could be a way of quantifying the percentage of tweets that are positive and negative in a given set of texts about a topic.

## 1 Introduction

In the past decade, new forms of communication, such as microblogging and text messaging have emerged and become ubiquitous. There is no limit to the range of information conveyed by tweets and texts. These short messages are extensively used to **share opinions and sentiments** that people have about their topics of interest. Working with these informal text genres presents challenges for Natural Language Processing (NLP) beyond those encountered when working with more traditional text genres. Typically, this kind of texts are short and the language used is very informal. We can find creative spelling and punctuation, slang, new words, URLs, and genre-specific terminology and abbreviations that make their manipulation more challenging.

Representing that kind of text for automatically mining and understanding the opinions and sentiments that people communicate inside them has very recently become an attractive research topic (Pang and Lee, 2008). In this sense, the experiments reported in this paper were carried out in the framework of the SemEval 2016<sup>1</sup> (**Semantic Evaluation**) which has created a series of tasks for sentiment analysis on Twitter (Nakov et al., 2016b). Among the proposed tasks we chose Task 4, subtask D which was named **tweet quantification according to a two-point scale** and was defined as follows:

"Given a set of tweets known to be about a given topic, estimate the distribution of the tweets across the Positive and Negative classes". In order to solve this task we created an algorithm that builds up graphs to compare each topic against all possible sentiments for obtaining the polarity percentage of each one. The steps involved in our sentiment quantification process are then discussed in detail.

The rest of the paper is structured as follows: in Section 2 we present some related work found in the literature with respect to the quantification of sentiments in text documents. In Sections 3 to 5 the algorithm and the graph representation used to detect the percentage of texts for each sentiment are explained. In Section 6, the experimental results are presented and discussed. Finally, in Section 7 the conclusions as well as further work are described.

## 2 Related Work

There exist a number of works in literature associated to the automatic quantification of sentiments in documents. Some of these works have focused on the contribution of particular features, such as the use of the vocabulary to extract lexical elements associated to the documents (Kim and Hovy, 2006), the use of part-of-speech tag n-grams and syntactic phrase patterns (Esuli et al., 2010) to capture syntactic features of texts associated with a sentiment, the use of dictionaries and emoticons of positive and negative words (Go et al., 2009) as well as man-

ually and semiautomatically constructed syntactic and semantic phrase and lexicons (Gao and Sebastiani, 2015; Whitelaw et al., 2005).

On the other hand, many contributions focused on the use of structures to represent the features associated to a document like the frequency of occurrence vector (Manning et al., 2008; Balinsky et al., 2011) or the vectors that represent the presence or absence of features (Kiritchenko et al., 2014). But research works that use graph representations for texts in the context of sentiment quantification barely appear in the literature (Pinto et al., 2014; Poria et al., 2014). It has usually been proposed the concept of n-grams with a frequency of occurrence vector to solve it (Pang and Lee, 2008). However, there is still an enormous gap between this approach and the use of more detailed graph structures that represent in a natural way the lexical, semantic and stylistic features.

## 3 Sentiment Quantification

Algorithm 1 shows the steps involved in computing the percentage of positive and negative tweets for each topic in the test dataset (see section 6.1) considering the use of graphs to represent the word interaction for each sentiment in the training dataset and for each topic in the test dataset. The algorithm consists of five relevant stages:

1. Preprocess all documents in the dataset. This task includes elimination of punctuation symbols and all the elements that are not part of the ASCII encoding. Then, all the remaining words are changed to lowercase.
2. Create a graph for each sentiment using the **training** dataset documents (see Section 4).
3. Create a graph for each topic using the **test** dataset documents (see Section 4).
4. Compare each topic graph against the sentiment graphs and calculate the similarity score between both (see Section 5).
5. Compare those similarities and take the highest to use it as a base to calculate the quantification score for each sentiment in a topic, considering

that the sum of all percentages related to a topic must be equal to one<sup>2</sup>.

## 4 Graph Based Representation

Among different proposals for mapping texts to graphs, the co-occurrence of words (Sonawane and Kulkarni, 2014; Balinsky et al., 2011) has become a simple but effective way to represent the relationship of one term over another one in texts where there is no syntactic order (usually social media texts like Twitter or SMS). Formally, the proposed co-occurrence graph used in the experiments is represented by  $G = (V, E)$ , where:

- $V = \{v_1, \dots, v_n\}$  is a finite set of **vertices** that consists of the words contained in one or several texts.
- $E \subseteq V \times V$  is the finite set of **edges** which represent that two vertices are connected if their corresponding lexical units **co-occur within a window of maximum 2 words** in the text (at least once). We consider this type of window because it represents the natural relationship of words.

As an example, consider the following sentence  $\zeta$  extracted from a text  $T$  in the dataset: “Axel Rose needs to just give up. Now. Not later, not soon, not tomorrow.”, which after the preprocessing stage (see Section 3) would be as follows: “axel rose needs to just give up now not later not soon not tomorrow”. Based on the proposed representation, preprocessed sentence  $\zeta$  can be mapped to the co-occurrence graph shown in Figure 1.

## 5 Graph similarity

After having created the graph representation for each topic and sentiment in the dataset, the steps involved in computing the similarity score (Castillo et al., 2015) are shown in algorithm 2. The algorithm consists of four relevant stages:

1. Obtain all vertices (words) that share the topic graph as well as the sentiment graph.
2. Apply the Dice similarity measure (Montes et al., 2000; Adamic and Adar, 2003) for each

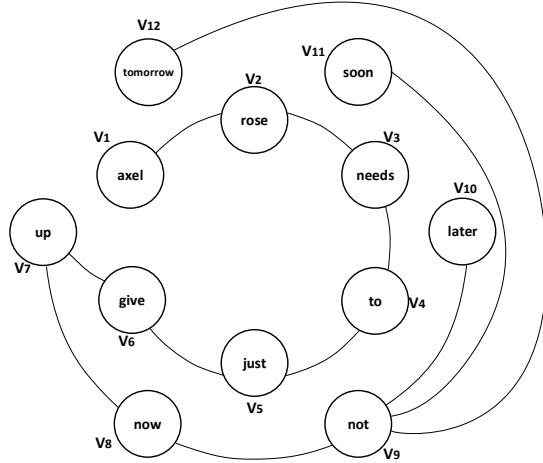

Figure 1: co-occurrence graph example.

graph, taking as input the shared vertices of the previous step and the graph to be analyzed. The result is a matrix that represents the similarity scores for each pair of input vertices, based on their connection patterns. Formally, Dice similarity calculates the similarity of two vertices  $(x, y)$  as twice the number of common neighbors ( $ngb$ ) divided by the sum of the neighbors of the vertices (see equation 1).

$$Dice(x, y) = \frac{2 |ngb(x) \cap ngb(y)|}{|ngb(x)| + |ngb(y)|} \quad (1)$$

3. Obtain the upper triangular values for each matrix and use them to build a vector representation (Manning et al., 2008). The rest of the matrix values are not useful, because the main diagonal represents the similarity of an input vertex with itself and the lower triangular is the same as the upper one.
4. Apply the normalized Euclidean distance (Cancho, 2004) between the vector representing the topic and the vector representing a sentiment. The result is a value in the range of 0 to 1 that indicates how similar the two graphs are. The Euclidean distance of vector  $A$  and  $B$  is calculated using equation 2.

$$Euclidean(A, B) = \sqrt{\sum_{i=1}^n \frac{(A_i - B_i)^2}{n}} \quad (2)$$

<sup>2</sup>SemEval 2016 task 4, subtask D requirement.

## 6 Experimental results

The results obtained with the proposed approach are discussed in this section. First, we describe the dataset used in the experiments and, thereafter, the results obtained.

### 6.1 Dataset

The document collection used in the experiments is a subset of the SemEval 2016 task 4 corpus (Nakov et al., 2016b), which includes, several text documents in English on different topics and genres. The dataset is divided in two groups:

- **Training documents:** It contains a set of topics each one with a set of known documents. For each document a label that indicates the polarity of the text (positive or negative) is assigned.

- **Test documents:** It contains a set of topics<sup>3</sup> each one with a set of known documents. In this case there is no label that indicates the polarity of the text. These documents are used to test our algorithm taking into account the writing style samples of the training documents.

In Table 1, main dataset features are shown, including the number of documents per topic for the training and test dataset.

Table 1: SemEval task 4 subtask D dataset features.

| Feature                       | Training | Test   |
|-------------------------------|----------|--------|
| Type of documents             | Tweet    | Tweet  |
| Number of documents           | 5205     | 10551  |
| Number of topics              | 59       | 100    |
| Number of documents per topic | 70-100   | 60-250 |
| Avg. words per document       | 68       | 52     |
| Avg. words per sentence       | 5        | 5      |
| Vocabulary size               | 6869     | 9732   |

### 6.2 Obtained results

In Table 2 we present results obtained with the test dataset considered in the SemEval 2016 task 4 subtask D. The results were evaluated according to the Kullback-Leibler Divergence (KLD), which is a measure of the error made in estimating a true distribution  $p$  over a set  $C$  of classes by means of a predicted distribution  $\hat{p}$ . KLD (Nakov et al., 2016a) is a measure of error, so lower values are better (see equation 3).

$$KLD(\hat{p}, p, C) = \sum_{c_j \in C} p(c_j) \log \frac{p(c_j)}{\hat{p}(c_j)} \quad (3)$$

Table 2: Evaluation of the proposed algorithm using the test dataset.

| System                   | KLD score    |
|--------------------------|--------------|
| Competition, best result | 0.034        |
| <b>UDLAP team</b>        | <b>0.261</b> |
| Competition, baseline 1  | 0.887        |
| Competition, baseline 2  | 0.175        |

Taking into account obtained results, our approach performed above the baseline 1 and slightly

<sup>3</sup>Different from the training topics.

below baseline 2. We consider that these results were obtained even though the training corpus was very unbalanced (there were more positive texts than others) and there was a high difference between the vocabulary of the topics of the training and test datasets. The proposed algorithm showed an effective and relative fast way<sup>4</sup> (00:02:48 minutes) to get the percentage of positive and negative documents although it is necessary to perform different experiments using the proposed approach on a test dataset with more topics. Further analysis on the use of a co-occurrence graph and the similarity measure will allow us to find more accurate features that can be used for the sentiment quantification problem.

## 7 Conclusions

We have presented an approach that incorporates the use of a graph representation to solve the sentiment quantification problem (task 4 subtask D). The results obtained show a competitive performance that is above one of the baseline scores. However there is still a great challenge to improve the techniques for dealing with the quantification problem where the text could be smaller and there are different topics, each one with his own vocabulary. One of the contributions of this paper is that we proposed a graph based representation and a similarity measure for the quantification problem instead of using traditional classification techniques like a supervised learning method based on the extraction of stylistic features (Kharde and Sonawane, 2016). As further work we propose the following:

- Use different co-occurrence windows for modeling the text using a graph based representation.
- Experiment with other graph representations for texts that include alternative levels of language descriptions such as the use of sentence chunks, pragmatic sentences, etc (Mihalcea and Radev, 2011).
- Propose a similarity measure that uses the semantic information of a graph (Alvarez and Yan, 2011).

---

<sup>4</sup>The execution runtime consider all the steps involved in algorithm 1.

- Explore different techniques that can be used in the sentiment quantification problem (Pang and Lee, 2008).
- Compare the algorithm presented with other classical approaches like the use of stylistic features or the N-gram model (Stamatatos, 2008).
- Explore different supervised/unsupervised classification algorithms (Cook and Holder, 2000).

## Abstract

This paper presents the approach of the GTI Research Group to SemEval-2016 task 4 on Sentiment Analysis in Twitter, or more specifically, subtasks A (Message Polarity Classification), B (Tweet classification according to a two-point scale) and D (Tweet quantification according to a two-point scale). We followed a supervised approach based on the extraction of features by a dependency parsing-based approach using a sentiment lexicon and *Natural Language Processing* techniques.

## 1 Introduction

In recent years, research on the field of *Sentiment Analysis* (SA) has increased considerably, due to the growth of user content generated in social networks, blogs and other platforms on the Internet. These are considered valuable information for companies, which seek to know or even predict the acceptance of their products, to design their marketing campaigns more efficiently. One of these sources of information is Twitter, where users can write about any topic, using colloquial and compact language. As a consequence, SA in Twitter is specially challenging, as opinions are expressed in one or two short sentences.

Many approaches have been proposed for SA, and can be roughly divided into two categories. The first one tries to capture and model linguistic knowledge through the use of dictionaries (Taboada et al., 2011) containing words that are tagged with their semantic orientation. These methods detect the words present in a text using different strategies involving

lexics, syntax or semantics (Quinn et al., 2010). The other one is machine learning-based, which is currently the most predominant approach including supervised learning and deep learning. They widely use classifiers including *Support Vector Machines* (SVM), *Maximum Entropy Models* (MAXENT), and *Naïve Bayes* classifiers. Most of the time, they are built from features of a “*bag of words*” representation (Pak and Paroubek, 2010).

Our group has participated in SemEval-2016 task 4 on Sentiment Analysis in Twitter, subtasks A (Message Polarity Classification), B (Tweet classification according to a two-point scale) and D (Tweet quantification according to a two-point scale) (Nakov et al., 2016b).

The remainder of this article is structured as follows: Section 2 presents in detail the system proposed for the performance of these subtasks, and Section 3 shows the results obtained and discusses them. Finally, Section 4 summarizes the main findings and conclusions.

## 2 System Overview

Our main objective was to create a supervised system using extracted features from an unsupervised system described in (Fernández-Gavilanes et al., 2015). This last approach comprises different processing stages, including the generation of sentiment lexicons, test preprocessing and the application of different methods for determining contextual polarity based on syntactical structure. This makes our approach robust in diverse contexts without the need for previous manual tagging of datasets. As we can decide independently which modules

of the unsupervised system to use or not, it was easy to extract different features from each one individually or together. Once extracted, classification was applied using *Weka* tool (Hall et al., 2009). This environment contains a collection of *machine learning-based* algorithms for data mining tasks, such as, classification, regression, clustering, association rules, and visualization. The new supervised system was built with a *Naive Bayes* classifier.

## 2.1 Modules combination features

The first extracted features of the unsupervised system were the different sentiment outputs of the modules combination. As mentioned before, modules can be enabled and disabled independently. With this feature, multiple sentiment outputs were obtained from these combinations.

The unsupervised system has four different modules (“*intensification treatment*” (I), “*negation treatment*” (N), “*polarity conflict treatment*” (C) and “*adversative/concessive clause treatment*” (A/CO)). In total, there were 14 possible combinations: one by one, combining pairs or groups of three of them, and all of them at once (the latter is the default output of the unsupervised system). In subtask A, each output obtained is defined by a sentiment value contained between three possible ones: *negative*, *neutral* or *positive*. However, in subtask B, the sentiment value obtained for each combination only can be contained between two possible ones: *negative* or *positive*. So, the result of each one of these 14 combinations was considered as a feature. All of them are defined in Table 1.

| Combination  | Subtask A | Subtask B |
|--------------|-----------|-----------|
| I            |           |           |
| N            |           |           |
| C            |           |           |
| A/CO         |           |           |
| I + N        |           |           |
| I + C        |           |           |
| I + A/CO     |           |           |
| N + C        |           |           |
| N + A/CO     |           |           |
| C + A/CO     |           |           |
| I + N + C    |           |           |
| I + N + A/CO |           |           |
| N + C + A/CO |           |           |
| ALL          |           |           |

**Table 1:** Possible combinations of modules.

## 2.2 Individual modules features

In addition to the previous modules combination results extracted, other features were also extracted from each module independently. Each tweet was represented as a vector of generic and relational features. Generic features are those that are not related to a scope in a given tweet, and relational features represent the corresponding scope needed for each module. For example, in the negation module, the scope would begin in the unigram that caused the negation (the negator term itself), and would cover all affected unigrams in a branch of the dependencies tree, detected by its syntactic function. For this reason, both types of features can be distinguished. The option chosen to mark the scope was to use relational attributes. With them, unigram to unigram can be stored with all its associated features: such as it is an intensifier, a negator, a part of the scope of negation, etc.

**Generic features:** The first features introduced are not related to a scope, and involve:

- *Phrases*: the number of phrases of a particular tweet.
- *Adjectives*: the number of existing adjectives in a given tweet.
- *Common names*: the number of existing common names in a given tweet.
- *Verbs*: the number of existing verbs in a given tweet (except auxiliary verbs).
- *Positive/negative polarity unigrams*: the number of unigrams with positive/negative polarity in a given tweet.
- *Positive/negative emoticons*: the number of positive/negative emoticons (with positive/negative polarity) in a given tweet.
- *Positive/negative intensifications*: the number of positive/negative intensifications in a given tweet.
- *Unigrams*: all lemmas were considered (except *hashtag*, *mention*, *URL*, unigrams with numbers, unigrams with length 1 and punctuation marks).

**Relational features:** They can be defined as an array of features. Each unigram of a given tweet has assigned all the features defined in the relational, so it is easy to mark the scope of treatment of each of the separate modules. Then, all features introduced for each unigram in the relational are detailed.

- *Part of speech:* it can take one of the next five values: adjective, common name, verb, adverb or other.
- *Polarity value:* it can take one of the next seven values: negative +, negative, negative -, none, positive -, positive and positive +.
- *Is intensifier:* it indicates if an unigram is an intensifier. It can take one of the next five values: intensity --, intensity -, none, intensity +, intensity ++.
- *Was intensified:* it indicates if an unigram was intensified. It can take one of the next seven values: negative +, negative, negative -, none, positive -, positive and positive +.
- *Conflict unigram:* it indicates if an unigram causes a polarity conflict, with its polarity converted to intensity. It can take one of the next five values: intensity --, intensity -, none, intensity +, intensity ++.
- *Affected unigram:* it indicates when an unigram is affected by a conflict unigram, modifying its polarity value. It can take one of the next seven values: negative +, negative, negative -, none, positive -, positive and positive +.
- *Negator unigram:* it indicates when an unigram is a negator, modifying the polarity value of the subsequent unigrams. It can take one of the next two values: 0 if it isn't a negator or 1 if it is.
- *Negated unigram:* it indicates when an unigram is affected by a negator, modifying its polarity value. It can take one of the next seven values: negative +, negative, negative -, none, positive -, positive and positive +. This is the value contributed by that unigram in a negated branch of the dependencies tree (the scope).

## 2.3 Sentiment prediction

Once features were extracted, the next step was to create a model to predict sentiment in testing datasets. Previously, it was said that *Weka* contains a collection of machine learning algorithms for data mining tasks. Several algorithms were tested, such as *Support Vector Machines* (SVM) (Mullen and Collier, 2004), *Large-Scale Linear* (LIBLINEAR) (Fan et al., 2008) or *Hidden Markov Model* (HMM) (Soni and Sharaff, 2015), but the best results obtained were with *Naive Bayes* (Tan et al., 2009). Also, *10-fold cross-validation* was used to obtain the best classification model with the training dataset. Once all classification models were obtained, in subtask A the model with the best *F-measure* was selected, while in subtask B the selected model was the one with the best *recall* (R), as the organization proposed. For the subtask D, the subtask B results were taken into account.

A previous step before the selection of the best classification model is needed. Most algorithms do not accept as input relational attributes, so it was necessary to apply an unsupervised filter by attribute, *RELAGG*, both in training and test files. It processes all relational attributes that fall into the user defined range, making them nominal attributes. In *Naive Bayes* algorithm, the default settings were used, for both the training and the testing datasets, as they are defined in *Weka*. Finally, applying the best model for each subtask on the corresponding testing dataset, the final sentiment prediction for all tweets was obtained.

## 3 Experimental results

In this section, the conducted experiments for subtasks A, B and D are described. The experiments were carried out using the datasets provided by SemEval-2016 task organizers. These datasets are composed of texts extracted from Twitter, and in the case of the subtasks B and D, with a given topic. In subtask A, the number of tweets is 32009 and the performance of the system is measured by means of the *F-score*. In subtask B, the number of tweets is 10551 and the performance of the system is measured by means of the *macroaveraged recall*. Finally, in subtask D, as in subtask B, the number of tweets is 10551 (same dataset) but this time, the

performance of the system is measured by means of the normalized cross-entropy, better known as *Kullback-Leibler Divergence* (KLD). In this last case, there is a minor modification in the formula, with a smoothed version of the originals  $p(c_j)$  and  $\hat{p}(c_j)$ , and a smoothing factor  $\epsilon$ . All of these measurements are described in (Nakov et al., 2016a).

Table 2 presents the overall scores for subtasks A, B and D, in their respective test sets: *F-measure*, *recall* and KLD, respectively. The third column shows the unsupervised approach results (UAR) and the fourth shows the supervised approach results (SAR) obtained this year.

|                  | <b>Test set</b> | <b>UAR</b> | <b>SAR</b> |
|------------------|-----------------|------------|------------|
| <b>Subtask A</b> | <i>Tw 2013</i>  | 59.44%     | 61.17%     |
|                  | <i>SMS 2013</i> | 52.19%     | 52.38%     |
|                  | <i>Tw 2014</i>  | 62.45%     | 63.90%     |
|                  | <i>TwS 2014</i> | 46.77%     | 46.77%     |
|                  | <i>LJ 2014</i>  | 61.16%     | 62.32%     |
|                  | <i>Tw 2015</i>  | 57.64%     | 58.44%     |
|                  | <i>Tw 2016</i>  | 53.17%     | 53.94%     |
| <b>Subtask B</b> | <i>Tw 2016</i>  | 73.36%     | 73.60%     |
|                  | <b>Test set</b> | <b>UAR</b> | <b>SAR</b> |
| <b>Subtask D</b> | <i>Tw 2016</i>  | 0.067      | 0.055      |

**Table 2:** Results of the approach for subtasks A, B and D. *Tw* refers to Twitter, *TwS* to Twitter Sarcasm and *LJ* to LiveJournal.

After performing several experiments on the training, development and development-test datasets provided by organizers, the neutral sentiment intervals were set to [-0.5, 0.5] for subtask A and [-0.05, 0.05] for subtask B (subtask D depends on subtask B). More specifically, in subtask A, our supervised approach was tested with SemEval-2014 development-test, SemEval-2015 development-test and 2016 development-test datasets provided; in subtask B, it was tested with 2016 development-test dataset; and for subtask D, the 2016 development-test dataset results in subtask B were taken into account. In development time, the improvement of our supervised system was between 1 and 3 % compared to our unsupervised system for subtasks A and B, and for subtask D a difference of -0.02 KLD.

In order to assess the improvement of our supervised system regarding our unsupervised system, a comparison is performed in the test sets of this year, as it can be seen in Table 2. With these results, we

can say that the new approach, in most cases, improves the unsupervised system, between 0.19 and 1.73 % for subtask A and B (except in Twitter Sarcasm 2014), and a difference of -0.012 in subtask D.

## 4 Conclusion

This paper describes the participation of the GTI Research Group, AtlantIC Centre, University of Vigo, in SemEval-2016 task 4: Sentiment Analysis in Twitter. The results were achieved using a supervised system with extracted features from an unsupervised system, described in (Fernández-Gavilanes et al., 2015). Table 3 shows the position of this approach in the ranking published for subtasks A, B and D for the datasets evaluated.

|                  | <b>Test set</b>             | <b>Position</b> |
|------------------|-----------------------------|-----------------|
| <b>Subtask A</b> | <i>Twitter 2013</i>         | 13 / 34         |
|                  | <i>SMS 2013</i>             | 17 / 34         |
|                  | <i>Twitter 2014</i>         | 16 / 34         |
|                  | <i>Twitter Sarcasm 2014</i> | 7 / 34          |
|                  | <i>LiveJournal 2014</i>     | 17 / 34         |
|                  | <i>Twitter 2015</i>         | 19 / 34         |
|                  | <i>Twitter 2016</i>         | 20 / 34         |
| <b>Subtask B</b> | <i>Twitter 2016</i>         | 9 / 19          |
| <b>Subtask D</b> | <i>Twitter 2016</i>         | 5 / 14          |

**Table 3:** Positions of the approach for subtasks A, B and D.

The unsupervised approach consists of sentiment propagation rules on dependencies where features were selected (as the different sentiment outputs of the modules combination), and a vector of generic (features not related to a scope in a given tweet) and relational (features extracted from the scope in each treatment performed in each module) features. The results denote a low/medium improvement in subtask A regarding the unsupervised system, and a low improvement in the subtask B (also reflected in the subtask D). Although the new approach is supervised, the fact of using only features of an unsupervised system makes it totally different from other approaches, and still has margin of improvement adding new external features.

No. 39 Nanjing Road, Capitaland International Trade Center Block B 1604

Tianjin China

{steven, zhangxi}@aicyber.com

## Abstract

This paper introduces aicyber's systems for SemEval 2016 , Task 4A. The first system is build on vector space model (VSM), the second system is build on a new framework to estimate sentence vector, it is inspired by the i-vector in speaker verification domain. Both systems are evaluated on SemEval 2016 (Task4A) as well as IMDB dataset. Evaluation results show that the i-vector based sentence vector is an alternative approach to present sentence.

## 1 Introduction

The SemEval 2016 Task 4 is sentiment analysis in tweets. The subtask, task A focused on classifying tweets into three classes: positive, negative or neutral sentiment (Nakov et al., 2016).

This paper will first presents the submitted system used by team aicyber. Then a new framework of estimating sentence vector will be introduced and evaluated.

## 2 The aicyber system

This section introduces the submitted system for team aicyber. The text data is first being processed by tweet tokenizer, emoticons are preserved as tokens. Bag-of-ngram feature is extracted and filtered by a TF-IDF (Salton, 1991) selection. Resulting feature dimension is around 3800, it is then reduced to 400 by truncated singular value decomposition (SVD) (Klema and Laub, 1980; Halko et al., 2009). This process is also known as Latent Semantic Analysis (LSA) or Vector Space Model (Turney and Pan-

tel, 2010). Finally a Linear Discriminant Analysis (LDA) classifier (Hastie et al., 2009) is trained to classify the test data.

The SemEval 2016 training dataset which contains 3887 tweets are selected to train the TF-IDF, SVD and LDA. Development dataset is used for tuning parameters and develop-test dataset are used for local testing.

Task A adopted Macro-F1 measure as evaluation metric (Nakov et al., 2016):

$$F_1^{PN} = \frac{F_1^{Pos} + F_1^{Neg}}{2} \quad (1)$$

The Macro-F1 for Aicyber system measured on development, develop-test and 2016 Tweet set, are respectively 0.4514, 0.4787 and 0.4024.

It is obvious that this classification problem has not been satisfactorily answered. One possible reason is the unbalanced training data causes system bias towards positive classes. There are 2101 positive, 1292 neutral but only 494 negative tweets.

Another reason is the size of labeled training set is too small,with only 3887 tweets, which could hardly cover a reasonable amount of words. As a result, the bag-of-ngram features learned from this training set, could not generalized well. This motivate us to seeking alternative feature representation of tweet, that is sentence vector.

## 3 Sentence vector

(Le and Mikolov, 2014) proposed sentence vector or paragraph vector (PV) which could learn the continuous distributed vector representation for

text of variable-length and achieved promising result on movie review texts. It is inspired by word2vec (Mikolov et al., 2013) embedding which captures rich notions of semantic relatedness and constitutionality between words. (Mesnil et al., 2014) shows the ensemble of sentence vector, RNN language model (Mikolov et al., 2010) and NB SVM (Wang and Manning, 2012) achieved new state-of-the-art result.

(Dai et al., 2015) extends the study and provide a more thorough comparison of PV to other task such as document modeling. It concluded PV can effectively be used for measuring semantic similarity between long pieces of texts.

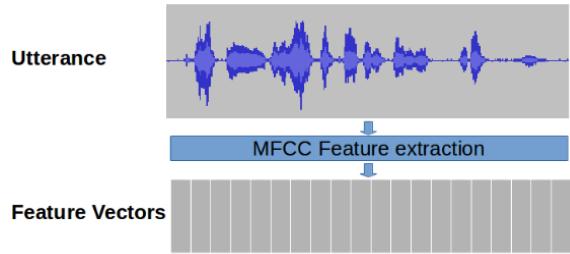

However such approach assume testing data is known during learning of vector representation. Access of testing data during training may not allowed for certain machine learning task, and it is not practical for real application.

Thus we would like to introduce a new approach to estimate sentence vector or PV for variable-length of texts from word embeddings by using i-vector framework.

### 3.1 i-vector framework in speech domain

i-vector (Dehak et al., 2011) is one of the dominant approaches in speaker verification (SV) research in the recent years. It projects variable length speech utterances into a fixed-size low-dimensional vector, namely i-vector. Its development advanced from traditional techniques such as the Gaussian Mixture Models (GMMs) (Rose and Reynolds, 1990; Reynolds and Rose, 1995), adapted GMMs (Reynolds et al., 2000), GMM supervectors (Campbell et al., 2006) and Joint Factor Analysis (Kenny et al., 2007).

To understand i-vector, firstly we need to understand the speech data, the speech data is a sequence of frames. At each frame a fixed-size feature vector is extracted, such as MFCC (Davis and Mermelstein, 1980), with addition of dynamics features such as "delta" and "delta-delta" (Furui, 1986). Thus one utterance could be viewed as a list of continuous-valued vectors as shown in Fig.1. A large amount of utterances are used to train the background GMM in i-vector framework. Secondly we need to learn the supervector. Its aim was to convert a spoken utterance with arbitrary duration to a fixed length vec-

**Figure 1:** In i-vector framework of SV system, during data pre-processing, spoken utterance is presented as a list of feature vectors. A trained i-vector extractor could map utterances of various length into fixed-size vectors.

tor. The supervector mentioned here is specific to the GMM supervector constructed by stacking the means of the mixture components. For example, a GMM with 2048 components built on 60 dimensional feature vectors results a 122880 (2048\*60) dimensional supervector. A review of GMM and supervector is presented in (Kinnunen and Li, 2010).

Given an utterance, its GMM supervector  $s$  can be represented as follows:

$$s = m + Tw \quad (2)$$

where  $m$  denotes Universal Background Gaussian Mixture Model's (UBM) supervector,  $T$  is the total-variability matrix, which is used to represent the primary directions' variation across a large amount of training data. The coefficients  $w$  of this total variability is known as identity vector or simply i-vector.

Extraction of this i-vector can be done as follows (Given a SV system built on  $F$  dimensional MFCC features and UBM with  $C$  Gaussian components):

$$w = (I + T^t \Sigma^{-1} N T)^{-1} T^t \Sigma^{-1} A \quad (3)$$

where  $I$  is  $F \times F$  identity matrix,  $N$  is a  $CF \times CF$  diagonal matrix whose diagonal blocks are  $N_c I (c=1,2,\dots,C)$ , and the supervector  $A$  is generated by the concatenation of the centralized first-order Baum-Welch statistics.  $\Sigma$  is the covariance matrix of the residual variability not captured by  $T$ . The i-vector's dimension is usually 400, much lower than that of supervectors. This thus allows the use of various techniques that were not practical in high dimensional space. To give a completed review of i-vector is out of scope of this paper, interested individuals are strongly encouraged to read (Kenny et al., 2008; Dehak et al., 2011).

**Figure 2:** Data preprocessing of proposed NLP i-vector framework. Sentence is represented by its word embedding. A trained i-vector extractor could map sentence of arbitrary length into one fixed-size vector.

### 3.2 i-vector framework for Natural Language Processing task

(Shepstone et al., 2016) points out that *the central to computing the total variability matrix and i-vector extraction, is the computation of the posterior distribution for a latent variable conditioned on an observed feature sequence of an utterance*. In Natural Language Processing(NLP) when observations (words) could be represented as sequences of feature vectors, will the same methodology apply? This motivated us to bring i-vector from speech to NLP domain. Fig. 2 illustrates the fundamental principle of proposed i-vector framework for NLP task, where a sentence is represented through its word embedding during data preprocessing. Delta and delta-delta feature is added during training in order to capture the context information. Compare to Fig. 1 where spoken utterance is viewed as list of frame level MFCC feature vectors. The proposed i-vector framework replace MFCC features by word vectors, and trained using similar implementation as of speech data.

### 3.3 The implementation of i-vector framework

Many implementations of i-vector framework are developed recently, (Glembek et al., 2011) use standard GMM approach. (Snyder et al., 2015) incorporated time delayed deep neural network (TDNN) trained on speech recognition task into i-vector framework. A 50% relative improvement is obtained when TDNN instead of GMM is used to collect first-order Baum-Welch statistics. In this paper we use the light weighted conventional GMM approach for proof of concept purpose.

## 4 Experiment and evaluation

Training of i-vector system is in a completely unsupervised manner, it includes training of word2vec and training of i-vector extractor. Evaluation is done on IMDB similar to (Maas et al., 2011; Le and Mikolov, 2014; Mesnil et al., 2014) and SemEval 2016 Task4A.

### 4.1 Word2vec training

Word2vec training is done by using gensim<sup>1</sup>. Training dataset is selected from IMDB, it contains 25000 labeled training samples and 50000 unlabeled data, a total of 75000 movie reviews.

The training use a context window of 7, minimum word count of 10 and the resulting dimension of word vector is 20.

### 4.2 i-vector extractor training

Same data from word2vec training is used for i-vector extractor training. As illustrated in Fig 2, the data preprocessing involved word-to-vector conversion. Words that not appear in the word2vec model are ignored. Each review is treated as one sentence. The sentence is saved as list of word vectors, can be viewed as a  $M \times 20$  matrix. Where  $M$  denotes number of words in that sentence.

The proposed i-vector extractor training system<sup>2</sup> is developed using the Kaldi Speech Recognition Toolkit (Povey et al., 2011)<sup>3</sup>. Feature used is a 60 dimensional features consisting of the 20 dimensional word vector and its delta, double delta. Mean and variance normalization is not applied. During training, a universal background model (UBM) with 2048 Gaussian mixture components is trained on 64000 sentences. Each Gaussian in UBM has a full covariance matrix. After UBM is trained, the total variability matrix is similar trained with all the 75000 sentences. Learned i-vector extractor is then used to estimate vectors for IMDB and SemEval 2016 dataset. The output dimension of i-vector is 200. Note that, test data of IMDB and all data in SemEval 2016 are not observed during training.

<sup>3</sup><https://github.com/kaldi-asr/kaldi>

| System                  | Training Data        | Accuracy (%) |
|-------------------------|----------------------|--------------|
| <b>State-of-the-art</b> | train+test+unlabeled | <b>92.57</b> |
| Sentence Vectors        | train+test+unlabeled | 88.73        |
| Aicyber's system        | train                | 88.38        |
| <b>i-vector</b>         | train+unlabeled      | <b>87.52</b> |
| <b>i-vector+VSM</b>     | train+unlabeled      | <b>89.94</b> |

**Table 1:** Proposed i-vector based sentence vector evaluated on the IMDB dataset. It didn't beat the state-of-the-art, an ensemble of three sub systems.

### 4.3 Evaluation of proposed framework

The i-vector framework is first evaluated on the IMDB dataset then on the SemEval 2016 dataset.

#### 4.3.1 Evaluation on IMDB

Evaluation metric is accuracy measured on IMDB database. Table 1 shows the performance of different systems. The current state-of-the-art system is an ensemble of RNN language model, sentence vectors and NB SVM, achieved 92.57% (Mesnil et al., 2014) testing accuracy. Sentence vector system is one of sub-system used in ensemble and achieved 88.73% accuracy alone. Aicyber's system is the same system mentioned in Section 2, a VSM approach, it obtained 88.38%. To make a fair comparison same type of classifier, LDA is used to train and classify i-vector system, a 87.52% accuracy is reported. Concatenation of i-vector and vector from VSM a 89.94% accuracy can be achieved.

#### 4.3.2 Evaluation on SemEval 2016

Evaluation metric for SemEval 2016 task is Macro-F1 introduced in Equation 1. During evaluation period we validate the performance on development and develop-test dataset. Results as shown in Table 2 indicate i-vector system is worse than our baseline system. So we only submitted the baseline system.

### 4.4 Discussion

Judging from the IMDB evaluation, the idea of i-vector from speech domain is successfully applied for NLP task. Though it didn't beat the state-of-the-art, it is well-known that basic machine learning techniques can yield strong baselines (Wang and Manning, 2012) on this dataset.

Performance dropped in SemEval 2016 could due

| System                      | Aicyber's system | i-vector system |
|-----------------------------|------------------|-----------------|
| Development (Macro-F1)      | 0.4514           | 0.3732          |
| Development-test (Macro-F1) | 0.4787           | 0.3814          |

**Table 2:** Proposed i-vector based sentence vector evaluated on the SemEval 2016 dataset. Aicyber's system is VSM approach and trained on 3887 tweets. The i-vector extractor learned from IMDB dataset and apply on SemEval data. The results show that the i-vector system could not beat our submitted system.

to data mis-match, the word2vec and i-vector extractor is trained on the movie review texts which are much longer, more formal than tweets and are of different vocabulary.

Further improvement can be made in the following aspects.

1. The word-to-vector conversion is done via word2vec, using of Glove word vectors (Pennington et al., 2014), either alone or as concatenation of two type of word vectors for system training is worth to explored.
2. Parameters in word2vec, GMM and i-vector training is not yet optimized to the task. For example, word vector is set to 20 dimensions which is much smaller than 300 dimensional Google word vector. Finding the best parameters will bring more insight of semantical meaning of sentence vector.
3. In this paper, the implementation of i-vector framework is a GMM based approach. Incorporating deep neural network (Snyder et al., 2015) or a Convolutional Neural Network (Kalchbrenner et al., 2014) for NLP task is worth to investigated.

### 5 Conclusion

This paper had presented a vector space model approach for team aicyber and a new idea of estimating sentence vector. Proposed i-vector framework had evaluated on SemEval 2016 as well as IMDB dataset. Result shows that the i-vector based sentence vector is an alternative approach to present sentence.

## Abstract

In this paper, we propose a classifier for predicting message-level sentiments of English micro-blog messages from Twitter. Our method builds upon the convolutional sentence embedding approach proposed by (Severyn and Moschitti, 2015a; Severyn and Moschitti, 2015b). We leverage large amounts of data with distant supervision to train an ensemble of 2-layer convolutional neural networks whose predictions are combined using a random forest classifier. Our approach was evaluated on the datasets of the SemEval-2016 competition (Task 4) outperforming all other approaches for the *Message Polarity Classification* task.

## 1 Introduction

Sentiment analysis is a fundamental problem aiming to give a machine the ability to understand the emotions and opinions expressed in a written text. This is an extremely challenging task due to the complexity of human language, which makes use of rhetorical devices such as sarcasm or irony. Deep neural networks have shown great promises at capturing salient features for these complex tasks (Mikolov et al., 2013b; Severyn and Moschitti, 2015a). Particularly successful for sentiment classification were Convolutional Neural Networks (CNN) (Kim, 2014; Kalchbrenner et al., 2014; Severyn and Moschitti, 2015a; Severyn and Moschitti, 2015b; Johnson and Zhang, 2015), on which our work builds upon.

These networks typically have a large number of parameters and are especially effective when trained on large amounts of data. In this work, we use a distant supervision approach to leverage large amounts of data in order to train a 2-layer CNN<sup>1</sup>, extending the 1-layer architecture proposed by (Severyn and Moschitti, 2015a). More specifically, we train a neural network using the following three-phase procedure: *i*) creation of word embeddings for initialization of the first layer; *ii*) distant supervised phase, where the network weights and word embeddings are trained to capture aspects related to sentiment; and *iii*) supervised phase, where the network is trained on the provided supervised training data. We also combine the predictions of several neural networks using a random forest meta-classifier. The proposed approach was evaluated on the datasets of the SemEval-2016 competition, Task 4 (Nakov et al., 2016)<sup>2</sup> for which it reaches state-of-the-art results.

## 2 System Description

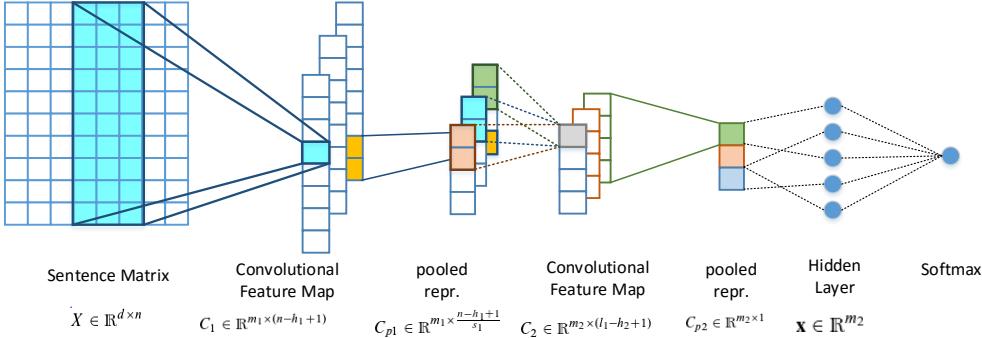

### 2.1 Convolutional Neural Networks

We combine the outputs of two 2-layer CNNs having similar architectures but differing in the choice of certain parameters (such as the number of convolutional filters). These two networks were also initialized using different word embeddings and used slightly different training data for the distant supervised phase. The common architecture of the two

<sup>1</sup>We here refer to a layer as one convolutional and one pooling layer.

<sup>2</sup><http://alt.qcri.org/semeval2016/>

\* These authors contributed equally to this work

**Figure 1:** The architecture of the CNNs used in our approach.

CNNs is shown in Figure 1 and described in details below.

**Sentence model.** Each word is associated to a vector representation, which consists in a  $d$ -dimensional vector. A sentence (or tweet) is represented by the concatenation of the representations of its  $n$  constituent words. This yields a matrix  $\mathbf{X} \in \mathbb{R}^{d \times n}$ , which is used as input to the convolutional neural network.

**Convolutional layer.** In this layer, a set of  $m$  filters is applied to a sliding window of length  $h$  over each sentence. Let  $\mathbf{X}_{[i:i+h]}$  denote the concatenation of word vectors  $\mathbf{x}_i$  to  $\mathbf{x}_{i+h}$ . A feature  $c_i$  is generated for a given filter  $\mathbf{F}$  by:

$$c_i := \sum_{k,j} (\mathbf{X}_{[i:i+h]})_{k,j} \cdot \mathbf{F}_{k,j} \quad (1)$$

A concatenation of all vectors in a sentence produces a feature vector  $\mathbf{c} \in \mathbb{R}^{n-h+1}$ . The vectors  $\mathbf{c}$  are then aggregated over all  $m$  filters into a feature map matrix  $\mathbf{C} \in \mathbb{R}^{m \times (n-h+1)}$ . The filters are learned during the training phase of the neural network using a procedure detailed in the next section.

**Max pooling.** The output of the convolutional layer is passed through a non-linear activation function, before entering a pooling layer. The latter aggregates vector elements by taking the maximum over a fixed set of non-overlapping intervals. The resulting pooled feature map matrix has the form:  $\mathbf{C}_{\text{pooled}} \in \mathbb{R}^{m \times \frac{n-h+1}{s}}$ , where  $s$  is the length of each interval. In the case of overlapping intervals with a stride value  $s_t$ , the pooled feature map matrix has the form  $\mathbf{C}_{\text{pooled}} \in \mathbb{R}^{m \times \frac{n-h+1-s}{s_t}}$ . Depending on

whether the borders are included or not, the result of the fraction is rounded up or down respectively.

**Hidden layer.** A fully connected hidden layer computes the transformation  $\alpha(\mathbf{W} * \mathbf{x} + \mathbf{b})$ , where  $\mathbf{W} \in \mathbb{R}^{m \times m}$  is the weight matrix,  $\mathbf{b} \in \mathbb{R}^m$  the bias, and  $\alpha$  the rectified linear (*relu*) activation function (Nair and Hinton, 2010). The output vector of this layer,  $\mathbf{x} \in \mathbb{R}^m$ , corresponds to the sentence embeddings for each tweet.

**Softmax.** Finally, the outputs of the final pooling layer  $\mathbf{x} \in \mathbb{R}^m$  are fully connected to a soft-max regression layer, which returns the class  $\hat{y} \in [1, K]$  with largest probability. i.e.,

$$\begin{aligned} \hat{y} &:= \arg \max_j P(y = j | \mathbf{x}, \mathbf{w}, \mathbf{a}) \\ &= \arg \max_j \frac{e^{\mathbf{x}^\top \mathbf{w}_j + a_j}}{\sum_{k=1}^K e^{\mathbf{x}^\top \mathbf{w}_k + a_j}}, \end{aligned} \quad (2)$$

where  $\mathbf{w}_j$  denotes the weights vector of class  $j$  and  $a_j$  the bias of class  $j$ .

**Network parameters.** Training the neural network consists in learning the set of parameters  $\Theta = \{\mathbf{X}, \mathbf{F}_1, \mathbf{b}_1, \mathbf{F}_2, \mathbf{b}_2, \mathbf{W}, \mathbf{a}\}$ , where  $\mathbf{X}$  is the sentence matrix, with each row containing the  $d$ -dimensional embedding vector for a specific word;  $\mathbf{F}_i, \mathbf{b}_i (i = \{1, 2\})$  the filter weights and biases of the first and second convolutional layers;  $\mathbf{W}$  the concatenation of the weights  $\mathbf{w}_j$  for every output class in the soft-max layer; and  $\mathbf{a}$  the bias of the soft-max layer.

## 2.2 Ensemble of classifiers

We combine the results of the two 2-layer CNN described in Section 2.1 with the intent of increasing the generalizability of the final classifier. This is

achieved relying on two systems trained using different procedures as well as different word embeddings. The network parameters of the two CNNs are summarized in Table 1. The preprocessing and training phases of the two systems are described below.

### 2.2.1 System I

#### Preprocessing and word embeddings.

The word embeddings are initialized using word2vec (Mikolov et al., 2013a) and then trained using an unlabelled corpus of 200M tweets. We apply a skipgram model of window size 5 and filter words that occur less than 5 times (Severyn and Moschitti, 2015b). The dimensionality of the vector representation is set to  $d = 52$ .

**Training.** During a first distant-supervised phase, we use emoticons to infer the polarity of a balanced set of 90M tweets (Read, 2005; Go et al., 2009). The resulting dataset contains 45M tweets for both the positive and negative class. The neural network is trained on these 90M tweets for one epoch, before training for 10 to 15 epochs on the labelled data provided by SemEval-2016. The word-embeddings  $\mathbf{X} \in \mathbb{R}^{d \times n}$ , are updated during both the distant and the supervised training phases, as back-propagation is applied through the entire network.

### 2.2.2 System II

**Preprocessing and word embeddings.** A corpus of 90M tweets<sup>3</sup> (30M contain positive emoticons, 30M negative ones and 30M contain none) is employed to create embedding vectors of  $d = 50$  dimensions using *GloVe* (Pennington et al., 2014). Words which appear less than 5 times are discarded. Additionally, special flags  $\in \{0, 1\}$  are assigned to some words, by appending a flag vector to their word embeddings. Four different flags can be set, marking (*i*) words that belong to hashtags, (*ii*) words that have been elongated (e.g. 'hellooo', which is mapped to the same vector as 'hello'), (*iii*) words in which all characters are capitalized, and (*iv*) punctuations that are repeated more than three times (e.g. '!!!!' and '!!!' being mapped to the same vector).

**Training.** In the distant supervised phase, the network is trained for one epoch on a set of 60M tweets,

---

<sup>3</sup>This set differs to the 90M set used in System I, but is drawn from the same larger corpus of tweets

containing an equal amount of samples with positive and negative emoticons. Similarly to System I, this pre-trained network is further refined by supervised training for about 15 epochs on the SemEval-2016 data. We apply  $L_2$  regularization to reduce overfitting to the cost function (negative log likelihood) by adding a penalty of the form of  $\lambda \|\theta\|_2^2$ , with regularization strength<sup>4</sup>  $\lambda$ , where  $\theta \in \Theta$  are the network parameters of each layer.

### 2.2.3 Optimization

The network parameters are learned using *AdaDelta* (Zeiler, 2012), which adapts the learning rate for each dimension using only first order information. We used the hyper-parameters  $\epsilon = 1e-6$  and  $\rho = 0.95$  as suggested by (Zeiler, 2012).

### 2.2.4 Meta-Classifier

Each aforementioned system outputs three real values  $\hat{y}$  corresponding to the three sentiment classes. In addition, it outputs the categorical value for the predicted sentiment class. The meta-classifier uses these values (sentiment class and categorical value of systems I and II) as input features. We trained a random forest using the Weka (Hall et al., 2009) library on the training data. We selected the number of trees (300), maximum depth of the forest (2) and the number of features used per random selection (18) as to obtain the best overall performance over the previous years' test sets.

## 2.3 Computing Resources

The core routines are written in Python, making heavy use of mathematical routines in Theano (Bergstra et al., 2010) that exploits GPU acceleration. For further performance improvement, we used the CuDNN library (Chetlur and Woolley, 2014). The framework requires approximately 10 hours for the distant supervised phase and only 20-30 minutes for the supervised phase.

Experiments were conducted on g2.2xlarge instances of *Amazon Web Services* (AWS), which offer a *GRID K520* GPU with 3072 CUDA cores and 8 GB of GDDR5 RAM.

---

<sup>4</sup> $\mathbf{X}: \lambda = 1^{-6}$ ,  $\mathbf{F}_1: \lambda = 1^{-5}$ ,  $\mathbf{F}_2: \lambda = 1^{-5}$ ,  $\mathbf{W}: \lambda = 1^{-7}$ .

|                                    | SYSTEM I                | SYSTEM II               |
|------------------------------------|-------------------------|-------------------------|
| Number of convolutional filters    | $m = 200$               | $m = 300$               |
| Filter window size $h$             | $h_1 = 6, h_2 = 3$      | $h_1 = 6, h_2 = 4$      |
| Size of first max-pooling interval | width = 6, striding = 2 | width = 3, striding = 3 |
| Activation function $\alpha$       | <i>relu</i>             | <i>relu</i>             |

**Table 1:** Summary of the parameters used in System I and II

### 3 Data

The training and development datasets used in our experiments were provided by the SemEval-2016 competition. A fraction of the tweets (10-15%) from the period 2013-2015 were no longer available on Twitter, which made the results of this year competition not directly comparable to the ones of previous years. For testing, in addition to last year’s data (tweets, SMS, LiveJournal), new tweets were accessible. An overview of the data available for download is given in Table 2.

**Table 2:** Overview of datasets and number of tweets (or sentences) provided in SemEval-2016. The data was divided into training, development and testing sets.

| Dataset                      | Total | Posit. | Negat. | Neutr. |
|------------------------------|-------|--------|--------|--------|
| <i>Train 2013 (Tweets)</i>   | 8224  | 3058   | 1210   | 3956   |
| <i>Dev 2013 (Tweets)</i>     | 1417  | 494    | 286    | 637    |
| <i>Train 2016 (Tweets)</i>   | 5355  | 2749   | 762    | 1844   |
| <i>Dev 2016 (Tweets)</i>     | 1269  | 568    | 214    | 487    |
| <i>DevTest 2016 (Tweets)</i> | 1779  | 883    | 276    | 620    |
| Test: <i>Twitter2016</i>     | 20632 | 7059   | 3231   | 10342  |
| Test: <i>Twitter2015</i>     | 2390  | 1038   | 365    | 987    |
| Test: <i>Twitter2014</i>     | 1853  | 982    | 202    | 669    |
| Test: <i>Twitter2013</i>     | 3813  | 1572   | 601    | 1640   |
| Test: <i>SMS2013</i>         | 2093  | 492    | 394    | 1207   |
| Test: <i>LiveJournal2014</i> | 1142  | 427    | 304    | 411    |
| Test: <i>Tw2014Sarcasm</i>   | 86    | 33     | 40     | 13     |

**Data preparation.** Before extracting features, the tweets were preprocessed using the following procedure:

- URLs and usernames were substituted by a replacement token
- The text was lowercased
- The NLTK twitter tokenizer was employed in System I and a customized version of the *CMU ARK Twitter Part-of-Speech Tagger* (Gimpel et al., 2011) in System II.

### 4 Results

The F-1 score was computed by the competition organizers as evaluation measure. As a result, the presented system was ranked 1<sup>st</sup> out of 34 participants, with an F1-score of 63.30 on the Twitter-2016 test set. See (Nakov et al., 2016) for further details.

Table 4 summarizes the results of individual subsystems, as well as the final system on each test set. For each test set the best score is marked in bold face. In case of the *Twitter2016* and *Twitter2015* test sets we marked the best performing subsystem in italics. For System I (S1), we observed that during the supervised phase, the F-1 scores measured on the different test sets presented large deviations. Hence, to improve robustness, we considered six different models of S1 (S1a, ..., S1f), varying the number of epochs between 12 and 25 during the supervised phase, stopping determined by the validation score on different sets. For System II (S2), the number of epochs, equal to 12, is determined by the one achieving the highest score on the *DevTest2016* set.

The final system (FS) using the meta-classifier trained on the outputs of systems S1a-f and S2, achieves the highest accuracy on the 2016 test set with the competition-winning F1-score of 63.30%. These results improve the score of the best performing subsystem (S1b) by 0.57 points. For the 2015 test set, FS shows an improvement of 0.35 points with respect to the score of the best subsystem (S1f).

|                        | S1a          | S1b          | S1c          | S1d          | S1e          | S1f          | S2           | FS           |
|------------------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|
| <i>Twitter2016</i>     | 60.47        | <b>62.73</b> | 61.89        | 60.58        | 57.19        | 62.20        | 62.36        | <b>63.30</b> |
| <i>Twitter2015</i>     | 64.26        | 65.80        | 64.80        | 64.20        | 61.02        | <b>66.70</b> | 66.63        | <b>67.05</b> |
| <i>Twitter2014</i>     | 73.98        | <b>74.60</b> | <b>75.70</b> | 74.15        | 69.12        | 72.00        | 72.45        | 71.55        |
| <i>Twitter2013</i>     | <b>71.52</b> | 70.10        | 70.90        | <b>71.50</b> | 67.00        | 68.00        | 70.05        | 70.01        |
| <i>LiveJournal2014</i> | <b>73.86</b> | 70.57        | 72.54        | <b>74.00</b> | 71.32        | 68.00        | 70.86        | 69.51        |
| <i>Tw2014Sarcasm</i>   | 57.84        | 52.04        | 51.50        | 57.84        | <b>62.00</b> | 57.30        | <b>62.74</b> | 56.63        |

**Table 3:** Overall results of the proposed subsystems. S1: System(s) I; S2: System II; FS: Final system, using the meta-classifier. Best (second-best) results are highlighted in bold (underlined) face.

## 5 Conclusion

We described a deep learning framework to predict the sentiment polarity of short phrases, such as tweets. The proposed approach is based on an ensemble of Convolution Neural Networks and relies on a significantly large amount of data for the distant-supervised phase. The final random forest classifier resulted in state-of-the-art performance, ranking 1<sup>st</sup> in the SemEval-2016 competition for the task of Message Polarity Classification.

## Abstract

This paper describes a classification system that participated in SemEval-2016 Task 4: Sentiment Analysis in Twitter. The proposed approach competed in subtasks A, B, and C, which involved tweet polarity classification, tweet classification according to a two-point scale, and tweet classification according to a five-point scale. Our system is based on an ensemble consisting of Random Forests, SVMs, and Gradient Boosting Trees, and involves the use of a wide range of features including: n-grams, Brown clustering, sentiment lexicons, Wordnet, and part-of-speech tagging. The proposed system achieved 14<sup>th</sup>, 6<sup>th</sup>, and 3<sup>rd</sup> place in subtasks A, B, and C, respectively.

## 1 Introduction

In recent years, sentiment analysis (Liu, 2012) has become a common yardstick for many new text mining algorithms. This trend is a direct result of the rapid growth of social media, where users express their views and opinions regarding a wide range of topics. As a result, social networks like Twitter have become a crucial resource in product design, assessing marketing campaigns, and detecting news bursts (Liu, 2012; Mathioudakis and Koudas, 2010).

However, while the merits of resources such as Twitter are evident, there are several difficulties with the use of social media data. In contrast to classical sentiment analysis methods, which were originally designed for dealing with well-written product reviews, texts from social media often contain misspellings, letter substitutions, ambiguities, non-standard abbreviations, and improper use of gram-

mar (Sarker et al., 2015). Furthermore, resources such as Twitter generate thousands of new texts per second and introduce challenges characteristic for stream processing (Krempl et al., 2014). Moreover, the limited length of these texts makes classical n-gram feature vectors extremely sparse, which in turn hinders generalization abilities of classification algorithms. Finally, sentiments are usually unevenly distributed (Kiritchenko et al., 2014), resulting in class imbalance and, therefore, additional difficulties for classifiers (He and Garcia, 2009).

To promote research in this area, Task 4 of SemEval-2016 was devoted to sentiment analysis in Twitter. The task consisted of five subtasks involving standard classification, ordinal classification, and distribution estimation; for a more detailed description see (Nakov et al., 2016).

In this paper, we present our approach to learn a classification system which participated in subtasks A, B, and C of SemEval-2016 Sentiment Analysis in Twitter. The proposed approach combines Random Forests, Support Vector Machines, and Gradient Boosting Trees, trained on a wide range of lexical and semantic features including: n-grams, k-grams, Brown clustering, sentiment lexicons, SentiWordNet, and part of speech tagged 1-grams. These components were carefully combined and optimized to create a separate version of the system for each of the tackled subtasks.

In the following sections, we describe each group of features used in our system. Moreover, we explain the details of the proposed classification algorithm with respect to each realized subtask. Finally, we conclude the paper with a discussion on the ob-

tained results, importance of each feature group, and possible lines of future research.

## 2 Basic Features

We briefly describe the features used in our system. The same set of developed features was used in all three subtasks our algorithms participated in. However, for some of the component classifiers we additionally performed feature selection using a filter method based on the F-statistic. Details on this subject will be discussed later.

### 2.1 Preprocessing

Prior to extracting features, we performed standard natural language processing procedures to clean the data. First, each tweet was tokenized into words, hashtags, punctuation marks, and special symbols. Next, tokens were lemmatized by NLTK WordNetLemmatizer<sup>1</sup> to unify different versions of the same words. Subsequently, certain words were removed based on a hand-crafted stop list. Finally, certain symbols (urls, hashtags, numbers, percentages, prices, dates, hours) that occurred less than five times in the dataset were grouped according to their meaning, and those tokens that could not be grouped were removed from the training data.

### 2.2 Word n-grams

The first feature set consisted of word n-grams, i.e., sequences of  $n$  continuous words in a text segment. For our system, we generated 1-, 2-, 3-, 4-, and 5-grams based on all available tweet messages.

### 2.3 Negation n-grams

In addition to traditional n-grams, we also utilized n-grams in negation context (Remus, 2013). Negation n-grams are sequences of words that appear in a negated context. Negations were discovered based on “not” and “n’t” tokens, and a negated context was defined as a set of words falling between a negation and a “terminal” punctuation symbol {., ;, !, ?}. We used 1- and 2-negation-grams in our system.

### 2.4 Character k-grams

Another group of features was created by generating character k-grams. Character k-grams were cre-

ated by extracting sequences of  $k$  continuous characters from each word. To distinguish character-grams from word-grams, we will refer to character sequences as *k-grams*. We used 3-, 4-, and 5-character-grams as features.

### 2.5 POS 1-grams

Another set of n-grams was created by using a part-of-speech tagger. This approach combines words with the part of speech they represent, in an attempt to distinguish different meanings of the same word. In our system, we used the NLTK PerceptronTagger<sup>2</sup> to add concatenated {word, part-of-speech} pairs as features.

### 2.6 Sentiment Lexicons

A major group of features used in our system was formed by sentiment scores, which were created by summing word-sentiment associations for a given tweet. More precisely, for each tweet we counted the number of words conveying each sentiment defined in a given lexicon. We used this procedure for four sentiment lexicons: the NRC emotion lexicon (Mohammad and Turney, 2013), Hu and Liu Opinion lexicon (Hu and Liu, 2004), the Multi-perspective Question Answering corpus (Wiebe et al., 2005), and SentiWordNet (Baccianella et al., 2010).

The NRC emotion lexicon is a list of words and their associations with eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive). Combined this gives a total of ten real valued sentiment scores, which were added to our feature set.

The Opinion Lexicon, assembled by Hu and Liu, consists of two lists: one containing positive and one containing negative words. Because intensities of these two sentiments are not specified, we counted the occurrences of lexicon words in each tweet to create two sentiment scores.

The Multi-perspective Question Answering (MPQA) corpus contains four sentiment word lists: positive, negative, both, and neutral. As with the Opinion Lexicon, we counted the occurrences of each in-lexicon word to create four additional features.

Finally, the SentiWordNet is a sentiment tagged

<sup>1</sup><http://www.nltk.org/api/nltk.stem.html>

<sup>2</sup><http://www.nltk.org/api/nltk.tag.html>

wordnet. We used this network to find synsets (semantical equivalents) of words and used their sentiment scores as features.

## 2.7 Hashtag Lexicon

An interesting addition to the aforementioned word lexicons was the use of the NRC Hashtag Affirmative/Negated Context Sentiment Lexicon (Kiritchenko et al., 2014). This lexicon contains a real-valued sentiment score associated with single words and 2-grams designed specifically for Twitter. For each tweet we calculated the minimal, maximal, and mean sentiment score based on all words in a tweet.

## 2.8 Brown Clustering

Our final set of features was created using Brown clustering (Brown et al., 1992). Brown clustering is a form of hierarchical clustering of words based on the contexts in which they occur. We used a precompiled clustering of English tweets into 1000 clusters provided by Owoputi et al. (2013).

# 3 Classification

## 3.1 Multi-class classification (subtask A)

The goal of subtask A was to correctly classify tweets into three classes: positive, neutral, and negative. Macro-averaged  $F_1$  score over the positive and negative class was used as an evaluation metric. The provided training set consisted of 5459 tweets<sup>3</sup> and the test set, which was used for internal model verification and validation, consisted of 1806 tweets.

Gradient Boosting Trees (Friedman, 2001) is a popular classifier which combines the idea of a boosting ensemble and gradient descent optimization. We have chosen it, because it proved to work well in many data mining competitions and on a variety of problems. GBT are also robust to very sparse features, which makes them a good choice for tweet classification.

In our system we used GBT with softmax as the loss function, the maximum depth of a single tree was set to 40 and no tree pruning was performed afterwards. To prevent overfitting the L2 regularization factor was added to the optimization func-

---

<sup>3</sup>The dataset provided by task organizers was a little bit bigger, but we report the number of tweets which we were able to download successfully.

tion. Additionally, to increase the diversity of the model, each ensemble component was trained on a subset of features. Each subset was constructed using randomly chosen 40% of the features. Furthermore, each tree component was trained on a random sample of the training set which contained 80% of the examples.

From the training set 10% of examples were extracted to form a validation set. This additional dataset was used for verification of the early stopping condition. After learning every new tree, the performance of the whole classifier was verified on the validation set in terms of macro-averaged  $F_1$  score. The lack of improvement during 30 iterations triggered the early stopping condition and terminated the ensemble construction. GBT was always fitted until the early stopping condition was met, without any constraint on the maximal number of ensemble components<sup>4</sup>.

During initial experiments we discovered, that the classifier made wrong predictions on negative and neutral examples more often than on instances belonging to the positive class. The trained model suffered from class imbalance, which often leads to generalization problems of many classification techniques (He and Garcia, 2009). Indeed, the dataset in this subtask contains 2804 positive examples (51%) together with only 781 negative (14%) and 1874 neutral (34%) examples.

To overcome this problem, inspired by solutions in the field of cost-sensitive learning (He and Garcia, 2009), we assigned each instance a weight  $w = 1/(c \cdot |C_i|)$  where  $|C_i|$  is the number of examples belonging to the true class of the  $i$ -th example in the training set and  $c$  is the total number of classes (in this subtask  $c = 3$ ). The use of such instance weights in the loss function ensures that each class is equally important for optimization, because the sums of example weights for each class are equal.

We also tested Random Forests (Breiman, 2001) and linear Support Vector Machines (Cortes and Vapnik, 1995) classifiers. As preliminary experiments showed that the performance of Random Forests and SVM was sensitive to the increasing number of features, we decided to carry out addi-

---

<sup>4</sup>In practice we always set the maximum number of iterations to a big number (10000).

tional feature selection. Hence, we trained them on 5000 best features selected by the F value of ANOVA which improved micro-averaged  $F_1$  and also had a positive influence on training time. The best results for Random Forest, according to macro-averaged  $F_1$ , were achieved when each leaf of a single tree was enforced to contain at least three examples, the number of trees was equal to 5000 and instance weighting (as described above) was used. Also SVM gave best results with instance weighting. Despite the fact that both Random Forests and SVMs achieved results that were a little worse than GBT (macro-averaged  $F_1$  score was about 3% lower for both of them) we decided to use them to refine predictions of GBT.

Finally, our classification system is a heterogeneous multiple-classifier consisting of three different components: Random Forests, Gradient Boosting Trees, and Support Vector Machines. Each of them is trained on the same training set and the final classification of the ensemble is a result of simple majority voting. We use a well-known scikit-learn (Pedregosa et al., 2011) implementation of Random Forests, and SVMs in Python as well as a very effective Gradient Boosting Trees implementation from the XGBoost library<sup>5</sup>.

### 3.2 Binary classification (subtask B)

The goal of subtask B also involved the classification of tweets, however, only two classes (positive and negative) were considered. Just as in subtask A, the dataset was highly imbalanced: only 17% (679) of examples were negative.

In subtask A we could not use more advanced methods for tackling class imbalance since most of them are designed for binary classification only. One of such techniques is Roughly Balanced Bagging (Hido et al., 2009), which proved to give the best results among extensions of bagging for class imbalance (Błaszczyński and Stefanowski, 2015).

RBBag learns each base classifier on a random sample of the training set and then the final class prediction is a result of averaging predictions of components. The main difference between classical bagging and RBBag is its specialized sampling scheme. First, the training set is divided into two

subsets, each containing examples from only one class. From the subset containing minority examples, RBBag creates a classical bootstrap sample which contains  $N$  instances, where  $N$  is the number of minority examples in the training set. To this sample,  $M$  majority examples are added randomly where  $M$  is not the number of majority examples, but it is taken from a negative binomial distribution with parameters  $p = 0.5$  and  $n = N$ .

We used Roughly Balanced Bagging with GBT as the base classifier. All parameters of GBT were set just like described in section 3.1, however during experiments different learning rates and regularization factors were selected. Additionally, RBBag was tested with 5, 7, 15 and 30 base classifiers, but the best results were obtained for 7 GBTs, which confirms earlier observations of Lango and Stefanowski (2015) that RBBag does not require many components to achieve good performance.

### 3.3 Ordinal classification (subtask C)

Subtask C concentrated on classifying tweets into 5 classes: very negative, negative, neutral, positive and very positive. Since the order in the classes is established, this subtask can be considered as an ordinal classification problem.

We implemented an ensemble algorithm described by Frank and Hall (2001), which decomposes ordinal classification into several binary classification problems. Each classifier is trained on the same training set, but the class label of every example is changed by the function  $I(x_{class} > i)$  where  $I()$  is an indicator function,  $x_{class}$  is a class of a given example and  $i$  is the reference class. The reference class for the first classifier is “very negative”, for the second “negative” etc. Finally, we have four classifiers and each of them returns the likelihood of a positive response to the question “is the class of the analyzed example higher than the reference class”. The final set of likelihoods can be easily transformed to the likelihood of every class.

Again, we used GBT as a base classifier with the same setup as described in section 3.1. However, we also tested linear SVM, Random Forests, Factorization Machines (Rendle, 2010) and transductive SVMs (Joachims, 1999). Linear SVM achieved results very similar to GBT in terms of macro-averaged mean absolute error ( $MAE^M$ ). Despite

---

<sup>5</sup><https://github.com/dmlc/xgboost>

this fact, during the analysis of responses of both classifiers on the test set, for several examples we discovered significant differences in responses (e.g. “very negative” vs “positive”). Since both models performed almost equally good and  $MAE^M$  highly punishes significant differences between classes on the ordinal scale, we decided to create a meta-classifier from these two models. In our ensemble the final prediction is an average of predictions of GBT and SVM-based models, which is rounded towards the decision of the GBT-based model (since its  $MAE^M$  score was a little higher).

## 4 Results and feature analysis

This section includes the experimental results of our system for all three sub-tasks. We present the scores and ranks achieved by our system followed by a discussion on the relative importance of the proposed features.

The evaluation metric was different in each sub-task (Nakov et al., 2016). For subtask A, it was required to optimize the macro-averaged  $F_1$ -score ( $F_1^M$ ) calculated over the positive and negative classes. In subtask B, the goal was to achieve a high macro-averaged recall ( $R^M$ ), while subtask C took into account a macro-averaged mean absolute error ( $MAE^M$ ). Table 4 presents the overall performance of our system.

| Subtask | Metric  | Our score | Best score | Rank |
|---------|---------|-----------|------------|------|
| A       | $F_1^M$ | 0.576     | 0.633      | 14   |
| B       | $R^M$   | 0.763     | 0.797      | 6    |
| C       | $MAE^M$ | 0.860     | 0.719      | 3    |

**Table 1:** Overall performance of the system.

We also performed an analysis of feature importance using one trained Gradient Boosting Trees classifier (GBT). For this classifier the feature importance can be easily measured by observing the increase of purity while performing splits on a particular feature, following an approach from (Breiman and Friedman, 1984).

In subtasks A and C we used a meta-classifier of many different algorithms, so the results would not accurately reflect the feature importance in the whole system. Hence, we decided to run this experiment on the dataset from subtask B only.

Table 2 presents 15 features with the highest rel-

ative importance in our classifier. The most important feature was the mean of word sentiments in a tweet according to the NRC Hashtag Lexicon (the maximum word sentiment on this lexicon is also pretty high in the ranking). Other lexicon features, based on the Opinion Lexicon and SentiWordNet, also achieved high relative importance. Note that many features with high importance come from Brown clustering and k-grams.

In Table 3, we present results of feature importance aggregated in groups. The most important features are those created from character k-grams and their total relative importance is almost 70%. The contribution of features created from Brown clustering, negated n-grams and from n-grams with part-of-speech tags is also very significant. The importance of the rest of the features sums up to only 10%. The poor results of lexicon-based features can be justified by the fact that the number of features in these groups is very small (from 2 to 8 features).

| Feature name                   | Rel. impor. [%] |
|--------------------------------|-----------------|
| NRC Hashtag Lexicon: mean      | 0.79            |
| Brown cluster: 01110110        | 0.73            |
| SentiWordNet: sum of negative  | 0.63            |
| 5 k-gram: “d &am”              | 0.55            |
| Brown cluster: 1110011001111   | 0.49            |
| NRC Hashtag Lexicon: max       | 0.48            |
| Opinion Lexicon: negative      | 0.47            |
| Brown cluster: 111101011101    | 0.42            |
| 3 k-gram “ok ”                 | 0.41            |
| 4 k-gram “ nor”                | 0.40            |
| Brown cluster: 0100100         | 0.38            |
| 3 k-gram “ NY”                 | 0.35            |
| 2 n-gram: not against          | 0.35            |
| Brown cluster: 111101111100100 | 0.34            |
| 5 k-gram “ Anth”               | 0.34            |

**Table 2:** Relative feature importances (%) of top 15 features.

For Random Forests and SVM we used feature selection according to the F-statistics. We analyzed how features selected by this approach relate to importances estimated by GBT.

Surprisingly, feature importances estimated by the F-statistic and GBT are quite coherent. Almost 80% of features selected by the F-statistic were character-grams, 12% of features were negated n-grams, and features from POS constituted 3,9% of all selected features. The main difference between these two methods is that the F-statistic selected

| Feature group       | Rel. impor. [%] |
|---------------------|-----------------|
| 5 character-gram    | 26.03           |
| 4 character-gram    | 21.75           |
| 3 character-gram    | 21.74           |
| Brown clusters      | 6.92            |
| Negated 1-gram      | 6.62            |
| 1-gram + POS        | 4.24            |
| Negated + 2-gram    | 3.48            |
| 1-gram              | 2.69            |
| 2-gram              | 1.87            |
| NRC Hashtag Lexicon | 1.49            |
| SentiWordNet        | 1.00            |
| NRC Lexicon         | 0.93            |
| Opinion Lexicon     | 0.62            |
| 3-gram              | 0.34            |
| MPQA corpus         | 0.25            |
| 4-gram              | 0.03            |

**Table 3:** Relative feature importances (%) for features groups.

only one feature from Brown clustering. However, once again simple n-grams were used very rarely (2% of all selected features). This result, together with earlier observations from importances estimated by GBT, seem to show that features created from character-grams are superior to those created by word-grams. It is also worth mentioning that the entire GBT model used only 3579 features, which is an indicator of its feature selection abilities.

## 5 Conclusions and Future Work

Our system achieved relatively good performance in SemEval-2016 Task 4: Sentiment Analysis in Twitter. Among 34 participants of subtask A we reached rank 14, we took 6<sup>th</sup> place among 19 competitors in subtask B, and won 3<sup>rd</sup> place in subtask C where 11 teams competed. The analysis of features used by our system shows that character-grams seem to perform better than word n-grams for Twitter’s short-text messages. Furthermore, results obtained by Gradient Boosting Trees in our system confirmed good feature filtering capabilities of this algorithm.

One possible way to further improve our system could be to transfer features selected by GBT to other classifiers (e.g. SVM). Another possible line of the future research is the development of new features based on character-grams, such as negated character-grams or character-gram lexicons.

## Abstract

This work presents our team solution for task 4a (Message Polarity Classification) at the SemEval 2016 challenge. Our experiments have been carried out over the Twitter dataset provided by the challenge. We follow a supervised approach, exploiting a SVM polynomial kernel classifier trained with the challenge data. The classifier takes as input advanced NLP features. This paper details the features and discusses the achieved results.

## 1 Introduction

Revealing the sentiment behind a text is motivated by several reasons, e.g., to figure out how many opinions on a certain topic are positive or negative. Also, it could be interesting to span positivity and negativity across a n-point scale. As an example, a five-point scale is now widespread in digital scenarios where human ratings are involved: Amazon, TripAdvisor, Yelp, and many others, adopt the scale for letting their users rating products and services.

Under the big hat of sentiment analysis (Liu, 2012), polarity recognition attempts to classify texts into positive or negative, while the rating inference task tries to identify different shades of positivity and negativity, e.g., from strongly-negative, to strongly-positive. There currently exists a number of popular challenges on the matter, as those included in the SemEval series on evaluations of computational semantic analysis systems<sup>1</sup>. Both polarity recognition and rating inference have been applied

to recommendation systems. Recently, Academia has been focusing on the feasibility to apply sentiment analysis tasks to very short and informal texts, such as tweets (see, e.g. (Rosenthal et al., 2015)).

This paper shows the description of the system that we have set up for participating into the Semeval 2016 challenge in (Nakov et al., 2016b), task 4a (Message Polarity Classification). We have adopted a supervised approach, a SVM polynomial kernel classifier trained with the data provided by the challenge, after extracting lexical and lexicon features from such data.

The paper is organised as follows. Next section briefly addresses related work in the area. Section 3 describes the features extracted from the training data. In Section 4, we present the results of our attempt to answer to the challenge. Finally, we give concluding remarks.

## 2 Related work

In the last recent years, the SemEval tasks series challenges the polarity evaluation of tweets. This represents a detachment from the traditional polarity detection task. Tweets usually features the use of an informal language, with misspellings, new words, urls, abbreviations and specific symbols (like RT for “re-tweet” and # for hashtags, which are a type of tagging for Twitter messages). Existing approaches and open issues on how to handle such new challenges are in related work like (Kouloumpis et al., 2011; Barbosa and Feng, 2010).

At the 2015 challenge (Rosenthal et al., 2015), the top scored systems were those using deep learning, i.e., semantic vector spaces for single words, used

<sup>1</sup><https://en.wikipedia.org/wiki/SemEval>

as features in (Turney and Pantel, 2010). Other approaches, as (Basile and Novielli, 2015), exploited lexical and sentiment lexicon features to classify the sentiment of the tweet through machine learning.

In (Priyanka and Gupta, 2013), the authors also exploited different lexical and lexicon features for evaluating the sentiment of a review corpus. The current work inherits most of such features. While they used the lexicon SentiWordNet (Esuli and Sebastiani, 2006), we rely instead on two different ones, LabMT in (Dodds et al., 2011) and SenticNet3.0 presented in (Cambria et al., 2014).

All the above cited lexicons (Cambria et al., 2014; Esuli and Sebastiani, 2006; Dodds et al., 2011) are popular and extensively adopted lexicons for sentiment analysis tasks.

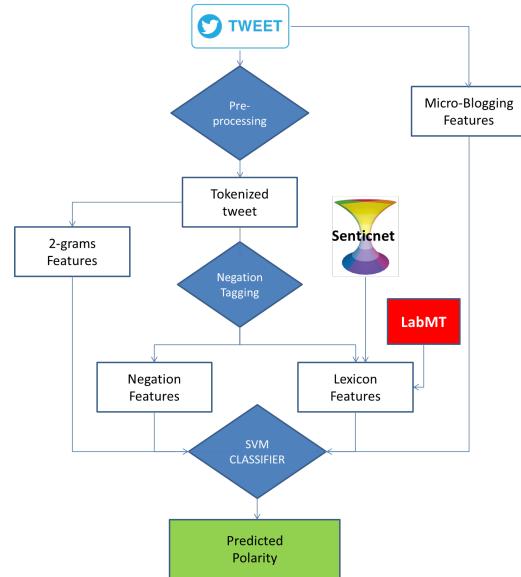

### 3 Sentiment analysis

The SemEval 2016 Sentiment Analysis challenge (Nakov et al., 2016b) requires the labelling of a test set of 28,481 tweets. In order to facilitate the application of supervised machine learning approaches, the challenge organisers provide the access to a gold dataset: a set of labeled tweets, where the labels - positive, negative or neutral - were manually assigned. In detail, the labeled dataset is divided in a training set of 4,000 tweets and a development set of 2,000 tweets. 340 tweets in the training data and 169 ones in the development data could have not be accessed, since such tweets were "Not Available" at crawling time. We rely on the provided labeled dataset (train + devel) in order to respectively train and evaluate a Support Vector Machine (SVM) classifier (Chang and Lin, 2011) to learn a model for automatic Sentiment Analysis on Twitter. We investigate four groups of features based on: keyword and micro-blogging characteristics, n-grams, negation, and sentiment lexicon.

After evaluating the feature set, we built a new classifier model for annotating the unlabeled test set provided by the challenge (prediction phase, see Figure 1). In this phase, we used as features the best combination of the features previously extracted (actually, all of them) and as the training corpus the overall labeled tweet data (devel+test). The results were not satisfactory, being our team ranked 30 (over 34 teams). The challenge results are reported

and discussed in (Nakov et al., 2016b).

In the following, we will detail the process of test cleaning and feature extractions. Then, we present our evaluation, which has been designed to test the efficacy of our feature set for sentiment analysis. Finally, we provide the results obtained at the challenge.

**Figure 1:** Sentiment analysis: Prediction phase

In the following, we will use the following tweet as a running example.

Happy hour at @Microsoft #msapc2015 with @sarah-vaughan and friends. Good luck for tomorrow's keynote  
<http://t.co/emvqoeRS6j>

#### 3.1 Micro-blogging features

The microblogging features have been extracted from the tweet original text, without pre-processing it. We have defined such features with the aim of capturing some typical aspects of micro-blogging. These have been extracted by simply matching regular expressions. First of all, we have cleaned the text from the symbols of mentions "@" and hashtags "#", from urls, from emoticons. Indeed, their presence makes challenging to analyze the text with a traditional linguistic pipeline. Before deleting symbols, emoticons and urls, we have counted them, having as features:

- the number of hashtags;
- the number of mentions;

- the number of urls;
- EmoPos, i.e., the number of positive emoticons;
- EmoNeg, i.e., the number of negative emoticons;

Also, we have also focused on vowels repetitions, exclamations and question marks, introducing the following features:

- the number of vowels repetitions;
- the number of question marks and exclamation marks repetitions.

Concerning the marks, we consider a repetition when they are repeated more than once, as in “!!”. Instead, we have considered a vowel as repeated when it occurs more than twice, as in “baaad”. The positive and negative emoticons we considered are those on the Wikipedia’s page<sup>2</sup>.

### 3.2 Text pre-processing

In order to extract syntactic and semantic features from the text, we pre-processed it with the *Tanl pipeline* (Attardi et al., 2010), a suite of modules for text analytics and natural language processing, based on machine learning. Pre-processing has consisted in first dividing the text in sentences and then into the single word forms composing the sentence. Then, for each form, we have identified the lemma (when available) and the part of speech (POS). As an example, starting from the sentence *Happy hour at Microsoft msapc2015 with sarahvaughan and friends* in the above sample tweet, we obtain the annotation shown in Figure 2. The last column gives the part of speech that a word form yields in a sentence, according to the *Penn Treebank Project*<sup>3</sup>.

The last phase of pre-processing is data cleaning. For each sentence, we removed conjunctions, number, determiners, pronouns, and punctuation (still relying on the Penn Treebank POS tags). For the remaining terms, we keep the lemma. Thus, the example sentence results in the following list of lemmas:

| Form         | Lemma        | POS |
|--------------|--------------|-----|
| Happy        | happy        | JJ  |
| hour         | hour         | NN  |
| at           | at           | IN  |
| Microsoft    | Microsoft    | NNP |
| msapc2015    | msapc2015    | ,   |
| with         | with         | IN  |
| sarahvaughan | sarahvaughan | NN  |
| and          | and          | CC  |
| friends      | friend       | NNS |

**Figure 2:** Annotation with Tanl English Pipeline (<http://tanl.di.unipi.it/en/>)

(*happy, hour, microsoft, msapc2015, sarahvaughan, friend*).

In the following, we describe the features we have extracted from the pre-processed text. Among others, we inherit some of the features in (Priyanka and Gupta, 2013) and (Basile and Novielli, 2015), which face with sentiment analysis on Twitter.

### 3.3 n-grams features

Upon pre-processing, we have obtained a words vector representation of each tweet. Then, we have extracted n-grams, i.e., all the pairs of sequencing lemmas in the vector. As an over simplification, we have considered only the case of n=2. We thought this was reasonable, since tweets are short portions of text bounded to 140 characters. In the example sentence, some are (*happy-hour, hour-microsoft*). The 2-grams have been discretised into binary attributes representing their presence or not in the text. There are 1,237 unique 2-grams.

### 3.4 Negation-based features

Handling negations is an important step in sentiment analysis, as they can reverse the meaning of a sentence. Also, negations can often occur with sarcastic and ironic goals, which are quite difficult to detect. We consider 1-grams and we prefix them with P (N) when they are asserted (negated). To identify if the unigram appears in a negated scope, we have applied a rule-based approach<sup>4</sup>. The approach works as follows. Considering a negative sentiment tweet, like, e.g., “*It might be not nice but it’s the reality*”, the “nice” unigram is in the scope of negation, and, thus, it will be labeled as N\_nice. The “but” unigram changes again the scope, thus “reality” will be

<sup>2</sup><https://it.wikipedia.org/wiki/Emoticon>

<sup>4</sup><http://sentiment.christopherpotts.net/lingstruc.html#negation>

labeled as P\_reality.

We have identified the following features as suitable for handling negations:

- Unigrams with scope;
- Positiveterms: Number of lemmas with positive scope;
- Negativeterms: Number of lemmas with negative scope;

The first feature has been discretised into binary attributes representing the presence (or not) of the 1-gram. The number of unique unigrams (with scope) are 5,110.

### 3.5 Sentiment lexicon-based features

Several lexicons are available for sentiment analysis. In this work, we consider SenticNet 3.0 (Cambria et al., 2014) and the LabMT (Dodds et al., 2011).

SenticNet 3.0 is a large concept-level base of knowledge, assigning semantics, sentics, and polarity to 30,000 natural language concepts. In particular, polarity is a floating number between -1 (extreme negativity) and +1 (extreme positivity)<sup>5</sup>. We rely on SenticNet 3.0 to compute features based on polarity, according to the SenticNet lexicon:

- Min, max, average and standard deviation polarity of lemmas;
- PA Positive Asserted: number of lemmas with a positive polarity, e.g., "good";
- PN Positive Negated: number of lemmas with a positive polarity, but negated, e.g., "not good";
- NA Negative Asserted: n. lemmas with a negative polarity (e.g., "bad");
- NN Negative Negated: n. lemmas and with a negative polarity, and negated (e.g., "not bad").

To assign the polarity to "not good", we consider the polarity of "good" in the SenticNet lexicon (0.667) and we revert it, assigning -0.667.

Also, SenticNet provides the polarity score to complex expressions. As an example, the popular idiomatic expression "32 teeth" obtains a polarity score of 0.903. Thus, beside unigrams polarity

| Class       | Precision | Recall | F1   |
|-------------|-----------|--------|------|
| negative    | 0.16      | 0.17   | 0.16 |
| neutral     | 0.46      | 0.27   | 0.34 |
| positive    | 0.50      | 0.75   | 0.60 |
| avg / total | 0.42      | 0.43   | 0.51 |

Table 2: MIB results (Tweets 2016 - dev, all feats)

scores, we have also considered 2-grams polarity scores.

Since not all the lemmas in the dataset were covered by the SenticNet lexicon, we have enlarged the covering by relying on LabMT (Dodds et al., 2011). LabMT is a list of words, manually labeled with a sentiment score through crowdsourcing. In particular, we considered the happiness score. This value ranges over 1 and 9 (1 is very unhappy, while 9 absolutely happy). We have normalised such values to range over -1 and 1, using the linear function  $y=(x-5)/4$ .

## 4 Evaluation and results

We have preliminarily built a prediction model trained with the 2016 challenge data, in details we have used the train and the devel data, respectively for training and evaluation. The prediction model is based on an SVM linear kernel classifier. For the experiments, the classifier has been implemented through sklearn<sup>6</sup> in Python. We have used a linear classifier suitable for handling unbalanced data: SGDClassifier with default parameters<sup>7</sup>. The model exploits the four groups of features presented in Section 3. Upon extracting the features from the training dataset, we obtained 6,547 features. In the following, we will show some feature ablation experiments, each of them corresponds to remove one category of features from the full set. Results are in terms of Precision and Recall, see Table 1.

The features evaluation shows that we do not have a set of dominant features group, leading to a not satisfying discrimination among positive, negative, and neutral tweets. Ablation tests show that negation-based features are the most relevant ones. Polarity lexicon features are influential to identify the nega-

**Table 1:** Ablation tests

tive class, but, overall, less than we have expected.

In (Cozza et al., 2016), the authors have proposed a similar approach to the one here presented. The aim was to evaluate the sentiment of a large set of online reviews. In online reviews, the textual opinion is usually accompanied by a numerical score, and sentiment analysis could be a valid alley for identifying misalignment between the score and the satisfaction expressed in the text. Work in (Cozza et al., 2016) shows that the features’ set was discriminant for evaluating the sentiment of the reviews. In part, this would support the thesis that standard sentiment analysis approaches are more suitable for “literary” texts than for short, informal texts featured by tweets.

It is worth noting that the lexicons we rely on are based on lemmas, while there exist other lexicons that consider also the part of speech, see, e.g., SentiWordNet (Esuli and Sebastiani, 2006). Let the reader consider the following tweet, from the SemEval 2016 training set:

#OnThisDay1987 CBS records shipped out the largest pre-order in the company’s history for Michael Jackson’s album Bad <http://t.co/v4fkY0x2eW>

In this example, the word “Bad” should not be considered as a negative adjective, since it is an album name. However, in the current work, we have not discriminated between nouns and adjectives with same spelling.

#### 4.1 Challenge results

The results over the challenge test set are available on the SemEval website<sup>8</sup>, according to the challenge score system described in (Nakov et al., 2016a). Table 3 shows the comparison of our results with the ones of the winning team. In the submitted result, the classifier has been trained over the training + development dataset, annotated with the best combination of features, as analyzed before.

|-------------|--------|
| SwissCheese | 63.301 |
| MIB         | 40.10  |

**Table 3:** SemEval 2016 task 4a results (Tweet 2016)

## 5 Conclusions

The approach proposed in this work achieved unsatisfactory results. This was in part due to a data preprocessing phase and a feature extraction phase that do not consider characteristics intrinsic to microblogging. Indeed, we mostly dealt with tweets handling them as regular text. The challenge data have been preprocessed by supervised approached, where features have been extracted through a NLP pipeline, trained on newswire domain. Within our proposed features, the sentiment lexicon-based features has proved to work well. However, we believe their extraction could take advantage of the adoption of other lexicons, different to those we have relied on. Specifically, there exist lexicons trained over tweets, such as the NCR emotion lexicon (Mohammad and Turney, 2013). Finally, we expect that a better solution could be achieved by extending the approach to include features extracted by unsupervised approaches (word embeddings), or by adopting a deep learning classifier, instead of a linear one.

Baltimore, MD 21250, USA

## Abstract

This paper describes our system submitted for the Sentiment Analysis in Twitter task of SemEval-2016, and specifically for the Message Polarity Classification subtask. We used a system that combines Convolutional Neural Networks and Logistic Regression for sentiment prediction, where the former makes use of embedding features while the latter utilizes various features like lexicons and dictionaries.

## 1 Introduction

Recently, rapid growth of the amount of user-generated content on the web prompts increasing interest in research on sentiment analysis and opinion mining. A typical example is Twitter, where lots of users express feelings and opinions about various subjects. However, unlike traditional media, language used in social network services like Twitter is often informal, leading to new challenges to corresponding text analysis.

The SemEval-2016 Sentiment Analysis in Twitter task (SESA-16) is a task that focuses on the sentiment analysis of tweets. As a continuation of SemEval-2015 Task 10, SESA-16 introduces several new challenges, including the replacement of classification with quantification, movement from two/three-point scale to five-point scale, etc.

We participated in Subtask A of SESA-16, namely message polarity classification, a task that seeks to predict a sentiment label for some given text. We model the problem as a multi-class classification problem that combines the predictions given by two different classifiers: one is a Convolutional

Neural Network (CNN) and the other is Logistic Regression (LR). The former takes embedding-based features while the latter utilizes various features such as lexicons, dictionaries, etc.

The remainder of this paper is structured as follows. In Section 2, we describe our system in detail, including feature description and approaches. In Section 3, we list the details of datasets for the experiments, along with hyperparameter settings and training techniques. In Section 4, we report the experiment results and present the corresponding discussion.

## 2 System Description

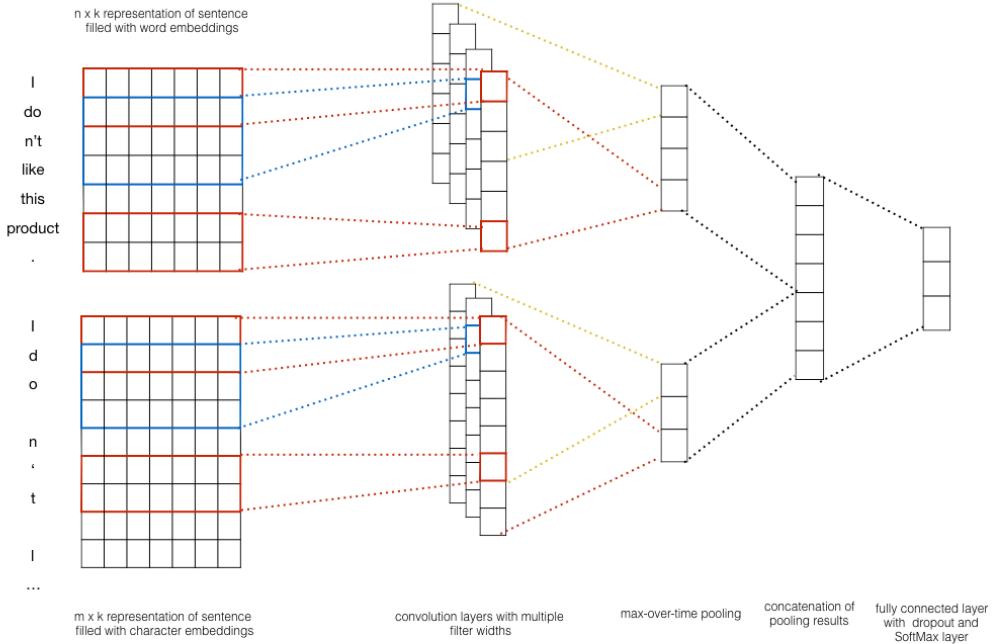

Our system aims at predicting the sentiment of a given message, i.e., whether the message expresses positive, negative or neutral emotion. To achieve that, we adopt two separate classifiers, CNN and LR, designed to utilize different types of features. The final prediction for sentiment is a combination of predictions given by both classifiers.

### 2.1 Data Preprocessing

Tweets often include informal text, making it essential to preprocess tweets before they are fed to the system. However, we keep the preprocessing to a minimum by only removing URLs and @User tags. We then further tokenize and tag tweets with arktweetnlp (Gimpel et al., 2011). In addition, all tweets are lower-cased.

### 2.2 Logistic Regression

We use the LR classifier for features from sentiment lexicons and token clusters. We have used the fol-

**Figure 1:** CNN architecture for an example with both word-based and character-based input maps.

lowing:

- **clusters:** 1000 token clusters provided by the CMU tweet NLP tool. These clusters are produced with the Brown clustering algorithm on 56 million English-language tweets.
- **manually-constructed sentiment lexicons:** NRC Emotion Lexicon (Mohammad and Turney, 2010), MPQA (Wilson et al., 2005), Bing Liu Lexicon (Hu and Liu, 2004) and AFINN-111 Lexicon (Nielsen, 2011).
- **automatically-constructed sentiment lexicons:** Hashtag Sentiment Lexicon and Senti-ment140 Lexicon (Mohammad et al., 2013).

For the Senti-ment140 Lexicon and Hashtag Sentiment Lexicon, we compute separate lexicon features for uni-grams and bi-grams, while for other Lexicons, only uni-gram lexicon features are produced. For each lexicon, let  $t$  be the token (uni-gram or bi-gram),  $p$  be the polarity and  $s$  be the score provided by the lexicon. We use the same features that are

also adopted by the NRC-Canada system (Mohammad et al., 2013):

- the total count of tokens in a tweet with  $s(t, p) > 0$ .
- the total score of tokens in a tweet  $\sum_w s(t, p)$ .
- the maximum score of tokens in a tweet  $\max_w s(t, p)$ .
- the score of the last token in the tweet with  $s(t, p) > 0$ .

For each token, we also use features to describe whether it is present or absent in each of the 1000 token clusters. There are in total 1051 features for a tweet.

### 2.3 Convolutional Neural Network

Deep learning models have achieved remarkable results for various NLP tasks, with most of them based on embeddings that represent words, characters, etc. with vectors of real values. Some work on embeddings suggests that word vectors generated by some

embedding algorithms preserve many linguistic regularities (Mikolov et al., 2013a).

Among the various deep learning models, we use Convolutional Neural Networks, which have already been used for sentiment classification with promising results (Kim, 2014). We show the network architecture in Figure 1.

In general, the architecture contains two separate CNNs: one is for word-based input maps while the other is for character-based input maps. In our system, an input map for a tweet is a stack of the embeddings of its words/characters w.r.t. their order in the tweet. We initialize word embeddings with the publicly available 300 dimension Google News embeddings trained with Word2Vec, but randomly initialize character embeddings with the same dimension. We fine tune both kinds of embeddings during the training procedure.

Each of the two separate CNNs has its own set of convolutional filters. We fix the width of all filters to be the same as the corresponding embedding dimension, but set their height according to predefined types of n-grams. For example, a filter for bi-grams on an input map constructed with 300 dimensional word embeddings will have shape (2, 300), where 2 is the height and 300 is the width. In other words, we use each filter to capture and extract features w.r.t. a specific type of n-gram from an input map.

The feature maps generated by a particular filter may have different shapes for different input maps, due to variable tweet lengths. Thus we adopt a pooling scheme called max-over-time pooling (Collobert et al., 2011), which captures the most important feature, i.e., the one with highest value, for each feature map. This pooling scheme naturally deals with the variable tweet length problem.

After pooling, we first generate a representation for each CNN by concatenating its own pooled features, and then form a final representation by concatenating the two separate representations. The final representation is then fed into a multi-layer perceptron (MLP) classifier for predictions.

### 2.3.1 Regularization

For regularization we employ dropout with a constraint on  $l_2$ -norms of the weight vectors (Hinton et al., 2012). The key idea of dropout is to prevent co-adaptation of feature detectors (hidden units) by ran-

domly dropping out a portion of hidden units in the training procedure. At test time, the learned weight vectors are scaled according to the portion while no dropout is needed.

In addition to dropout, we constrain weight vectors by introducing an upper limit on their  $l_2$ -norms. That is, for a weight vector  $w$ , we rescale it to have  $\|w\|_2 = l$ , whenever it has  $\|w\|_2 > l$ , after gradient descent step.

## 2.4 Combination

We combine the predictions of the two classifiers in the form of a weighted summation. Given the prediction  $P_{LR}$  by Logistic Regression and the prediction  $P_{CNN}$  by the CNN, we introduce a scalar  $w$ , such that the final prediction is given as,

$$P_{final} = (1 - w)P_{LR} + wP_{CNN} \quad (1)$$

In other words, let  $x$  be the input instance,

$$\begin{aligned} P_{final}(Y = y|x) &= wP_{CNN}(Y = y|x) \\ &\quad + (1 - w)P_{LR}(Y = y|x) \end{aligned} \quad (2)$$

We do not simply feed the features of LR along with the features generated by the CNN into a single classifier because they are naturally different. The features from LR are highly relevant with manually-created or automatically-generated dictionaries, scores, clusters, etc. They are a mixture of binary and real-value features with high variance. While for the CNN, the features are generated by convolutional kernels on distributed representations (embeddings), leading to strong correlation and relatively smaller variance. Our preliminary experiments show that by simply adding LR features to CNN features, the performance of our system does not increase, but drops.

## 3 Experiment

### 3.1 Datasets

We test our model on the SemEval-2016 benchmark dataset with two different settings. Setting 1 uses only the 2016 datasets while Setting 2 uses a combination of 2016 and 2013 datasets. We list the details of the two settings in Table 1.

For setting 2, the merge of two datasets is conducted w.r.t. the train/dev splits. Although we did

| Settings  | Train | Dev  | Test  |
|-----------|-------|------|-------|
| Setting 1 | 5975  | 1997 | 32009 |
| Setting 2 | 12964 | 3100 | 32009 |

**Table 1:** Statistics of our two settings of datasets for experiments. Setting 1: a dataset with only the SemEval-2016 dataset. Setting 2: a dataset that is a combination of the SemEval-2016 and SemEval-2013 datasets. In Setting 2, the merge is conducted w.r.t. train/dev splits, with "Not Available" tweets removed.

not remove any "Not Available" tweets for setting 1, we found a relatively high amount of such tweets in the combined dataset, which may significantly influence the system performance, thus we removed all the "Not Available" tweets for setting 2.

### 3.2 Hyperparameters and Training

#### 3.2.1 CNN

For both settings, we use rectified linear units. For the word-based CNN, we use filters of height 1,2,3,4, while for the character-based CNN, we use filters of height 3,4,5. And 100 feature maps are used for each filter. We also use a dropout rate of 0.5,  $l_2$ -norm constraint of 3, and mini-batch size of 50. These values were picked on the Dev dataset of Setting 1.

We perform early stop on dev datasets during training. We use Adadelta as the optimization algorithm (Zeiler, 2012).

#### 3.2.2 LR

We use the publicly available tool LibLinear for LR training. The cost is set to be 0.5 with all other parameters assigned with default settings. The cost is chosen based on the Dev dataset of Setting 1.

#### 3.2.3 Combination

The scalar  $w$  is picked via grid search on the Dev dataset for both settings. Because of the random initialization of weights and random shuffling of batches for the CNN during the training procedure,  $w$  is different for different runs. Thus we consider it as a weight to be trained with other weights.

### 3.3 Embeddings

It is popular to initialize word vectors with pre-trained embeddings obtained by some unsupervised algorithms trained over a large corpus to improve

|           |     | Actual |     |     |
|-----------|-----|--------|-----|-----|
|           |     | Pos    | Neu | Neg |
| Predicted | Pos | PP     | PU  | PN  |
|           | Neu | UP     | UU  | UN  |
|           | Neg | NP     | NU  | NN  |

**Table 2:** The confusion matrix for Subtask A. Cell XY stands for "the number of tweets that were labeled as X and should have been labeled as Y", where P U N stand for Positive Neutral Negative, respectively.

system performance (Kim, 2014) (Socher et al., 2011). We use the publicly available Word2Vec vectors trained on 100 billion words from Google News using the continuous bag-of-words architecture (Mikolov et al., 2013b) to initialize word embeddings, but randomly initialize character embeddings. All embeddings have dimensionality of 300. We also randomly initialize word embeddings that are not present in the vocabulary of those pre-trained word vectors.

## 4 Results and Discussion

The same evaluation measure as the one used in previous years is adopted, i.e.,

$$F_1^{PN} = \frac{F_1^{Pos} + F_1^{Neg}}{2} \quad (3)$$

where  $F_1^{Pos}$  is defined as,

$$F_1^{Pos} = \frac{2\pi^{Pos}\rho^{Pos}}{\pi^{Pos} + \rho^{Pos}} \quad (4)$$

with  $\rho^{Pos}$  defined as the precision of predicted positive tweets, i.e., the fraction of tweets predicted to be positive that are indeed positive,

$$\rho^{Pos} = \frac{PP}{PP + PU + PN} \quad (5)$$

and  $\pi^{Pos}$  defined as the recall of predicted positive tweets, i.e., the fraction of positive tweets that are predicted to be such,

$$\pi^{Pos} = \frac{PP}{PP + UP + NP} \quad (6)$$

where PP, PU, PN, UP, NP are defined in Table 2, a confusion matrix for Subtask A provided by (Nakov et al., ).  $F_1^{Neg}$  is defined similarly as  $F_1^{Pos}$ .

| Rank | System       | 2013                |                     | 2014                |                     |                     | 2015                | 2016                      |

**Table 3:** Evaluation Results of the top 15 systems with ranks provided as subscripts. aueb\* stands for "aueb.twitter.sentiment". Our model with setting 1 ranks 12th among 34 systems. We also show the evaluation results and our reported ranks of MDSENT with setting 2 among the 34 systems in MDSENT\*.

| Runs    | Setting 1 |            | Setting 2 |            |
|---------|-----------|------------|-----------|------------|
|         | w         | $F_1^{PN}$ | w         | $F_1^{PN}$ |
| Run 1   | 0.66      | 0.582      | 1.00      | 0.603      |
| Run 2   | 0.81      | 0.583      | 1.00      | 0.604      |
| Run 3   | 0.60      | 0.587      | 0.98      | 0.607      |
| Run 4   | 0.60      | 0.591      | 0.97      | 0.603      |
| Run 5   | 0.60      | 0.592      | 0.95      | 0.601      |
| Average | 0.654     | 0.587      | 0.98      | 0.604      |

**Table 4:** Statistics of 5 individual runs for both settings.

We show the evaluation results of our system in Table 3, along with the top 15 systems reported. Originally we tested the system with only setting 1 and it ranks 12th among 34 systems. However, we find the system with setting 1 perform poorly on older datasets, which may due to the lack of training data. Thus we then test our model with setting 2 and report ranks generated from the same list of evaluation results reported by the 34 systems. It is apparent that our system can benefit from more training data and shows significant performance improvement (rank 6th).

Another interesting observation is that when provided with large amounts of training data, the CNN itself can perform very well, with LR assigned a very small weight during the combination proce-

dure. We further test this finding by making 5 individual runs for both settings and checking the combination scalar weight  $w$  and final evaluation score  $F_1^{PN}$ . We list corresponding results in Table 4. With more training data,  $w$  increased from an average of 0.654 to an average of 0.98, which is very close to 1, while the performance improved from an average of 0.587 to an average of 0.604. This suggests the possibility to use only deep learning techniques along with embeddings to achieve similar or even better performance than traditional systems that require a lot of human engineered features and knowledge bases.

Our future work includes finer-design of the CNN, e.g., performing two stages of classification: first for subjectivity detection and then for polarity classification. We will also seek the possibility of conducting unsupervised learning with the CNN, which allows us to make use of the large amount of tweets on the Internet. With such increased amount of training data, our system may further improve its performance.

## Abstract

This paper presents our approach for SemEval 2016 task 4: Sentiment Analysis in Twitter. We participated in Subtask A: Message Polarity Classification. The aim is to classify Twitter messages into positive, neutral, and negative polarity. We used a lexical resource for pre-processing of social media data and train a neural network model for feature representation. Our resource includes dictionaries of slang words, contractions, abbreviations, and emoticons commonly used in social media. For the classification process, we pass the features obtained in an unsupervised manner into an SVM classifier.

## 1 Introduction

In this paper, we describe our approach for the SemEval 2016 task 4 “Sentiment Analysis in Twitter” subtask A (Nakov et al., 2016), where the goal is to classify a tweet message as either positive, neutral, or negative. The main goal of our approach is to improve the feature representation obtained by a well-known neural network method—Doc2vec (Le and Mikolov, 2014), using dictionaries of abbreviations, contractions, slang words, and emoticons.

Approaches based on neural networks for unsupervised feature representation (or embeddings) often do not perform data cleaning (Le and Mikolov, 2014; Socher et al., 2011), considering that the network itself would solve the related problems. These approaches treat special characters such as „!# and user mentions as a regular word (Le and Mikolov, 2014; Brigadir et al., 2014). Still, in some works

which use embeddings a basic data cleaning process (i.e., stopwords removal, URL filtering, and removal of rare terms) improves the feature representation and, consequently, the performance of the classification task (Yan et al., 2014; Rangarajan Sridhar, 2015; Jiang et al., 2014).

The problem with the content of social media messages is that they usually have a lot of non-standard language expressions (Pinto et al., 2012; Atkinson et al., 2013). Due to the short nature of the messages, most of the users use a large vocabulary of slang words, abbreviations, and emoticons (Das and Bandyopadhyay, 2011). Slang words are not considered as a part of the standard vocabulary of a language, and they are mostly used in informal messages, while abbreviations are shortened forms of a word or name that are used in order to replace the full forms. Emoticons usually convey the current feeling of the message writer.

For this task we propose a preprocessing phase using the dictionaries that we previously built for the task of Authorship Attribution (Posadas-Durán et al., 2015). These dictionaries are useful for preprocessing and cleaning messages obtained from several social networks, such as Facebook, Google+, Instagram, etc.

The rest of the paper is structured as follows. Section 2 describes related work. Section 3 introduces the social media lexical resource used for this work. Section 4 presents our proposed approach. Section 5 presents the evaluation of the task using the neural network based feature representation. Finally, Section 6 draws the conclusions from our experiments and points out the possible directions of future work.

## 2 Related Work

There are many works that tackle the problem of social media texts pre-processing (Baldwin, 2012; Clark and Araki, 2011; Das and Bandyopadhyay, 2011); however, to the best of our knowledge, the research based on neural network for feature representation did not consider the effect that data cleaning have on the quality of the representation (specially on social media data).

Several approaches have been proposed for vector-space distributed representations of words and phrases. These models are used mainly for predicting a word given a surrounding context. However, most of the authors indicate that distributed representations of words and phrases can also capture syntactic and semantic similarity or relatedness (Le and Mikolov, 2014; Socher et al., 2013; Mikolov et al., 2013). This particular behaviour makes these methods attractive to solve several NLP tasks, nevertheless, at the same time, it raises new issues, such as dealing with unnormalized texts, which are typically present in social media forums such as Twitter, Facebook, Instagram, among others. Researchers have proposed several pre-processing steps in order to overcome this issue, which led to an overall performance increase. Yan et al. (Yan et al., 2014) obtained almost 2% increase using standard NLP pre-processing, which consists in tokenization, lowercasing, removing stopwords and rare terms. Kumar et al. (Rangarajan Sridhar, 2015) focused on the spelling issues in social media messages, which includes repeated letters, omitted vowels, use of phonetic spellings, substitution of letters with numbers (typically syllables), use of shorthands and user created abbreviations for phrases. In a data-driven approach, Brigadir et al. (Brigadir et al., 2014) apply URL filtering combined with standard NLP pre-processing techniques.

## 3 Resources

We developed the dictionaries with the aim of pre-processing tweets for the author profiling task at PAN 2015 (Posadas-Durán et al., 2015). First, we reviewed the tweets present in the PAN corpus and found excessive use of shortened vocabulary, which can be divided into three categories: slang words, abbreviations, and contractions. Moreover, we came

**Table 1:** Number of entries of the English dictionary

| Type of Dictionary | English |
|--------------------|---------|
| Abbreviations      | 1,346   |
| Contractions       | 131     |
| Slang words        | 1,249   |
| Emoticons          | 482     |
| Total              | 3,208   |

across a large number of emoticons, which are a typographic display of a facial representation.

The lexical resource was originally built for 4 languages, but for the purposes of this work we only use the English dictionary. The statistics for the English dictionary are presented in Table 1. The dictionaries are freely available on our website<sup>1</sup>.

## 4 Approach to Sentiment Classification

From a machine learning point of view, the Message Polarity Classification task can be considered as a supervised multi-class classification problem, where a set of tweets  $\mathbf{T} = \{t_1, t_2, \dots, t_i\}$  is given, and each sample is assigned to one of the target classes  $\{\text{positive}, \text{negative}, \text{neutral}\}$ . So, the problem is to build a classifier  $F$  that assigns a sentiment class to unclassified tweets.

Since the tweets are very noisy, we perform the preprocessing over each dataset (train, unlabeled and test). In the preprocessing phase, we executed the following steps:

**Expand slang words and abbreviations** Not all tweets use slang words and abbreviation in the same way. There are Twitter users that do not use slang words and due to this reason we expanded all slang words and abbreviations with their full meaning using the dictionaries described in section 3.

**Remove url** ULR do not provide information about the sentiment of the tweet and because of this reason every ULR is removed from the text.

**Remove hashtags symbols** Hashtags in tweets carry useful information about the topic and

<sup>1</sup><http://www.cic.ipn.mx/~sidorov/lexicon.zip>

polarity of the message. We only remove the hashtag symbol, keeping the words.

**Remove emoticons** In order to obtain a distributed representation of a tweet, we used only words and punctuation symbols. So, unlike traditional preprocessing for sentiment analysis we removed the emoticons from tweets by looking up in our emoticons dictionary.

For training, a vector representation of each tweet is obtained in an unsupervised manner by a neural network based model, i.e.,  $v^i = \{v_1, v_2, \dots, v_j\}$  where  $v^i$  is the vector representation of the tweet  $t_i$ . In order to obtain the vector representation of the tweets, a neural network based distributed representation model is trained using the doc2vec algorithm (Le and Mikolov, 2014). It is an unsupervised algorithm that aggregates all the words in a sentence (of variable length) into a vector of fixed length. The algorithm takes into account the contexts of words, and it is able to capture the semantics of the input texts. We used a freely available implementation of doc2vec included in the *Gensim*<sup>2</sup> python module. The doc2vec model is trained with both labeled and unlabeled tweets in order to learn the distributed representation. The learned vector representations have 300 dimensions, we set the windows size to 3 and minimal word frequency is set to 2. Then, a classifier is trained using the vector representations of the labeled tweets. We perform the experiments with the SVM liblinear classifier (Fan et al., 2008), specifically the *LinearSVC* algorithm implemented in the *Scikit Learn*<sup>3</sup> python module with default parameters.

For the evaluation, the vector representations of the test tweets are obtained retraining the doc2vec model built in the training stage, plus the test tweets. Finally, the vector representation of the tweets are passed to the SVM model in order to assign the corresponding polarity label to each tweet.

We used the train set of SemEval-2014 Task 9: Sentiment Analysis in Twitter - subtask B (Rosenthal et al., 2014), consisting of 6124 tweets (removing the tweets with the objective class). Besides, we

expanded the training set with some tweets of this year training set (the ones we could download) and with Stanford Sentiment Analysis Dataset (Go et al., 2009). So, in total we employed 11377 classified tweets for training. For the neural network based feature representation we used the 1.7 millions unlabeled tweets for training the Doc2Vec model.

## 5 Results

In this section we present the results obtained in the competition when various test datasets are used. The evaluation metric used in the competition is the macro-averaged F measure calculated over the positive and negative classes. Table 2 presents the overall performance of our approach for different datasets. It can be observed that our approach overcome the baseline for almost all datasets.

**Table 2:** Obtained results for 2016 Test and Progress

| Year | Corpus        | Ours  | Baseline score |
|------|---------------|-------|----------------|
| 2013 | Tweet         | 0.194 | 0.292          |
|      | SMS           | 0.193 | 0.190          |
| 2014 | Tweet         | 0.335 | 0.346          |
|      | Tweet Sarcasm | 0.393 | 0.277          |
|      | Live-Journal  | 0.326 | 0.272          |
| 2015 | Tweet         | 0.303 | 0.303          |
| 2016 | Tweet         | 0.303 | 0.255          |

## 6 Conclusions

We presented our results for sentiment analysis on Twitter. We rely on a supervised approach, which is based on top of a deep learning system enhanced with special preprocesing techniques using a lexical social media resource. We reported the overall accuracy for the sentiment classification task in three classes: positive, negative and neutral.

In the future, we will improve our preprocessing phase by removing the target mentions, numbers and repeated sequences of characters.

## Abstract

In this paper, we present a novel deep learning architecture for sentiment analysis in Twitter messages. Our system **finki**, employs both convolutional and gated recurrent neural networks to obtain a more diverse tweet representation. The network is trained on top of GloVe word embeddings pre-trained on the Common Crawl dataset. Both neural networks are used to obtain a fixed length representation of variable sized tweets, and the concatenation of these vectors is supplied to a fully connected softmax layer with dropout regularization. The system is evaluated on benchmark datasets from the Sentiment Analysis in Twitter task of the SemEval 2016 challenge where our model achieves best and second highest results on the 2-point and 5-point quantification subtasks respectively. Despite not relying on any hand-crafted features, our system manages the second highest average rank on the considered subtasks.

## 1 Introduction

Twitter sentiment analysis is an area of Natural Language Processing (NLP) dealing with the classification of sentiment polarity in Twitter messages. Most of the approaches to this problem are generally based on hand crafted features and sentiment lexicons (Mohammad et al., 2013; Pak and Paroubek, 2010). These features are then used as input to classifying algorithms such as, Support Vector Machines (SVM) and naive Bayes classifier. However, such approaches require extensive domain knowledge, are laborious to define, and can lead to incomplete or over-specific features.

Deep learning methods for sentiment analysis, on the other hand, handle the feature extraction automatically which provides for robustness and adaptability. Notably, most popular deep learning methods are convolutional neural networks (CNN), which have been shown to achieve state-of-the-art results (Kim, 2014; dos Santos and Gatti, 2014), though some works propose different models such as Recursive Neural Tensor Network (Socher et al., 2013).

Recurrent neural networks (RNN) are intuitive architectures for NLP as they inherently take into account the ordering of words in the text as opposed to CNNs which take only a small limited context window. However, to our knowledge, these networks have not been applied to sentiment analysis in Twitter messages. Le et al. (Le and Zuidema, 2015) report state-of-the-art results with Long Short Term Memory (LSTM) networks on binary and fine-grained classification on the Stanford Sentiment Treebank dataset.

In this paper, we present a novel deep learning architecture for sentiment classification and quantification in Twitter messages. The model consists of a convolutional and a gated recurrent neural network (GRNN). Both neural networks are used to model a suitable representation of a tweet. The feature representations output from the networks are fused and fed to a standard softmax regression classifier. The system leverages unsupervised pre-training of word embeddings. For this, we utilize the publicly available GloVe<sup>1</sup> word embeddings (Pennington et al., 2014), specifically ones trained on the Common

<sup>1</sup><http://nlp.stanford.edu/projects/glove>

Crawl dataset. In previous work (Stojanovski et al., 2015), we have experimented with multiple filters with additional window sizes of 4 and 5 and we leave such system implementation for future work.

We evaluate our deep learning system on four out of five subtasks of the Sentiment Analysis in Twitter task (Task 4) (Nakov et al., 2016) as part of the SemEval 2016 challenge. We competed in the 2-point and 5-point classification and quantification. Our model achieves high results on the quantification subtasks, getting second place on Subtask E and attaining the best score on Subtask D.

## 2 Deep learning architecture

The proposed model for sentiment analysis in this paper, consists of two neural networks. The first is a convolutional neural network with a single filter with windows size of 3. The second part of the architecture is a gated recurrent neural network. The system architecture is presented in Figure 1. The model is implemented using the Keras<sup>2</sup> library for deep learning on a Theano backend.

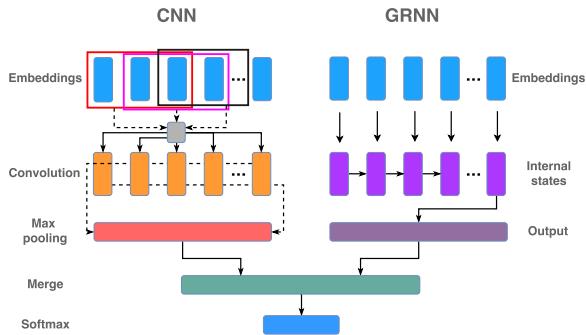

Figure 1: Deep neural network architecture.

### 2.1 Preprocessing

Twitter constraints tweet length to a maximum of 140 characters. Consequently, users are forced to find new and unpredictable ways of expressing themselves. Determining sentiment in these circumstances is very challenging and, as a result, we apply some preprocessing steps in order to clean tweets from unnecessary information. All URLs and HTML entities are removed from the tweets

<sup>2</sup><http://keras.io>

along with punctuation with the exception of question and exclamation marks. Emoticons and Twitter specifics such as hashtags are kept in their original form, unlike user mentions, which are completely removed. We also lowercase all words. Additionally, each appearance of an elongated word is shortened to a maximum of three character repetitions. Since all tweets are in relation to some topic, and the model has to determine the overall sentiment for the quantification tasks, we decided to replace words matching the tweet topic with generic tokens.

### 2.2 Pre-trained word embeddings

Each word or token that is a part of a tweet is first mapped to an appropriate distributional feature representation, also known as word embedding. Before training, we define the so called lookup table, where each word is associated with the corresponding feature representation. For the purposes of this work, we utilize the publicly available GloVe embeddings, pre-trained on the Common Crawl dataset with a dimensionality of 300. We choose these over the GloVe embeddings trained on Twitter data because of the higher dimensionality, considerably larger training corpus and vocabulary of unique words.

For words in the dataset not present in the lookup table, we use random initialization of word embeddings. However, despite their effectiveness in encoding syntactic and semantic regularities of words, they are oblivious to the words' sentiment characteristics. To counteract this, word embeddings are continuously updated during network training by back-propagating the classification errors. Therefore, sentiment regularities are being encoded in the feature representation.

### 2.3 Convolutional neural network

One component of our architecture is a convolutional neural network for feature extraction of Twitter messages. Dealing with variable sized text is inherently built into CNNs. Additionally, these networks, to some extent, take into account the ordering of the words and the context each word appears in. Unlike applications of CNNs in image processing, we only employ one convolutional and max pooling layer. The convolutional layer is used to extract local features around each word window, while

the max pooling layer is used to extract the most important features in the feature map.

Let's consider a tweet  $t$  with length of  $n$  tokens. Because of the sliding window manner in which the filters are applied, we apply appropriate padding at the beginning and at the end of the tweet. Padding length is defined as  $h/2$  where  $h$  is the window size of the filter. Before we apply the convolutional operation, each word is mapped to its corresponding word embedding. A tweet is represented as a concatenation of these word embeddings,  $t = [w_1, w_2, \dots, w_n]$ , where  $w_i$  is the word embedding for the  $i$ -th word in the tweet and  $w_i \in R^{300}$ .

In this work, we only use a single filter with window size of 3. As tweets are limited in length, smaller window sizes are more favorable in contrast to larger ones. The network learns a filter  $W_c$  and a bias term for the filter. The convolutional operation is applied to every possible window of words and as a result a feature  $x_i$  is produced. We can formally express the operation as:

$$x_i = f(W_c \cdot t_{i:i+h-1} + b_c), \quad (1)$$

where  $t_{i:i+h-1}$  is the concatenation of word vectors from position  $i$  to position  $i + h - 1$ , while  $f(\cdot)$  is an activation function. In this work, we choose the hard rectified linear activation function. Each of the produced features are used to generate a feature map

$$x = [x_1, x_2 \dots x_{n-h+1}]. \quad (2)$$

Then, the max-over-time pooling operation is applied over the feature map, which takes the maximum value  $\hat{x} = \max\{x\}$ . The max pooling layer outputs a fixed sized vector with a predefined dimensionality.

## 2.4 Gated recurrent neural network

The accompanying part of the CNN in our deep learning architecture is a gated recurrent neural network. RNNs make use of sequential data. They perform the same task for every element in a sequence with the output being dependent on previous computations. These networks compute hidden states and each hidden state depends on its predecessor. They can also be seen as having a memory compo-

ment, enabling them to look back arbitrarily in the sequence of words.

RNNs suffer from the exploding and vanishing gradient problem. There are two proposed methods for overcoming this issue: the LSTM networks (Hochreiter and Schmidhuber, 1997) and the Gated Recurrent Unit (Chung et al., 2014). We decided to use GRU because of the fewer model parameters, potentially needing less data to generalize and enabling faster training. GRU has gating units that modulate the flow of information inside the unit. The activation  $s_t^j$  of the GRU at time  $t$  is a linear interpolation between the previous activation  $s_{t-1}^j$  and the candidate activation  $\hat{s}_t^j$ :

$$s_t^j = (1 - z_t^j)s_{t-1}^j + z_t^j \hat{s}_t^j, \quad (3)$$

where an update gate  $z_t^j$  decides how much the unit updates its activation or content. The update gate is computed as:

$$z_t^j = \sigma(W_z x_t + U_z s_{t-1})^j. \quad (4)$$

where  $\sigma$  is a logistic sigmoid function. The GRU unlike LSTM has no mechanism to control the degree to which it exposes its state and exposes the whole state each time. The candidate activation is computed as:

$$\hat{s}_t^j = \tanh(W_x x_t + U_s s_{t-1})^j, \quad (5)$$

where  $r_t$  is a set of reset gates and  $\odot$  is an element-wise multiplication. The reset gate is computed as:

$$r_t^j = \sigma(W_r x_t + U_r s_{t-1})^j. \quad (6)$$

This network also produces a fixed vector which is necessary in our model.

## 2.5 Network fusion

The outputs from both networks are concatenated to form a single feature vector. This vector is then fed to a fully connected softmax layer. The softmax regression classifier gives probability distribution over the labels in the output space. The label having the highest probability is chosen as the final prediction.

|       | Positive | Negative | Total |
|-------|----------|----------|-------|
| Train | 7374     | 2542     | 9916  |
| Dev   | 1009     | 234      | 1243  |
| Test  | 8202     | 2331     | 10535 |

Table 1: Dataset label distribution for Subtasks B and D.

## 2.6 Regularization and model parameters

Due to the high number of parameters being learned, deep learning methods suffer from overfitting. To counteract this issue, we utilize dropout regularization (Srivastava et al., 2014), which randomly drops a proportion of hidden units in each iteration of network training. The dropout parameter is set to 0.25. The output size of the convolutional network and the GRU network is set to 100. The network is trained using stochastic gradient descent over shuffled mini-batches using the RMSprop (Tieleman and Hinton, 2012) update rule.

## 3 Experiments and results

### 3.1 Dataset

We train our model on the benchmark datasets provided by the SemEval challenge. However, due to deletion or changed privacy settings, we were not able to retrieve all tweets. For the 2-point classification and quantification we used the datasets from SemEval 2016 and we apply the topic preprocessing step previously mentioned. Moreover, we use positive and negative tweets from previous editions of the challenge to additionally refine our model in spite of the fact that these tweets are not labeled with the related topic.

For the 5-point classification and quantification, we only used the dataset from this year’s edition of SemEval. The model is trained on the provided training and development sets while as validation set we use the provided devtest set. The testing sets are also provided by the SemEval challenge without the need to download the specific tweets. The distribution of the sentiment labels in both datasets are provided in Table 1 and Table 2.

|       | VN  | N    | Neu   | P    | VP  | Total |
|-------|-----|------|-------|------|-----|-------|
| Train | 107 | 871  | 2083  | 3654 | 419 | 7134  |
| Dev   | 28  | 200  | 520   | 835  | 191 | 1774  |
| Test  | 138 | 2201 | 10081 | 7830 | 382 | 20632 |

Table 2: Dataset label distribution for Subtasks C and E. (N - negative, VN - very negative, Neu - neutral, VP - very positive, P - positive)

### 3.2 Results

The performance our model achieves and the official ranking are provided in Table 3. The systems are ranked by the macroaveraged recall for the Subtask B where higher scores are better. On the other subtasks, systems are ranked by the error functions where lower scores are better. From the obtained results, we can see that our system notably performs best on the quantification subtasks.

The merging of the networks provides better performance over their distinctive versions for the quantification tasks. Separately, the CNN and GRNN achieve KLD scores of 0.045 and 0.035 on Subtask D respectively, while only managing 0.761 and 0.632 for the EMD score on Subtask E. On Subtask C, the model surpasses the CNN, which attains a MAE<sup>M</sup> score of 0.92, but fails in comparison to the GRNN which gets 0.812. On Subtask B, both networks achieve comparable accuracy and F1 score in comparison to our proposed model, but gain better results on the recall measure, improving the performance by  $\sim 5$  points.

For Subtask B, our model performs best according to the accuracy measure, being ranked 4th. According to the average recall and F1 score, the model does not achieve notable performance although it produces significant improvement over baseline scores, especially for the AvgF1 measure. For the 5-point classification, our model again obtains average performances when compared against other teams.

Concerning Subtask D, our deep learning system produces best KLD score and also a considerable improvement over baseline scores on all three measures. Furthermore, the system gains high results on the 5-point quantification subtask as well, being

| Measure                | Baseline | Score | Rank |
|------------------------|----------|-------|------|
| Acc                    | 0.778    | 0.848 | 4    |
| AvgF1                  | 0.438    | 0.748 | 7    |
| <b>AvgR</b>            | 0.5      | 0.72  | 10   |
| MAE <sup>μ</sup>       | 0.537    | 0.672 | 6    |
| <b>MAE<sup>M</sup></b> | 1.2      | 0.869 | 5    |
| AE                     | 0.184    | 0.074 | 1    |
| RAE                    | 2.11     | 0.707 | 3    |
| <b>KLD</b>             | 0.175    | 0.034 | 1    |
| <b>EMD</b>             | 0.474    | 0.316 | 2    |
| <b>AvgRank</b>         |          | 4.5   |      |

Table 3: Results and ranks for Subtask B, C, D and E respectively

ranked second. Our model averages a score of 4.3 on the all scores for each subtask, while averaging 4.5 on the main scores. The proposed method of our team is one of the most robust out of all other teams, as it manages second highest average rank on the considered subtasks.

## 4 Conclusion

In this paper, we presented a novel deep learning model for sentiment classification of Twitter messages. We proposed a fusion of CNN and GRNN for extracting features from Twitter messages and a softmax layer for generating class predictions. The deep neural network is trained on top of GloVe word embeddings pre-trained on the Common Crawl dataset. The model effectiveness is evaluated on the Sentiment Analysis in Twitter task from SemEval 2016 where our system achieved second best average rank on the 2-point and 5-point classification and quantification subtasks, testifying for its robustness.

Although our model achieved high results, there is room for improvement. For future work, we would like to pre-train word embeddings on a large set of distantly labeled tweets. Additionally, it would be interesting to see the effects of using bi-

directional GRNN.

## Abstract

We describe our submission to SemEval2016 Task 4: Sentiment Analysis in Twitter. The proposed system ranked first for the subtask B. Our system comprises of multiple independent models such as neural networks, semantic-affective models and topic modeling that are combined in a probabilistic way. The novelty of the system is the employment of a topic modeling approach in order to adapt the semantic-affective space for each tweet. In addition, significant enhancements were made in the main system dealing with the data preprocessing and feature extraction including the employment of word embeddings. Each model is used to predict a tweet’s sentiment (positive, negative or neutral) and a late fusion scheme is adopted for the final decision.

## 1 Introduction

Nowadays, the usage of social networks such as Twitter dominates the daily communication of hundreds of millions of people around the world. People often share opinions and express their feelings about various topics through social networks. Tasks such as opinion mining and sentiment analysis (Pang and Lee, 2008) have become very popular, since they can capture a large portion of the public opinion.

The sentiment analysis of tweets was applied in various domains, such as commerce (Jansen et al., 2009), disaster management (Verma et al., 2011)

or health (Chew and Eysenbach, 2010). This task is especially challenging due to the terse and informal writing style, the semantic diversity of content, as well as the often “unconventional” grammar and orthography. Many computational systems like those submitted to SemEval 2015 Task 10 (Rosenthal et al., 2015) incorporate bag-of-words models with Twitter-specific features like hashtags and emoticons (Davidov et al., 2010; Büchner and Stein, 2015). Word embeddings obtained from large amounts of tweets are used under the scope of an unsupervised approach for sentiment analysis (Astudillo et al., 2015). Additionally, deep learning models have recently become very popular for Twitter sentiment analysis (Severyn and Moschitti, 2015). Topic modeling approaches for sentiment analysis can also be found in literature, e.g., (Mei et al., 2007; Lin and He, 2009; Lu et al., 2011; Alam et al., 2016; Rao, 2016)

In this paper, we present systems submitted to the SemEval 2016 Task 4 (Nakov et al., 2016) that deal with the sentiment analysis of tweets on the sentence level. The submitted systems are based on the fusion of the different classifiers. Specifically, 1) we enhanced the system submitted by Malandrakis et al. (2014) to the SemEval 2014 Task 9 (Rosenthal et al., 2014), 2) we used the open-source system submitted by Büchner and Stein (2015) to the SemEval 2015 Task 10 (Rosenthal et al., 2015), 3) we trained a convolutional neural network on a large amount of unlabelled Twitter data, 4) we developed a system

based on topic modeling and 5) we trained a classifier using word embeddings as features. Our system was submitted on two subtasks, namely subtask A (message polarity classification) and subtask B (tweet classification according to a two-point scale) and ranked in the fifth<sup>1</sup> and the first place, respectively.

## 2 System Description

### 2.1 Baseline

The baseline system is an enhanced version of the system submitted by Malandrakis et al. (2014) to the SemEval 2014 Task 9 (Rosenthal et al., 2014). The major changes include the different manipulation of hashtags, multiword expressions and the affective features as well as the incorporation of new features. A plethora of features is extracted, the majority of which are affective. The feature extraction is performed at the tweet, suffix and prefix level. Assume the following tweet: “*Lol Red Sox just slid through 3rd base #out*” (tweet level). A window applied at the beginning estimates the prefix e.g., “*Lol Red Sox*” (prefix level) and a window at the end of the tweet estimates the suffix “*3rd base #out*” (suffix level).

#### 2.1.1 Affective features

The baseline is based on affective features derived from the semantic-affective model proposed by Malandrakis et al. (2013). The semantic-affective model relies on the assumption that semantic similarity implies affective similarity (Malandrakis et al., 2013). First, a semantic model is built and then affective ratings are estimated for unknown tokens exploiting the affective ratings of semantically similar words. It is applicable both to single words or short multiword expression as shown below:

$$\hat{v}(t_j) = \alpha_0 + \sum_{i=1}^N \alpha_i v(w_i) S(t_j, w_i), \quad (1)$$

where  $t_j$  is the unknown lexical token,  $w_{1..N}$  are the seed words,  $v(w_i)$ ,  $\alpha_i$  are the affective rating and the weight corresponding to the word  $w_i$  and  $S(\cdot)$  is the semantic similarity metric between two tokens. The

---

<sup>1</sup>The actual performance of the system is different from the official results due to an erroneous submission.

semantic model was built as shown in (Palogiannidi et al., 2015) using word-level contextual feature vectors and adopting a scheme based on mutual information for feature weighting. The dimensionality of the affective features was reduced by retaining only the polarity features (instead of using additional affective dimensions, like arousal and dominance). Affective lexica were created using a generic corpus (116M sentences) (Iosif et al., 2016) and a Twitter corpus (115M tweets) created for the purpose of our submission. In the former case task-independent affective ratings are estimated. Task-dependent affective ratings can be estimated by keeping domain-specific sentences in the generic corpus. A language model was built using domain relevant sentences and then the top 30% of the most relevant entries of the generic corpus were selected<sup>2</sup>.

Affective features were also derived through semantic models that were built from corpora that were collected based on the topic modeling approach described in Section 2.2. **Third party affective lexica** were also used. Affin (Nielsen, 2011) contains discrete polarity ratings in the range  $[-5, 5]$ , nrc, nrctag (Mohammad et al., 2013) contain continuous polarity ratings for tokens, generated from a collection of tweets that include a positive or a negative word hashtag.

#### 2.1.2 Tokenization

Based on the assumption that **hashtags** in different positions in a tweet may have different semantic interpretation, the tweets are transformed as follows: if a hashtag occurs at the end of the tweet it is assumed to convey semantic information. Otherwise, the hashtag is treated as a word or possibly a union of words. In the latter case, only the corresponding word is kept (e.g., “#moon is so beautiful tonight” → “moon is so beautiful tonight”, but “What a beautiful night under the moonlight #romantic” is preserved as is). A hashtag that contains a union of words is expanded, e.g., #Hockeyisback → Hockey is back. Hashtags were expanded using the Viterbi algorithm (Forney and David, 1973) exploiting n-gram datasets. The  $n$ -gram dataset

---

<sup>2</sup>Perplexity filtering was used in order to estimate the relevance of a sentence to the language model while 30% was selected to be the most appropriate percentage over other percentages that were examined.

we used is a concatenation of the Google  $n$ -gram corpus that contains 1 trillion tokens from publicly accessible web pages (Brants and Franz, 2006) and an  $n$ -gram corpus based on 75 million English tweets (Herdağdelen, 2013). The absolute and relative frequencies of hashtags to be expanded were also used as features, as well as the indicators (binary features) that a tweet contains hashtags that require expansion. **POS-tagging / Tokenization** was then performed using the ARK NLP tweeter tagger (Owoputi et al., 2013), a Twitter-specific tagger. A tweet contains single words or emoticons and punctuations or multiword expressions. **Multiword expressions (MWE)** are non-compositional expressions that are processed as a single token. They were detected using the Gensim library (Řehůřek and Sojka, 2010) and they were added to the affective lexica.

Some parts of the tweets may be crucial for the correct understanding of its affective meaning. We assume that such parts, are the prefix, the suffix and the negated parts. **Negations** were detected using the list proposed by Potts (2011). When a negation token is detected, the tokens that follow are marked as negated until a punctuation mark is reached. Then, feature extraction is applied on the negated part of the tweet. **Windows** are used for splitting a tweet into prefix and suffix attempting to estimate the cognitive dissonance phenomenon that is associated with sarcasm, irony and humour (Reyes et al., 2012). The suffix is extracted by applying windows that keep the 20%, 50% and 70% of tokens that occur at the end of the tweet. Feature extraction is performed for both suffixes and prefixes.

### 2.1.3 Word2vec features

In addition to the use of semantic similarity features as in (Malandrakis et al., 2014), we use semantic representations, i.e., word embeddings that are utilized for the semantic similarity estimation, i.e., the  $S(\cdot)$  in (1). **Word embedding features** were derived using word2vec (Mikolov et al., 2013), representing each word as a 300-D vector. Since tweet-level features are required, for each tweet a 300-D vector is generated by averaging the corresponding vectors of the constituent words.

### 2.1.4 Additional features

Additional features based on characters and subjectivity lexica were used. Character features include the absolute and relative frequencies of selected characters. The selected characters are the **capitalized** letters, the **punctuation** marks, the **emoticons** as well as characters **repetitions**, i.e., at least three same successive characters in a word. **Subjectivity** features were also extracted based on the subjectivity lexicon of (Wilson et al., 2005). Specifically, the absolute and the relative frequencies of the strong positive/negative and weak positive/negative words were used as features.

### 2.1.5 Statistics extraction

The statistics of the token-level polarity features were estimated in order to extract tweet-level features. The following statistics were computed: length (cardinality), min, max, max amplitude, sum, average, range (max minus min), standard deviation and variance. Normalized versions of the same statistics were also calculated.

## 2.2 Topic Modeling

Topic modeling is a method for discovering “topics” that occur in collections of documents. Typically, multiple topics are present in a document. The most widely used topic modeling approach is the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) which is based on Latent Semantic Analysis (LSA) (Deerwester, 1988) and probabilistic Latent Semantic Analysis (pLSA) (Hofmann, 2000). Here, we used topic modeling in order to adapt the semantic space on each tweet. In essence, the corpus was split in a probabilistic way based on the detected topics and then a semantic model was built for each subcorpus. Since this technique is probabilistic, each corpus sentence can belong to each revealed topic with a given probability. Then, clusters of sentences per topic were created by classifying each sentence to the most probable topic. A semantic model was built for each cluster, using word2vec (Mikolov et al., 2013). A mixture of the semantic models, weighted by the topic posteriors is used for the estimation of tweet’s semantic similarities, e.g.,  $S(\cdot)$  in (1).

## 2.3 Convolutional Neural Network

A deep convolutional neural network (CNN) was also developed. The neural network’s architecture is inspired by sentence classification tasks (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014). Each tweet is represented by a “sentence” matrix  $S$  that is created as follows. First, each word is represented as a 300-D vector using word2vec, and then, the word vectors are concatenated as follows:  $S = W_1 \oplus W_2 \oplus W_3 \oplus \dots \oplus W_n, S \in \mathbb{R}^{d \times n}$ , where  $\oplus$  indicates the concatenation operation. Each column  $i$  of  $S$  is a vector  $W \in \mathbb{R}^d$  that corresponds to the  $i^{th}$  word of the tweet. This way the sequence of the words in the tweet is kept. In order to preserve the same length for all tweets, zero padding was applied concatenating zero word vectors until the length  $n$  of the longest tweet is reached. The size of  $S$  is  $d \times n$ , where  $d$  is the dimension of the word embedding and  $n$  is the length of the longest tweet. The matrix  $S$  is the input to the network, where a convolution operation is applied between  $S$  and a kernel  $F \in \mathbb{R}^{d \times m}$ . The width  $m$  was set to 5 and the parameters of the model, i.e., the values of the kernel, the size of the sliding window  $h$  are learned. The result of the convolutional layer is a vector  $c \in \mathbb{R}^{n-m+1}$  (Kim, 2014). In fact, the convolution network uses multiple kernels with varying sliding windows and generates multiple features. These features are the inputs to the next layer which selects the maximum value of each feature by applying a max-over-time pooling operation (max-pooling layer) (Collobert et al., 2011). Next, the output of the max-pooling layer is passed to a dropout layer (Srivastava et al., 2014). A softmax layer that classifies each test instance to one of the possible classes is the final step.

## 2.4 Word2vec System

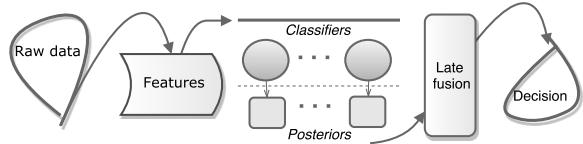

Based on the assumption that similarity of meaning implies affective similarity (Malandrakis et al., 2013) we build a system that relies exclusively on tweets’ semantic representation. Specifically, word2vec was applied over large text corpora in order to compute the semantic representations of words (formulated as vectors). Then, the vectors of each tweet’s constituent words were averaged in order to create a single vector. These vectors were used for training a random forest classifier.

## 2.5 Webis

The Webis open-source system (Büchner and Stein, 2015) that was submitted on (Rosenthal et al., 2015) is the ensemble of different subsystems that ranked at the top of SemEval 2013, SemEval 2014 Sentiment Analysis tasks (Nakov et al., 2013; Rosenthal et al., 2014). The following systems were combined in a late fusion scheme, based on the mean posterior probabilities: 1) NRC-Canada (Mohammad et al., 2013) is based on morphological, linguistic and polarity features, 2) GU-MLT-LT (Günther and Furrer, 2013) trains a linear classifier by stochastic gradient descent which uses social media specific text preprocessing and linguistic features, 3) KLUE (Proisl et al., 2013) employs a Maximum Entropy classifier with bag-of-words models, sentiment, emoticons and internet slang abbreviations features, 4) TeamX (Miura et al., 2014) is similar to NRC-Canada but uses more lexicon-based features and handles the unbalance distribution of tweets’ sentiment by adopting a weighting scheme to bias the output.

## 2.6 Fusion of the systems

The motivation behind the development of various systems for sentiment classification is that different systems may capture different aspects of the sentiment, and by combining them we can predict more accurately the sentiment of tweets. The system architecture including the fusion scheme is summarized in the figure below.

**Figure 1:** System Architecture.

As shown in Figure 1, the various classifiers were trained with features extracted from Twitter datasets and their posterior probabilities were combined in a late fusion scheme. Various techniques can be used for the late fusion of classifiers, e.g., voting-based (Tulyakov et al., 2008) methods, multi-classifiers fusion that use posteriors as features for training a new classifier (Kittler et al., 1998; Gutierrez et al., 2016)

| System       | Datasets |         |           |         |                |         |              |

or algebraic combinations (Kittler et al., 1998). Algebraic combinations are based on operations such as mean, median, product, max or min.

### 3 Experimental Procedure and Results

#### 3.1 Data

We trained our systems using both general purpose and Twitter data. We used a large generic corpus that contains 116M sentences (G-116M). The dataset was created by posing queries on a web search engine and aggregating the resulting snippets. A Twitter specific dataset was also created collecting 115M tweets (T-115M). We also used the training data provided by SemEval 2016 for subtasks A and B (Sem/A-2016, Sem/B-2016), as well as training data from the corresponding task of SemEval 2013 (Sem-2013). We also used ANEW (Bradley and Lang, 1999) for bootstrapping the affective lexicon expansion process.

#### 3.2 Systems

The following subsystems were combined for the subtask A: Baseline (B), CNN, Word2vec system

(W2V) and Webis (W). Baseline and Webis were trained on the concatenation of Sem/A-2016 and Sem-2013. A two-stage feature selection was applied, the first one took place on each feature set separately and the second to the combined feature set of the first stage. Finally, a Naive Bayes tree classifier was trained. Affective features derived by the topic modeling approach were also incorporated. The word vectors that are required for the CNN are derived from different corpora, i.e., the combination of a Google News dataset and the T-115M corpus. Specifically, for each word in the tweet, the word vector extracted from the latter corpus is used only if the word doesn't exist in the former corpus. The vectors of OOV words are initialized randomly from a uniform distribution. For the word2vec-based system we trained a random forest classifier with 100 trees using 300-D feature vectors on the concatenation of Sem/A-2016 and Sem-2013. We experimented with various fusion schemes and system combinations. The mean algebraic fusion scheme was selected for the reported results.

The submission for the subtask B includes the following systems: Baseline (B\*), Topic Model-

ing (TM) and three Webis subsystems, i.e., NRC-Canada, GU-MLT-LT and Team X. The Baseline ( $B^*$ ) and the selected Webis systems were trained on the Sem/B-2016 dataset. Both feature selection and the classification of  $B^*$  are similar to the Baseline that was used in subtask A. The difference between B and  $B^*$  is that the former, in contrast to the second, includes affective features extracted through the approach based on topic modeling. The topic modeling system applies the LDA algorithm on the G-116M, using 16 topics<sup>3</sup>. Then, affective ratings are estimated and they are used in order to train a Naïve Bayes tree classifier. Similarly to subtask A, a mean algebraic fusion scheme was selected for combining the systems.

### 3.3 Results

The developed systems for subtask A classify each tweet in one out of three sentiment classes (positive vs. negative vs. neutral), however the performance of the model is measured taking into consideration only the performance on the two polarity classes, i.e., positive and negative. The macro-averaged F-score of the positive and negative classes  $F_1^{PN} = \frac{F_1^{Pos} + F_1^{Neg}}{2}$  is reported in Table 1 for various datasets. In the first column the integrated systems are presented, while the submitted system is highlighted with grey color. Our system ranked fifth, while experimenting with different system combinations we can climb up to the third position.

Subtask B is a binary classification task (positive vs. negative). Macro-averaged recall  $p^{PN} = \frac{p^{Pos} + p^{Neg}}{2}$ ,  $p^{PN} \in [0, 1]$  and macro-averaged F-score are reported in Table 2 for various system combinations. The systems and their macro-averaged recall are listed in the first and second row of the table, respectively. The reported scores were derived by the test tweets of 2016 that belong to specific topics. Each row that follows indicates a unique combination and the submitted system is highlighted with grey color. In the case that all the available systems are combined, the marco-averaged recall (AvgR) is 0.803 and macro-averaged F-score (AvgF1) is 0.808. The combinations that follow contain a subset of the systems (the selected systems are

<sup>3</sup>The number of topics derived after the conduction of experiments on a news headlines dataset.

denoted with  $\checkmark$  and the omitted systems with  $\times$ ). The baseline was proved to be the most robust system achieving the highest performance among the others and higher performance than the submitted system (0.797). When using all the subsystems but one, performance decreases except in the case that the Webis system is omitted, then AvgR increased to 0.818. The highest performance drop is achieved when the baseline system is omitted. Investigating more combination schemes AvgR rises to 0.827. The combination of CNN, TM and  $B^*$  with two of the best Webis systems yields robust performance with AvgR and AvgF1 0.824 and 0.805, respectively.

## 4 Conclusions

We presented a system for the sentiment classification of tweets for the SemEval 2016 Task 4: Sentiment analysis in Twitter. We participated in subtasks A and B and we won subtask B. We developed various systems including a CNN and a topic modeling approach for the adaptation of the semantic space to each tweet. Regarding task A, the submitted system was ranked between the fifth and third position. The performance for subtask B can be higher (up to +3% compared to the submitted system) for various system combinations. Future work will focus on the fusion of the systems as well as their enhancement in order to achieve higher performance to the three-point scale sentiment classification.

# **UofL at SemEval-2016 Task 4: Multi Domain word2vec for Twitter Sentiment Classification**

**Omar Abdelwahab, Adel Elmaghrraby**

Computer Science and Engineering

University of Louisville, Louisville, KY

{omar.abdelwahab, adel}@louisville.edu

## **Abstract**

In this paper, we present a transfer learning system for twitter sentiment classification and compare its performance using different feature sets that include different word representation vectors. We utilized data from a different source domain to increase the performance of our system in the target domain. Our approach was based on training various word2vec models on data from the source and target domains combined, then using these models to calculate the average word vector of all the word vectors in a tweet observation, then input the average word vector as a feature to our classifiers for training. We further developed one doc2vec model that was trained on the positive, negative and neutral tweets in the target domain only. We then used these models in calculating the average word vector for every tweet in the training set as a preprocessing step. The final evaluation results show that our approach gave a prediction accuracy on the Twitter2016 test dataset that outperformed two teams that were among the top 10 in terms of AvgF1 scores.

## **1 Introduction**

Twitter sentiment analysis deals with classifying the polarity of a tweet as positive or negative or neutral. We have participated in Semeval 2016 Twitter Sentiment Analysis subtask-A. Where we had to predict the polarity of a whole tweet rather than part of a tweet. We have started off with feature engineering and data preprocessing. Then we have divided our task into five classification tasks. Then we worked on creating our feature sets that we later used to select the best classifier/feature set combination for

each classification task as will be explained further in the paper.

In section 2 we explain our transfer learning approach, system components, data preprocessing, aggregation approach, word2vec training and doc2vec training. In section 3, we present our experiments. Then in section 4, we review and discuss our results. Finally in section 5, we make conclusions and outline some future work.

## **2 Transfer Learning Approach**

Our transfer learning approach was based on using data from an additional source domain to supplement the provided target domain twitter data to train our word2vec models. The resultant models were later used in calculating the average word2vec vector of each tweet in our twitter training set as will be explained in section 2.4. We have also developed four binary classifiers and one arbiter three class label classifier. The four binary classifiers as well as the fifth arbiter classifier were a combination of logistic regression and SVM classifiers as we will show in the following sections.

### **2.1 System Components and Data Sets**

In this section, we will specify the system components that were used in predicting the final results that we have submitted to SEMEVAL Task number 4. We have trained six word2vec models that will be discussed in more detail in section 2.4.

After training our word2vec models, we have selected five classifiers based on experimentation results using the preprocessed combined Rosenthal et al. (2015) and Nakov et al. (2016) semeval training twitter data set.

Two SVM classifiers, one for classifying positive and negative tweets was trained on positive and negative tweets. The second was for classifying between negative and non-negative tweets and it was trained on negative and non-negative tweets. In addition, we have trained three Logistic Regression classifiers, one for classifying between positive, neutral sentiments and it was trained on positive and neutral tweets.

While the second classifier was trained on negative, neutral tweets for classifying between negative and neutral polarities. The third logistic regression classifier was for classifying between positive, negative, neutral tweets and it was trained on positive, negative and neutral tweets. Different sets of features were used with each classifier as we will discuss in section 2.3.

As mentioned earlier, we have combined the 2015 Semeval twitter sentiment analysis subtask B's training set and the 2016 Semeval twitter sentiment analysis subtask A's training set into one training set of 11,798 tweets named full\_training\_set. We then combined the Guestrin et al. (2015) amazon baby toys product reviews data set (source domain) which were around 150,000 reviews with the full\_training\_set to build our word2vec models. On the other hand, we used the full\_training\_set to train our doc2vec model as will be explained in section 2.5. After training our word2vec and doc2vec models, the full\_training\_set was preprocessed for training our five classifiers mentioned above.

The validation set used for every classifier in the ensemble had the same characteristics of the training set. For example, since the positive/negative classifier was trained on positive and negative tweets, its validation set contained positive and negative tweets only.

Finally, the output of our five classifiers is aggregated to produce the final system output as discussed in section 2.3.

## 2.2 Preprocessing and Feature Engineering

Before we have trained any of our classifiers, we have started with preprocessing our training data. Keeping in mind that any preprocessing we performed on the training set was applied on the test set. We started with the following preprocessing steps:

- Removed character repetitions by removing the character repetitions that could distract our classifiers. For example a word like LOOOOOOOL is replaced with LOL.
- Replaced patterns by replacing words like ‘won’t’ with ‘will not’, ‘can’t’ with ‘cannot’. ‘re’ with ‘are’, etc.
- Converted tweets to lower case by converting upper case characters to lower case.
- Replaced website links with URL so links to websites that start with www.\* or http?://\* were replaced with URL symbol.
- Converted @username to AT\_USER by replacing @username instances found in tweets with AT\_USER for our classifiers to easily identify that a user is being referenced.
- Removed additional white spaces in order to remove any noise that might affect our classifiers' performance.
- Replaced hash tags and removed stop words. As we replaced hash tags with the same word without the hash. For example, #fun is replaced with fun. As hash tags can give useful information. Also stop words are removed.
- Replaced Non-Alphabets and question words with space. Then we replaced numbers with \$NUM symbol.
- Performed stemming and lemmatization using porter stemmer and WordNet lemmatizer class in the NLTK library.
- We used Bing Liu et al. (2004) positive-word and negative-word lexicons that contained a list of thousands of words associated with positive sentiment and negative sentiment. We replaced positive words with \$po and negative words with \$ne. We also used the NRC Unigram lexicon that helped us in replacing words that are more likely to give a positive sentiment with ‘HAPO’ and words that will more likely result in a negative sentiment with ‘HANE’.

- The source domain data was preprocessed in the same way the target domain data (tweets) were preprocessed. However, the source domain data were only used in training the word2vec and doc2vec models.
- After finishing with the initial preprocessing steps discussed previously, the training set and the validation set were parsed into Graphlab Sframes for further manipulation.
- Then the Unigrams, bigrams and trigrams of every tweet in the training set were calculated and stored in additional columns in the same Sframe.
- Furthermore, the TFIDF of every tweet was calculated and stored in a new column.
- The six trained word2vec models that will be discussed in section 2.4 were each used in calculating the word vectors of each word in a tweet observation in the training set.
- Afterwards, the word vectors generated by each word2vec model were later averaged to get six averaged word vectors for every tweet in the training set. These average vectors were later saved in columns named w2v\_vectors\_pos\_neg, w2v\_vectors\_pos\_neutral, w2v\_vectors\_neutral\_neg, w2v\_vectors\_pos\_ornot, w2v\_vectors\_neg\_ornot, w2v\_vectors\_neutral\_ornot which were later used as features to our classifiers.

### 2.3 Features used and Aggregation

We have categorized our feature sets into four categories. There are different feature sets in each category. The first category is called feature category 1 that includes only base features tfidf, unigram, bigram, and trigrams. Then a second category containing the base as well as word2vec vectors and it's called feature category 2. Then a third feature category that contains base features in addition to doc2vec vectors only named feature category 3. Finally, a fourth category that contains base features, word2vec vectors, and doc2vec vectors is called feature category 4.

The features included in every feature set is presented in Appendix A while the feature sets in each category is shown in Appendix B.

When it came to aggregating the predictions from the four binary classifiers, we gave the highest priority to the neg\_ornot classifier. As it had a reasonably high accuracy in discriminating between negative and non-negative tweets on the validation set. Therefore if the neg\_ornot classifier classifies a tweet as negative, the final output of the system will be negative. However, if it classifies a tweet as non-negative, a majority vote is taken between the other three remaining binary classifiers. If two classifiers classify a tweet as positive, then the final system output will be positive, similarly if two classifiers classify a tweet as neutral, then the final system prediction is neutral, and likewise if two classifiers agree that a tweet is negative then the final sentiment output is negative. In the case when we get a tie from the other three classifiers and the neg\_ornot classifier classifies a tweet as non-negative, then the fifth arbiter three class label classifier is deployed to give the final classification output of the system.

### 2.4 Word2Vec

When Training our word2vec models for our final system, we used the continuous bag-of-words architecture. We combined positive amazon reviews and positive tweets into one file and named it pos\_text, then combined the negative tweets and negative amazon reviews into a second file named neg\_text, and similarly we combined the neutral amazon reviews with the neutral tweets in a third file named neutral\_txt. Our first word2vec\_pos\_neg model was trained on the pos\_text and neg\_text files.

While, the word2vec\_pos\_neutral model was trained on the pos\_text and neutral\_text. Then the word2vec\_neg\_neutral model was trained on the neg\_text and neutral\_text. Furthermore, the other three word2vec models were trained to be used to distinguish between negative and nonnegative tweets, positive and non-positive tweets, neutral and non-neutral tweets using pos\_text, neg\_text and neutral\_text files. The word2vec\_neg\_ornot model was trained on the neg\_text, and non\_neg\_text (pos\_text and neutral\_text combined). Also, word2vec\_pos\_ornot model was trained on the pos\_text and non\_pos\_text (neg\_text and neu-

| Classification  | Classifer | Feature Set | Category | Accuracy |
|-----------------|-----------|-------------|----------|----------|
| Neg-Nonnegative | SVM       | 6           | 2        | 0.894    |
| Neg-Neutral     | LR        | 7           | 3        | 0.778    |
| Pos-neg         | SVM       | 8           | 4        | 0.851    |
| pos-neg-neutral | LR        | 12          | 4        | 0.610    |
| Pos-Neutral     | LR        | 2           | 2        | 0.713    |

**Table 1:** Final classifier/feature set combinations selected.

tral\_text combined). Lastly, word2vec\_neutral\_or-not was trained on neutral\_text and non\_neutral\_text (pos\_text and neg\_text combined).

## 2.5 Paragraph Vector

We have trained a doc2vec model on all the positive, negative and neutral tweets in the training set to test whether paragraph vectors would improve fscores and prediction accuracies on the validation set. After building our doc2vec distributed memory model, we used it in inferring the tweet vector of every tweet in the training set and stored the result in the ‘vectors\_doc2vec\_tweetsonly\_dm’ column. Column vectors\_doc2vec\_tweetsonly\_dm is then added as a feature to our feature sets shown in Appendix A.

## 3 Experiments

We have carried out a number of experiments to help in selecting the feature sets to use for each classifier as well as which classifier type (SVM or Logistic Regression or boosted trees) to use for every binary classification and for the arbiter classifier.

Appendix C contains a flowchart describing the system structure. The flowchart illustrates our system’s sentiment prediction process.

Table 2.0 shows the validation prediction accuracies for each binary classifier and on the arbiter classifier when varying the feature set. The feature set, classifier combination was selected based on the combination that yielded the best validation prediction accuracies. However, when evaluating our whole system or our final system output, we use fscore as a measure of system performance and not the test set prediction accuracy.

We have set class weights to auto in all classifiers we trained to help protecting against data imbalance which would lead to misleading results.

| Classifier   | Feature Set    | Accuracy       |
|--------------|----------------|----------------|
| SVM          | Feature Set 6  | <b>0.89382</b> |
| LR           | Feature Set 9  | 0.87354        |
| SVM          | Feature Set 1  | 0.87309        |
| LR           | Feature Set 1  | 0.87156        |

| SVM          | Feature Set 7  | 0.66508        |
| SVM          | Feature Set 11 | 0.66180        |
| LR           | Feature Set 7  | 0.66033        |
| LR           | Feature Set 11 | 0.65693        |

**Table 2:** Validation Accuracy for different classifier/Feature Set combinations.

|  |      |
|--|------|
| Starting System Fscore on the test set | 0.26 |
| Final system Fscore on the test set    | 0.51 |

**Table 3:** Fscore of the whole system when using the least performing classifier/feature set combinations and when using the best performing classifier/feature set combination.

## 4 Results and Analysis

Table 3 shows the least Fscore of the system we started with (features set 1 for all classifiers in the system) and the final system fscore before submission on our test set. We used fscore as the overall system performance measure and not the system accuracy. However, we have put the validation accuracy as the top classifier/feature set combination selection criteria for the individual classifiers in our system while setting class weights to auto in all of our classifiers in our system. It is clear from Table 1.0 that feature categories 2 and 4 were associated with the best performing classifiers. As mentioned earlier feature category 2 uses word vectors in addition to the base features in feature set 1. While feature category 4 uses word vectors and paragraph vectors with feature set 1. Which indicates that the addition of paragraph vectors with word2vec vectors gave best validation accuracies with the positive/negative and the pos/neg/neutral classifiers. However, it did not give the best validation accuracies with the positive/neutral and negative/nonnegative classifiers. As Feature category 2 that uses word vectors with feature set 1 gave the best validation accuracies with the positive/neutral and the negative/nonnegative classifiers. Finally, using only paragraph vectors with feature set 1 yielded the best validation accuracy with the negative/neutral classifier. Even though our doc2vec model was only trained on data from the target domain (tweets), it managed to give slightly better validation accuracy than when using word2vec vectors trained on the source (amazon reviews) and target (tweets) domains combined. Nonetheless, for positive/negative, positive/neutral, negative/nonnegative, positive/negative/neutral classification using word2vec vectors that were generated by our word2vec models trained on the source and target domains combined gave better validation set accuracies than when using only the doc2vec vectors generated by our doc2vec model that was trained on the

full\_training\_set (tweets) with feature set 1 only. Since Le et al. (2014) concluded that paragraph vectors are competitive with the state of the art word representation methods. We inferred based on our results that combining the source and target data to train our word2vec models would give better results than when training them only on the target data. Thus the external source data helped in building word2vec models that gave us more powerful features when compared to those generated by doc2vec (paragraph vector) models trained only on the target data (tweets in full\_training\_set).

## 5 Conclusion

Our approach resulted in higher prediction accuracies on the 2016 twitter test data set outperforming eight teams that had better AvgF1scores. Two of the eight teams were in the top 10 in terms of AvgF1scores. In the future, we will focus more on cross domain word representation as illustrated in Bollegala et al. (2015) for improving our transfer learning approach.

## **Abstract**

In many areas, such as social science, politics or market research, people need to track sentiment and their changes over time. For sentiment analysis in this field it is more important to correctly estimate proportions of each sentiment expressed in the set of documents (quantification task) than to accurately estimate sentiment of a particular document (classification). Basically, our study was aimed to analyze the effectiveness of two iterative quantification techniques and to compare their effectiveness with baseline methods. All the techniques are evaluated using a set of synthesized data and the SemEval-2016 Task4 dataset. We made the quantification methods from this paper available as a Python open source library. The results of comparison and possible limitations of the quantification techniques are discussed.

## **1 Introduction**

In many areas, such as customer-relationship management or opinion mining, people need to track changes over time and measure proportions of documents expressing different sentiments. In these situations, the task of accurate categorization of each document is replaced by the task of providing accurate proportions of documents from each class (quantification). George Forman suggested defining the ‘quantification task’ as finding the best estimate for the amount of cases in each class in a test set, using a training set with substantially different class distribution (Forman, 2008).

Application of the quantification approach in opinion mining (Esuli et al., 2010), network-behavior analysis (Tang et al., 2010), word-sense disambiguation (Chan and Ng, 2006), remote sensing (Guerrero-Currieses et al., 2009), quality control (Sánchez et al., 2008), monitoring support-call logs (Forman et al., 2006) and credit

scoring (Hand and others, 2006) showed high performance even with a relatively small training set.

Although quantification techniques are able to provide accurate sentiment analysis of proportions in situations of distribution drift, the question of optimal technique for analysis of tweets still raises a lot of questions. It is worth mentioning that sentiment analysis of tweets presents additional challenges to natural language processing, because of the small amount of text (less than 140 characters in each document), usage of creative spelling (e.g. “happpyyy”, “some1 yg bner2 tulus”), abbreviations (such as “wth” or “lol”), informal constructions (“hahahaha yava quiet so !ma I m bored av even home nw”) and hashtags (BREAKING: US GDP growth is back! #kidding), which are a type of tagging for Twitter messages.

In our paper we used several quantification methods mentioned in literature as the best ones and evaluated them by comparing their effectiveness with one another and with baseline methods.

The paper is organized as follows. In Section 2, we first look at the notation, then we briefly overview six methods to solve the quantification problem. Section 3 describes two datasets we use in our research. Section 4 describes the results of our experiments, while Section 5 concludes the work defining open research issues for further investigation.

## **2 Quantification Methods**

In this section we describe the methods used to handle changes in class distribution.

First, let us give some definition of notation.

$X$ : vector representation of observation  $x$ ;

$C = \{c_1, \dots, c_n\}$ : classes of observations, where  $n$  is the number of classes;

$p_S(c)$ : a true prior probability (aka “prevalence” of class  $c$  in the set  $S$ ;

$\hat{p}_S(c_j)$ : estimated prevalence of  $c_j$  using the set  $S$ ;

$\hat{p}_S^M(c_j)$ : estimated  $\hat{p}_S(c_j)$  obtained via method  $M$ ;

- $p(c_j/x)$ : a posteriori probabilities to classify an observation  $x$  to the class  $c_j$ ;
- $TRAIN, TEST$ : training and test sets of observations, respectively;
- $TEST_c$ : a subset of  $TEST$  set where each observation falls within class  $c$ ;
- $TEST\_CD = \{p_{TEST}(c_i)\}; i=1, n$ : class probability distribution of the test set;
- $TRAIN\_CD = \{p_{TRAIN}(c_i)\}; i=1, n$ : class probability distribution of the training set;

The problem we study has some training set, which provides us with a set of labeled examples – TRAIN, with class distribution TRAIN\_CD. At some point the distribution of data changes to a new, but unknown class distribution – TEST\_CD, and this distribution provides a set of unlabeled examples – TEST. Given this terminology, we can state our quantification problem more precisely.

## 2.1 Classify and Count

The first approach provides information about proportions of document in each class just by classification of each document. In this case, the process starts with training the best available classifier, applying it to the test set and counting the amount of documents in each class. Forman named this obvious approach as Classify and Count (CC) (Forman, 2008).

The observed count  $P$  of positives from the classifier will include both true positives and false positives,  $P = TP + FP$ , as characterized by the standard  $2 \times 2$  confusion matrix.

Classifier Predictions:

| Actual\Prediction | P  | N  |
|-------------------|----|----|
| P                 | TP | FN |
| N                 | FP | TN |

## 2.2 Adjusted Classify and Count

Adjusted Classify and Count (ACC – aka the “confusion matrix model” quantification method (Forman, 2005) consists of six steps:

1. training a binary classifier on the entire training set
2. estimating its characteristics via many-fold cross-validation ( $tpr = TP/P$  and  $fpr = FP/N$ )
3. applying the classifier to the test set
4. counting the number of test cases on which the classifier outputs positives
5. estimating the true percentage of positives via Equation (1)
6. clipping the output to the feasible range.

$$\hat{p}^{ACC}(c) = \frac{\hat{p}_{CC}(c) - fpr(c)}{tpr(c) - fpr(c)} \quad (1)$$

As mentioned by Forman, the performance of the ACC method degrades severely in the situation of a highly imbalanced training sample. If one of the classes is rare in the training set, the classifier will learn not to vote for this class because of  $tpr = 0\%$ . Small denominator ( $tpr - fpr$ ) in Equation (1) makes the quotient highly sensitive in the estimation of  $tpr$  or  $fpr$ , and this leads to low quantification accuracy especially at the small training sets with high class imbalance (Forman et al., 2006).

## 2.3 Probabilistic Classify and Count

The Probabilistic Classify and Count (PCC) method differs from the CC algorithm by counting the expected share of positive predicted documents, i.e. the probability of membership in class  $c$  of observation  $x_i$  after classifying documents in the TEST set.

$$\hat{p}_{TEST}^{PCC}(c) = \frac{\sum_{x_i \in TEST} p(c|x_i)}{|TEST|} \quad (2)$$

## 2.4 Probabilistic Adjusted Classify and Count

The central idea of the Probabilistic Adjusted Classify and Count (PACC) algorithm is evidently to combine two algorithms above – ACC and PCC.  $\hat{p}_{CC}(c)$ ,  $fpr(c)$ ,  $tpr(c)$  should be replaced by their expected values, i.e.

$$\begin{aligned} \hat{p}^{CC}(c) &\sim \hat{p}^{PCC}(c), \\ tpr(c) &\sim E\{tpr(c)\}, \\ fpr(c) &\sim E\{fpr(c)\}, \end{aligned}$$

where

$$\begin{aligned} E\{tpr(c)\} &= \frac{\sum_{x_i \in TEST_c} p(c|x_i)}{|TEST_c|} \\ E\{fpr(c)\} &= \frac{\sum_{x_i \in TEST_{\bar{c}}} p(c|x_i)}{|TEST_{\bar{c}}|} \end{aligned}$$

then the form of the PACC is

$$\hat{p}^{PACC}(c) = \frac{\hat{p}^{PCC}(c) - E\{fpr(c)\}}{E\{tpr(c)\} - E\{fpr(c)\}} \quad (3)$$

## 2.5 Expectation Maximization

A simple procedure to adjust the outputs of a classifier to a new a priori probability is described in the study by (Saerens et al., 2002).

$$p(c_j/x_k) = \frac{\frac{p_{TEST}(c_j)}{p_{TRAIN}(c_j)} \hat{p}(c_j/x_k)}{\sum_{i=1}^n \frac{p_{TEST}(c_i)}{p_{TRAIN}(c_i)} \hat{p}(c_i/x_k)} \quad (4)$$

It is important that authors suggest using not only the well-known formula (4) to compute the corrected a posteriori probabilities, but also an iterative procedure to

adjust the outputs of the trained classifier with respect to these new a priori probabilities, without having to refit the model, even when these probabilities are not known in advance.

To make the Expectation Maximization (EM) method clear, we specify its algorithm in Figure 1 using a pseudo-code. The algorithm begins with counting start values for class probability distribution, using labels on the training set TRAIN (line 1), builds an initial classifier  $C_i$  from the TRAIN set (line 2) and classifies each item in the unlabeled TEST set (line3), where the `classify` functions return the a posteriori probabilities (`TEST_prob`) for the specified datasets. The algorithm then iterates in lines 4-9 until the maximum number of iterations (`maxIterations`) is reached. In this loop, the algorithm first uses the previous a posteriori probabilities `TEST_prob` to estimate a new a priori probability (line 6). Then, in line 7, a posteriori probabilities are computed using Equation (4). Finally, once the loop terminates, the last posteriori probabilities returns (line 9).

---

```
EM (TRAIN, TEST)
1. TEST_CD = prevalence(TRAIN)
2. C_i = build_clf(TRAIN)
3. TEST_prob = classify(C_i, TEST)
4. for (i=1; i<maxIterations; i++)
5. {
6.   TEST_CD = prevalence(TEST_prob)
7.   TEST_prob = bayes(TEST_CD, TEST_prob)
8. }
9. return TEST_CD
```

---

**Figure 1:** Pseudo-code for the EM algorithm.

To build a classifier in the function `build_clf`, we use support vector machines (SVM) with linear kernel.

## 2.6 Iterative Class Distribution Estimation

Another interesting method is iterative cost-sensitive class distribution estimation (CDEIterate) described in the study by (Xue and Weiss, 2009).

The main idea of this method is to retrain a classifier at each iteration, where the iterations progressively improve the quantification accuracy of performing the «classify and count» method via the generated cost-sensitive classifiers.

For the CDE-based method, the final prevalence is induced from the TRAIN labeled set with the cost of classes COST. The COST value is computed with Equation (5), utilizing the class distribution calculated during the previous step TEST\_CD. For each iteration, we recalculate:

$$COST = \frac{TEST_CD}{TRAIN_CD} \quad (5)$$

The CDEIterate algorithm is specified in Figure 2, using the pseudo-code. The algorithm begins with counting the class distribution TRAIN\_CD for training labels TRAIN (line 1). Then it builds an initial classifier  $C_i$  from the TRAIN set (line 2). In a loop, this algorithm uses the previous classifier  $C_i$  to classify the unlabeled TEST set by estimating a posterior probability TEST\_prob for each item in a test set (line 5). Then, in line 6, the a priori probability distribution is computed and the cost ratio information is updated (line 7). In line 8, a new cost-sensitive classifier  $C_i$  is generated using the TRAIN set with the updated cost ratio COST. The algorithm then iterates in lines 4-9 until the maximum number of iterations (`maxIterations`) is reached. Finally, once the loop terminates, the last a priori probability distribution of classes is returned TEST\_CD (line 10).

---

```
CDEIterate (TRAIN, TEST, COST_start)
1. TRAIN_CD = prevalence(TRAIN)
2. C_i = build_clf(TRAIN, COST_start)
3. for (i=1; i<maxIterations; i++)
4. {
5.   TEST_prob= classify(C_i, TEST)
6.   TEST_CD = prevalence(TEST_prob)
7.   COST = TEST_CD/TRAIN_CD
8.   C_i = build_clf(TRAIN, COST)
9. }
10. return TEST_CD
```

---

**Figure 2:** Pseudo-code for the CDE-Iterate algorithm.

To build a cost-sensitive classifier in the function `build_clf`, we tried a few ones and chose a fast logistic regression classifier.

We did not find any open library where baseline quantification methods were implemented. We, therefore, shared all the algorithms, which we had programmed using the Python language, on the Github repository<sup>1</sup>. We believe that this library can help pool information on quantification.

## 3 Experiment Methodology

This section describes our experimental setup. It describes the datasets we use, the specific experiments we run and the classifier induction algorithm we employ.

### 3.1 Simulations on Artificial Data

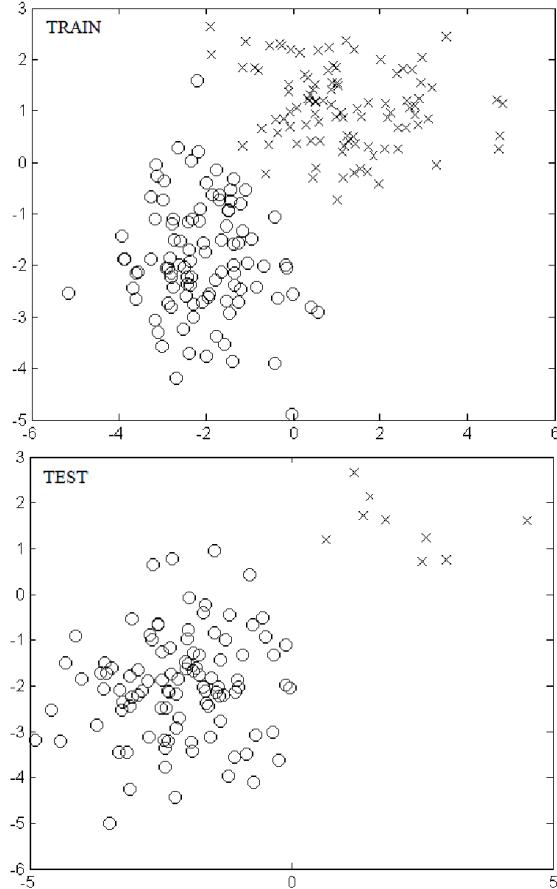

We present a simple experiment that illustrates the efficiency of iterative adjustment of the a priori probabilities.

---

<sup>1</sup><https://github.com/ArcticKirillras/Rubrication>

We use random sample generators from SkiKit-Learn Library to build artificial datasets of controlled size and complexity<sup>2</sup>. For each dataset we generate 10,000 records with 10 features. Figure 3 exemplifies 2 features of a dataset with two classes.

The initial prevalence for classes  $c_1$  and  $c_2$  was equal ( $p_{train}(c_1) = p_{train}(c_2) = 0.5$ ). The total set randomly splits into two subsets: 25% training set, 75% test set. For the training set, the class distribution remains unchanged. For the test set, we vary prevalence value  $p_{test}(c_1)$  from 0.05 to 0.95.

**Figure 3:** An example of TRAIN and TEST dataset items with  $TRAIN\_CD = \{0.5, 0.5\}$  and  $TEST\_CD = \{0.1, 0.9\}$  respectively (generated with 2 features).

For each prevalence value we generate a hundred different test sets. Therefore, nineteen hundred replications of the following experimental design are applied.

We used a Kullback-Leibler Divergence (KLD) between the true class prevalence and the predicted class

prevalence as a quality evaluation metrics for quantifiers.

### 3.2 Test Dataset

To evaluate the algorithms on the real data, we participated in the SemEval-2016 Task 4 called “Sentiment Analysis in Twitter”. Its dataset consists of Twitter messages (aka observations) divided into several topics. Task 4 consists of five subtasks, but we only participated in subtasks D and E: tweet quantification according to a two-point scale and five-point scale, respectively. These subtasks are evaluated independently for different topics, and the final result is counted as an average of evaluation measure out of all the topics (Nakov et al., 2016).

The organizers provide a default split of the data into training, development and development-time testing datasets. The algorithms evaluation is performed using these subsets. The training subset is used as a TRAIN set, development and development-time testing subsets are used as a TEST set.

Since observation  $x$  in this dataset is a message written in a natural language, we first need to transform it to the vector representation  $X$ . Based on a study by (Gao and Sebastiani, 2015), we choose the following components of the feature vector:

- TFIDF for word n-grams with n varying from 1 to 4
- TFIDF character n-grams where n varies from 3 to 5.

Feature vector is extracted with a Scikit\_Learn tool<sup>3</sup>. We also perform data preprocessing .Several text patterns (e.g. links, emoticons, numbers) were replaced with their substitutes. For word n-grams we apply lemmatization using WordNetLemmatizer.

It is interesting to characterize messages using the SentiWordNet library. For each token  $x_i$  in document X we obtain its polarity value from the SentiWordNet. First, we recognize the part of speech using a speech tagger from the NLTK library (Bird et al., 2009). Second, we get the SentiWordNet first polarity value for this token using the part of speech information.

We used polarity values to extend vector representation of documents in two ways: first we simply calculate the polarity score as a sum of positive minus a sum of negative polarity values and add this feature to the vector representation of a document. Second, we calculate the sum of positive polarities and the sum of negative

---

<sup>2</sup>[http://scikit-learn.org/stable/modules/generated/sklearn.datasets.make\\_classification.html](http://scikit-learn.org/stable/modules/generated/sklearn.datasets.make_classification.html)

<sup>3</sup>[http://scikit-learn.org/stable/modules/generated/sklearn.feature\\_extraction.text.TfidfVectorizer.html](http://scikit-learn.org/stable/modules/generated/sklearn.feature_extraction.text.TfidfVectorizer.html)

polarities and add these two features to the vector representation of a document.

The metrics that we use to evaluate the classifier performance are described in (Nakov et al., 2016) and are not described here.

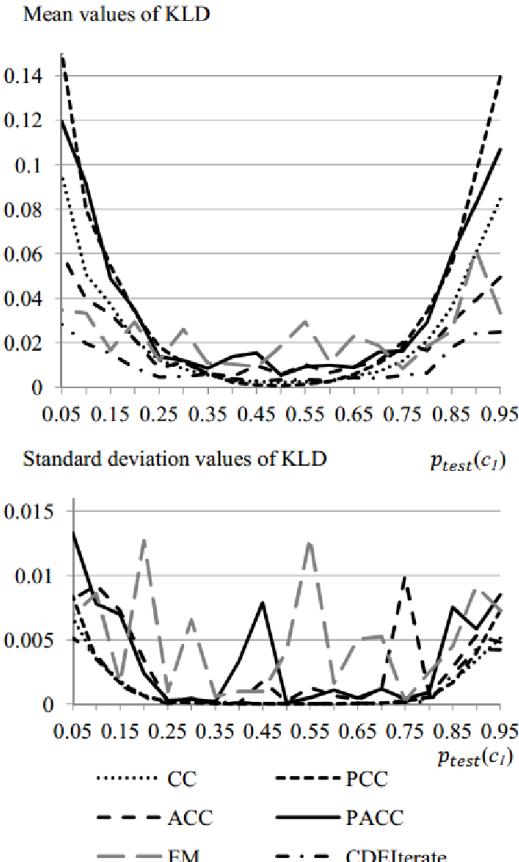

## 4 Experiment Results

We apply six quantification methods mentioned above in Section 2: CC, PCC, ACC, PACC, EM, CDEIterate and compare them.

### 4.1 Synthesized Data

First, we applied CC, PCC, ACC, PACC, EM and CDEIterate algorithms to generated data described in Section 3.1. Synthesized data allows us to perform a comparative analysis of these quantification methods with different amount of distribution drift.

In Figure 3, which demonstrates the means and standard deviation values of the evaluation measure – Kullback-Leibler Divergence (KLD), each point is obtained by averaging over one hundred generated datasets with different prevalence.

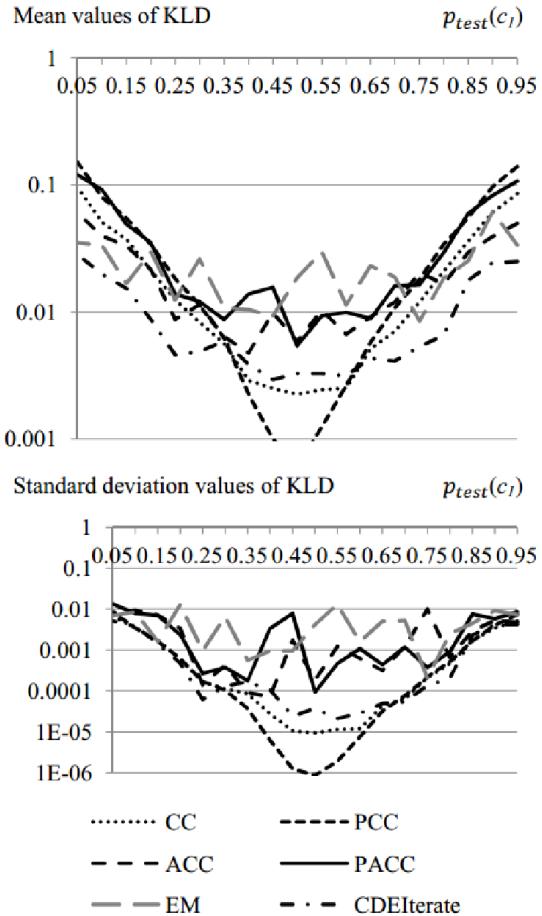

**Figure 4:** Mean and standard deviation values of Kullback-Leibler Divergence for different distribution drifts in the TEST set on the linear scale.

It is obvious from Figure 4 that the CDEIterate approach shows the lowest KLD mean values when a distribution drift is relatively large. A standard deviation value for the CDEIterate method remains the smallest one among all possible distribution drifts.

On the contrary, the EM approach shows very unstable results. Sometimes the EM algorithm converges far from the real value. Its standard deviation displays the same unstable behavior.

For more careful consideration, let us show its functions in the logarithmic scale in Figure 5.

**Figure 5:** Mean and standard deviation values of Kullback-Leibler Divergence for different distribution drifts in the TEST set on the logarithmic scale.

When distribution changes from the starting value  $p_{train}(c) = 0.5$  by less than 0.1, the simple methods like CC and PCC show better performance (lower KLD).

### 4.2 Test Data

We noticed that CDEIterate methods sometimes converge to different values, if an algorithm starts iteration from a different starting point. To support this, we add

the `COST_start` variable to the algorithm shown in Figure 2. The first starting point is a priori probability distribution of a training set. Therefore, for the starting iteration we assume `TEST_CD` to equal `TRAIN_CD`. The second starting point is when `TEST_CD` is uniformly distributed. This case is labeled as `CDEIterate_U`. In the previous Section 4.1, these two starting points were actually the same.

| Method       | Quantification accuracy measure |
|--------------|---------------------------------|
| CC           | 0.102469788749                  |
| ACC          | 0.192896311253                  |
| PCC          | 0.24076249451                   |
| PACC         | 0.23644037492                   |
| EM           | 0.24076249451                   |
| CDEIterate   | 0.101057466171                  |
| CDEIterate_U | 0.0886349793929                 |

**Table1:** Comparison of methods on test sample with a two-point scale (SemEval-2016 Task4 Subtask D).

| Method       | Quantification accuracy measure |
|--------------|---------------------------------|
| CC           | 0.940764808798                  |
| ACC          | 0.878280429893                  |
| PCC          | 1.02616631747                   |
| PACC         | 1.04546915144                   |
| EM           | 1.12790745311                   |
| CDEIterate   | 0.538279399063                  |
| CDEIterate_U | 0.536691406139                  |

**Table 2:** Comparison of methods on test sample with a five-point scale (SemEval-2016 Task4 Subtask E).

`CDEIterate_U` approach showed the best accuracy on the testing set among others with both five-point and two-point scales.

SentiWordNet is usually regarded as an important source of information about word sentiment (Baccianella et al., 2010; Esuli and Sebastiani, 2006). In our comparison, we add the sum of positive scores and the sum of negative scores of each word as two additional features to the feature vector. Only the first meaning, according to the recognized part of speech, was used. The quantification methods remain the same. The results provided in Table 3, show that the new features increase quantification accuracy for CC, ACC, but surprisingly decrease it for PCC, PACC, EM, CDEIterate and CDEIterate-U.

| Method       | Quantification accuracy measure |
|--------------|---------------------------------|
| CC           | 0.868282929268                  |
| ACC          | 0.861784553862                  |
| PCC          | 1.05532269963                   |
| PACC         | 1.0731851762                    |
| EM           | 1.11319538187                   |
| CDEIterate   | 0.58872710467                   |
| CDEIterate_U | 0.587811269105                  |

**Table 3:** Comparison of methods on test sample with a five-point scale with additional SentiWordNet features (SemEval-2016 Task4 Subtask E).

We explain this behavior as follows: simple algorithms cannot adjust to the whole singularity and such additional features increase dimension and, thereby, accuracy. In a more complex case, the classifier extracts information from features more efficiently. Additional information about polarity scores leads to algorithm overtraining. We can guess that, as tweets contain creative spelling and abbreviation common in Twitter (like “lol”, not presented in SentiWordNet), the existence of character n-grams contains more specific information than polarity scores of selected, properly written words. Therefore, we exclude SentiWordNet features from the final feature vector.

## 5 Conclusion and future work

The aim of this research was to perform comparative analysis of different approaches of state-of-the-art quantification techniques.

For tweet quantification on a five-point scale (Subtask E) and a two-point scale (Subtask D), the best performance was demonstrated by the adopted iterative method proposed by (Xue and Weiss, 2009), based on the iterative procedure with the cost-sensitive supervise learner. All the algorithms mentioned in the article, are available on the Github repository<sup>4</sup>.

In our future work, we are planning to move in two directions. First, we plan to extend the vector of features used for representation of documents. Second, we want to add more quantification methods to our open source library.

## Abstract

This paper describes our deep learning-based approach to sentiment analysis in Twitter as part of SemEval-2016 Task 4. We use a convolutional neural network to determine sentiment and participate in all subtasks, i.e. two-point, three-point, and five-point scale sentiment classification and two-point and five-point scale sentiment quantification. We achieve competitive results for two-point scale sentiment classification and quantification, ranking fifth and a close fourth (third and second by alternative metrics) respectively despite using only pre-trained embeddings that contain no sentiment information. We achieve good performance on three-point scale sentiment classification, ranking eighth out of 35, while performing poorly on five-point scale sentiment classification and quantification. An error analysis reveals that this is due to low expressiveness of the model to capture negative sentiment as well as an inability to take into account ordinal information. We propose improvements in order to address these and other issues.

## 1 Introduction

Social media allows hundreds of millions of people to interact and engage with each other, while expressing their thoughts about the things that move them. Sentiment analysis (Pang and Lee, 2008) allows us to gain insights about opinions towards persons, objects, and events in the public eye and is used nowadays to gauge public opinion towards companies or products, to analyze customer satisfaction, and to detect trends.

Its immediacy allowed Twitter to become an important platform for expressing opinions and public discourse, while the accessibility of large quantities of data in turn made it the focal point of social media sentiment analysis research.

Recently, deep learning-based approaches have demonstrated remarkable results for text classification and sentiment analysis (Kim, 2014) and have performed well for phrase-level and message-level sentiment classification (Severyn and Moschitti, 2015).

Past SemEval competitions in Twitter sentiment analysis (Rosenthal et al., 2014; Rosenthal et al., 2015) have contributed to shape research in this field. SemEval-2016 Task 4 (Nakov et al., 2016) is no exception, as it introduces both quantification and five-point-scale classification tasks, neither of which have been tackled with deep learning-based approaches before.

We apply our deep learning-based model for sentiment analysis to all subtasks of SemEval-2016 Task 4: three-point scale message polarity classification (subtask A), two-point and five-point scale topic sentiment classification (subtasks B and C respectively), and two-point and five-point scale topic sentiment quantification (subtasks D and E respectively).

Our model achieves excellent results for subtasks B and D, ranks competitively for subtask A, while performing poorly for subtasks C and E. We perform an error analysis of our model to obtain a better understanding of strengths and weaknesses of a deep learning-based approach particularly for these new tasks and subsequently propose improvements.

## 2 Related work

Deep-learning based approaches have recently dominated the state-of-the-art in sentiment analysis. Kim (2014) uses a one-layer convolutional neural network to achieve top performance on various sentiment analysis datasets, demonstrating the utility of pre-trained embeddings.

State-of-the-art models in Twitter sentiment analysis leverage large amounts of data accessible on Twitter to further enhance their embeddings by treating smileys as noisy labels (Go et al., 2009); Tang et al. (2014) learn sentiment-specific word embeddings from such distantly supervised data and use these as features for supervised classification, while Severyn and Moschitti (2015) use distantly supervised data to fine-tune the embeddings of a convolutional neural network.

In contrast, we observe distantly supervised data not to be as important for some tasks as long as sufficient training data is available.

## 3 Model

The model architecture we use is an extension of the CNN structure used by Collobert et al. (2011).

The model takes as input a text, which is padded to length  $n$ . We represent the text as a concatenation of its word embeddings  $x_{1:n}$  where  $x_i \in \mathbb{R}^k$  is the  $k$ -dimensional vector of the  $i$ -th word in the text.

The convolutional layer slides filters of different window sizes over the word embeddings. Each filter with weights  $w \in \mathbb{R}^{hk}$  generates a new feature  $c_i$  for a window of  $h$  words according to the following operation:

$$c_i = f(w \cdot x_{i:i+h-1} + b) \quad (1)$$

Note that  $b \in \mathbb{R}$  is a bias term and  $f$  is a non-linear function, ReLU (Nair and Hinton, 2010) in our case. The application of the filter over each possible window of  $h$  words or characters in the sentence produces the following feature map:

$$c = [c_1, c_2, \dots, c_{n-h+1}] \quad (2)$$

Max-over-time pooling in turn condenses this feature vector to its most important feature by taking its maximum value and naturally deals with variable input lengths.

A final softmax layer takes the concatenation of the maximum values of the feature maps produced by all filters and outputs a probability distribution over all output classes.

## 4 Methodology

### 4.1 Datasets

For every subtask, the organizers provide a training, development, and development test set for training and tuning. We use the concatenation of the training and development test set for each subtask for training and use the development set for validation.

Additionally, the organizers make training and development data from SemEval-2013 and trial data from 2016 available that can be used for training and tuning for subtask A and subtasks B, C, D, and E respectively. We experiment with adding these datasets to the respective subtask. Interestingly, adding them slightly increases loss on the validation set, while providing a significant performance boost on past development test sets, which we view as a proxy for performance on the 2016 test set. For this reason, we include these datasets for training of all our models.

We notably do not select the model that achieves the lowest loss on the validation set, but choose the one that maximizes the  $F_1^{PN}$  score, i.e. the arithmetic mean of the  $F_1$  of positive and negative tweets, which has historically been used to evaluate the SemEval message polarity classification subtask. We observe that the lowest loss does not necessarily lead to the lowest  $F_1^{PN}$ , as it does not include  $F_1$  of neutral tweets.

### 4.2 Pre-processing

For pre-processing, we use a script adapted from the pre-processing script<sup>1</sup> used for training GloVe vectors (Pennington et al., 2014). Besides normalizing urls and mentions, we notably normalize happy and sad smileys, extract hashtags, and insert tags for repeated, elongated, and all caps characters.

### 4.3 Word embeddings

Past research (Kim, 2014; Severyn and Moschitti, 2015) found a good initialization of word embed-

<sup>1</sup><http://nlp.stanford.edu/projects/glove/preprocess-twitter.rb>

dings to be crucial in training an accurate sentiment model.

We thus evaluate the following evaluation schemes: random initialization, initialization using pre-trained GloVe vectors, fine-tuning pre-trained embeddings on a distantly supervised corpus (Severyn and Moschitti, 2015), and fine-tuning pre-trained embeddings on 40k tweets with crowd-sourced Twitter annotations. Perhaps counter-intuitively, we find that fine-tuning embeddings on a distantly supervised or crowd-sourced corpus does not improve performance on past development test sets when including the additionally provided data for training. We hypothesize that additional training data facilitates learning of the underlying semantics, thereby reducing the need for sentiment-specific embeddings. Our scores partially echo this theory.

For this reason, we initialize our word embeddings simply with 200-dimensional GloVe vectors trained on 2B tweets. Word embeddings for unknown words are initialized randomly.

#### 4.4 Hyperparameters and pre-processing

We tune hyperparameters over a wide range of values via random search on the validation set. We find that the following hyperparameters, which are similar to ones used by Kim (2014), yield the best performance across all subtasks: mini-batch size of 10, maximum sentence length of 50 tokens, word embedding size of 200 dimensions, dropout rate of 0.3,  $l_2$  regularization of 0.01, filter lengths of 3, 4, and 5 with 100 filter maps each.

We train for 15 epochs using mini-batch stochastic gradient descent, the Adadelta update rule (Zeiler, 2012), and early stopping.

#### 4.5 Task adaptation and quantification

To adapt our model to the different tasks, we simply adjust the number of output neurons to conform to the scale used in the task at hand (two-point scale in subtasks B and D, three-point scale in subtask A, five-point scale in subtasks C and E).

We perform a simple quantification for subtasks D and E by aggregating the classified tweets for each topic and reporting their distribution across sentiments. We would thus expect our results on subtasks B and D and results on subtasks C and E to be closely correlated.

| Metric     | Our score    | Best score   | Rank  |
|------------|--------------|--------------|-------|
| $F_1^{PN}$ | <b>0.593</b> | <b>0.633</b> | 8/34  |
| $R^{PN}$   | 0.616        | 0.670        | 12/34 |
| $Acc^{PN}$ | 0.635        | 0.646        | 5/34  |

**Table 1:** Our score and rank for subtask A for each metric compared to the best team’s score (results for official metric in bold).

|   | 2013  |       | 2014  |       |       | 2015  |
|---|-------|-------|-------|-------|-------|-------|
|   | TW    | SMS   | TW    | TW    | LJ    | TW    |
| + | 72.49 | 66.73 | 76.84 | 64.52 | 69.08 | 65.56 |

| = | 67.53 | 77.83 | 65.51 | 45.71 | 67.28 | 65.23 |

**Table 2:**  $F_1$  scores of our model for positive, negative, and neutral tweets for each progress dataset of subtask A. TW: Tweet. /s: sarcasm. LJ: Live Journal. +: positive. -: negative. =: neutral.

## 5 Evaluation

We report results of our model in Tables 1 and 2 (subtask A), Table 3 (subtask B), Tables 5 and 6 (subtask C), Table 4 (subtask D), and Table 7 (subtask E). For some subtasks, the organizers make available alternative metrics. We observe that the choice of the scoring metric influences results considerably, with our system always placing higher if ranked by one of the alternative metrics.

**Subtask A.** We obtain competitive performance on subtask A in Table 1. Analysis of results on the progress test sets in Table 2 reveals that our system achieves competitive  $F_1$  scores for positive and neutral tweets, but only low  $F_1$  scores for negative tweets due to low recall. This is mirrored in Table 1, where we rank higher for accuracy than for recall. The scoring metric for subtask A,  $F_1^{POS}$  accentuates  $F_1$  for positive and negative tweets, thereby ignoring our good performance on neutral tweets and leading to only mediocre ranks on the progress test sets for our system.

**Subtasks B and D.** We achieve a competitive fifth rank for subtask B by the official recall metric in Table 3. However, ranked by  $F_1$  (as in subtask A), we place third – and second if ranked by accuracy. Similarly, for subtask D, we rank fourth (with a differential of 0.001 to the second rank) by  $KLD$ , but second and first if ranked by  $AE$  and  $RAE$  respectively. Jointly, these results demonstrate that classifi-

| Metric | Our score    | Best score   | Rank        |
|--------|--------------|--------------|-------------|
| $R$    | <b>0.767</b> | <b>0.797</b> | <b>5/19</b> |
| $F_1$  | 0.786        | 0.799        | 3/19        |
| $Acc$  | 0.864        | 0.870        | 2/19        |

**Table 3:** Our score and rank for subtask B for each metric compared to the best team’s score (results for official metric in bold).

| Metric | Our score    | Best score   | Rank        |
|--------|--------------|--------------|-------------|
| $KLD$  | <b>0.054</b> | <b>0.034</b> | <b>4/14</b> |
| $AE$   | 0.085        | 0.074        | 2/14        |
| $RAE$  | 0.423        | 0.423        | 1/14        |

**Table 4:** Our score and rank for subtask D for each metric compared to the best team’s score (results for official metric in bold).

cation performance is a good indicator for quantification without using any more sophisticated quantification methods. These results are in line with past research (Kim, 2014) showcasing that even a conceptually simple neural network-based approach can achieve excellent results given enough training data per class. These results also highlight that embeddings trained using distant supervision, which should be particularly helpful for this task as they are fine-tuned using the same classes, i.e. positive and negative, are not necessary given enough data.

**Subtasks C and E.** We achieve mediocre results for subtask C in Table 5, only ranking sixth – however, placing third by the alternative metric. Similarly, we only achieve an unsatisfactory eighth rank for subtask E in Table 7. An error analysis for subtask C in Table 6 reveals that the model is able to differentiate between neutral, positive, and very positive tweets with good accuracy. However, similarly to results in subtask A, we find that it lacks expressiveness for negative sentiment and completely fails to capture very negative tweets due to their low number in the training data. Additionally, it is unable to take into account sentiment order to reduce error for very positive and very negative tweets.

| Metric    | Our score    | Best score   | Rank        |
|-----------|--------------|--------------|-------------|
| $MAE^M$   | <b>1.006</b> | <b>0.719</b> | <b>6/11</b> |
| $MAE^\mu$ | 0.607        | 0.580        | 3/11        |

**Table 5:** Our score and rank for subtask C for each metric compared to the best team’s score (results for official metric in bold).

| Sentiment | -2   | -1   | 0    | 1    | 2    |
|-----------|------|------|------|------|------|
| $MAE^M$   | 2.09 | 1.29 | 0.78 | 0.17 | 0.71 |

**Table 6:** Macro-averaged mean absolute error ( $MAE^M$ ) of our model for each sentiment class for subtask C. Lower error is better.

| Metric | Our score    | Best score   | Rank        |
|--------|--------------|--------------|-------------|
| $EMD$  | <b>0.366</b> | <b>0.243</b> | <b>8/10</b> |

**Table 7:** Our score and rank for subtask E compared to the best team’s score.

## 5.1 Improvements

We propose different improvements to enable the model to better deal with some of the encountered challenges.

**Negative sentiment.** The easiest way to enable our model to better capture negative sentiment is to include more negative tweets in the training data. Additionally, using distantly supervised data for fine-tuning embeddings would likely have helped to mitigate this deficit. In order to allow the model to better differentiate between different sentiments on a five-point scale, it would be interesting to evaluate ways to create a more fine-grained distantly supervised corpus using e.g. a wider range of smileys and emoticons or certain hashtags indicating a high degree of elation or distress.

**Ordinal classification.** Instead of treating all classes as independent, we can enable the model to take into account ordinal information by simply modifying the labels as in (Cheng et al., 2008). A more sophisticated approach would organically integrate label-dependence into the network.

**Quantification.** Instead of deriving the topic-level sentiment distribution by predicting tweet-level sentiment, we can directly minimize the Kullback-Leibler divergence for each topic. If the feedback from optimizing this objective proves to be too indirect to provide sufficient signals, we can jointly optimize tweet-level as well as topic-level sentiment as in (Kotzias, 2015).

## 6 Conclusion

In this paper, we have presented our deep learning-based approach to Twitter sentiment analysis for two-point, three-point, and five-point scale sentiment classification and two-point and five-point

scale sentiment quantification. We reviewed the different aspects we took into consideration in creating our model. We rank fifth and a close fourth (third and second by alternative metrics) on two-point scale classification and quantification despite using only pre-trained embeddings that contain no sentiment information. We analysed our weaker performance on three-point scale sentiment classification and five-point scale sentiment classification and quantification and found that the model lacks expressiveness to capture negative sentiment and is unable to take into account class order. Finally, we proposed improvements to resolve these deficits.

## Abstract

This paper describes our sentiment classification system for microblog-sized documents, and documents where a topic is present. The system consists of a soft-voting ensemble of a `word2vec` language model adapted to classification, a convolutional neural network (CNN), and a long-short term memory network (LSTM). Our main contribution consists of a way to introduce topic information into this model, by concatenating a topic embedding, consisting of the averaged word embedding for that topic, to each word embedding vector in our neural networks. When we apply our models to SemEval 2016 Task 4 subtasks A and B, we demonstrate that the ensemble performed better than any single classifier, and our method of including topic information achieves a substantial performance gain. According to results on the official test sets, our model ranked 3rd for  $F^{PN}$  in the message-only subtask A (among 34 teams) and 1st for accuracy on the topic-dependent subtask B (among 19 teams).

## 1 Introduction

The rapid growth of user-generated content, much of which is sentiment-laden, has fueled an interest in sentiment analysis (Pang and Lee, 2008; Liu, 2010). One popular form of sentiment analysis involves classifying a document into discrete classes, depending on whether it expresses positive or negative sentiment (or neither). The classification can also be dependent

upon a particular topic. In this work, we describe the method we used for the sentiment classification of tweets, with or without a topic.

Our approach to the document classification task consists of an ensemble of 3 classifiers via soft-voting, 2 of which are neural network models. One is the convolutional neural network (CNN) architecture of Kim (2014), and another is a Long Short Term Memory (LSTM)-based network (Hochreiter and Schmidhuber, 1997). Both were first tuned on a distant-labelled data set. The third classifier adapted `word2vec` to output classification probabilities using Bayes' formula, a slightly modified version of Taddy (2015). Despite the `word2vec` classifier being intended as a baseline, and having a small weight in the ensemble, it proved crucial for the ensemble to work well. To adapt our models to the case where a topic is present, in the neural network models, we concatenated the embedding vectors for each word with a topic embedding, which consisted of the element-wise average of all word vectors in a particular topic.

We applied our approach to SemEval 2016 Task 4, including the message-only subtask (Task A) and the topic-dependent subtask (Task B) (Nakov et al., to appear). Our model ranked third for  $F^{PN}$  in the message-only subtask A (among 34 teams) and first for accuracy<sup>1</sup> on the topic-dependent subtask B (among 19 teams).

<sup>1</sup>There were some issues surrounding the evaluation metrics. We only got 7th for  $\rho^{PN}$  and 2nd for  $F^{PN}$  officially, but when we retrained our model using  $\rho^{PN}$  as the subtask intended, we place first across all metrics.

The source code for our approach is available at <https://github.com/stevenxxiu/senti>.

## 2 Models

We now describe the classifiers we used in detail, our ensemble method, and our motivations behind choosing these classifiers.

### 2.1 Convolutional neural network

We used the dynamic architecture of Kim (2014) for our convolutional neural network. This consists of a single 1-d convolution layer with a non-linearity, a max-pooling layer, a dropout layer, and a softmax classification layer.

This model was chosen since it was a good performer empirically. However, due to max-pooling, this model is essentially a bag-of-phrases model, which ignores important ordering information if the tweet contains a long argument, or 2 sentences. We now give a review of the layers used.

#### 2.1.1 Word embedding layer

The input to the model is a document, treated as a sequence of words. Each word can possibly be represented by a vector of occurrences, a vector of counts, or a vector of features. A vector of learnt, instead of hand-crafted features, is also called a word embedding. This tends to have dimensionality  $d \ll |V|$ , the vocabulary size. Hence the vectors are dense, which allows us to learn more functions of features with limited data.

Given an embedding of dimension  $d$ ,  $W_{\text{emb}} \in \mathbf{R}^{d \times |V|}$ , we mapped each document  $s$  to a matrix  $W_{\text{emb},s} \in \mathbf{R}^{d \times |s|}$ , with each word corresponding to a row vector in the order they appear in.  $W_{\text{emb}}$  can be trained.

#### 2.1.2 1-d convolution layer

A 1-d convolution layer aims to extract patterns useful for classification, by sliding a fixed-length filter along the input. The convolution operation for an input matrix  $S \in \mathbf{R}^{d \times |s|}$  and a single filter  $F \in \mathbf{R}^{d \times m}$  of width  $m$  creates a feature  $y_{\text{conv}} \in \mathbf{R}^{|s|+m-1}$  by:

$$y_{\text{conv},i} = \sum_{k,j} (S_{[:,i:i+m-1]} \odot F)_{k,j} + b_{\text{conv}}$$

where  $\odot$  is element-wise multiplication, and  $b_{\text{conv}}$  is a bias. There are typically  $n > 1$  filters, which by stacking the feature vectors, results in  $Y_{\text{conv}} \in \mathbf{R}^{n \times (|s|+m-1)}$ . Each filter has its own separate bias.

We used a common modification to the filter sliding, by padding the document embedding matrix with  $m - 1$  zeroes on its top and bottom. This is done so that every word in the document is covered by  $m$  filters.

#### 2.1.3 Max pooling layer

There may be very few phrases targeted by a feature map in the document. For this reason, we only need to know if the desired feature is present in the document, which can be obtained by taking the maximum. Formally, we obtain a vector  $d \in \mathbf{R}^n$ , such that:

$$y_{\text{pool},i} = \max_j Y_{\text{conv},i,j}$$

#### 2.1.4 Softmax layer

To convert our features into classification probabilities, we first use a dense layer, defined by:

$$y_{\text{dense}} = W_{\text{dense}} \cdot y_{\text{pool}} + b_{\text{dense}}$$

with a softmax activation function:

$$\text{softmax}(x)_i = \frac{e^{x_i}}{\sum_i e^{x_i}}$$

such that the output dimension is the same as the number of classes. Note that output values are non-negative and sum to 1, which form a discrete probability distribution.

#### 2.1.5 Regularization

To regularize our CNN model, dropout (Srivastava et al., 2014) is used after the max pooling layer. Intuitively, dropout assumes that we can still obtain a reasonable classification even when some of the features are dropped. To do this, each dimension is randomly set to 0 using a Bernoulli distribution  $B(p)$ . In order to have the training and testing to be of the same order, the test outputs can be scaled by  $p$ .

The softmax layer for the CNN model also uses a form of empirical Bayes regularization, where each row of  $W_{\text{soft}}$  is restricted using an  $\ell_2$

norm, by re-normalizing the vector if the norm threshold is exceeded.

## 2.2 Long short term memory network

We used an LSTM for our recurrent architecture, which consisted of an embedding layer, LSTM layer, and a softmax classification layer.

A recurrent neural network is a neural network designed for sequential problems. Even simple RNNs are Turing complete, and they can theoretically obtain information from the entire sequence instead of only an unordered bag of phrases. But finding good architectures which can capture this and training them can be difficult. Indeed, there were many instances where our LSTM failed to capture important ordering information. We now give a brief review of the LSTM.

Given an input sequence  $x = [x_1, \dots, x_T]$ , a recurrent network defines an internal state function  $f_c$  and an output function  $f_y$  to iterate over  $x$ , so that at time step  $t$ :

$$\begin{aligned} c_t &= f_c(x_t, y_{t-1}, c_{t-1}) \\ y_t &= f_y(x_t, y_{t-1}, c_t) \end{aligned}$$

where  $c_0$  and  $y_0$  are initial bias states. The simplest RNN, where:

$$f_y(x_t, y_{t-1}, c_t) = \tanh(W \cdot \begin{bmatrix} x_t \\ y_{t-1} \end{bmatrix})$$

suffers from the gradient vanishing and exploding problem (Hochreiter and Schmidhuber, 1997). In particular, products of saturated tanh activations can vanish the gradient, and products of  $W$  can vanish or explode the gradient.

The LSTM is a way to remedy this (Hochreiter and Schmidhuber, 1997). It sets:

$$\begin{aligned} i_t &= \sigma_i(W_{xi}x_t + W_{hi}h_{t-1} + w_{ci} \odot c_{t-1} + b_i) \\ f_t &= \sigma_f(W_{xf}x_t + W_{hf}h_{t-1} + w_{cf} \odot c_{t-1} + b_f) \\ c_t &= f_t \odot c_{t-1} + i_t \odot \sigma_c(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \\ y_t &= \sigma_o(W_{xo}x_t + W_{ho}h_{t-1} + w_{co} \odot c_t + b_o) \odot \sigma_h(c_t) \end{aligned}$$

Here,  $W_\bullet$  is made up of weights;  $i_t, f_t, c_t, y_t$  are the input gates, forget gates, cell states and output states. Cell states have an identity

activation function. The gradient will not vanish if input  $x_i$  needs to be carried to  $x_j$ , since this can only happen when the forget gates are near 1. However, gradient explosion can still be present. We use the common approach of cutting off gradients above a threshold for the gradients inside  $\sigma_i, \sigma_f, \sigma_c, \sigma_o$ .

To use the LSTM, we first used a document embedding matrix in the same manner as our convolutional neural network architecture. This was fed into to an LSTM layer. The output for the final timestep of the LSTM layer was then fed into a final softmax layer with the appropriate output size for classification.

We also experimented with a similar and commonly used network, the Gated Recurrent Network (GRU), but it was not used due to lower results compared to the LSTM.

## 2.3 word2vec Bayes

Our `word2vec` Bayes model is our baseline model, and described in Taddy (2015), with the inclusion of a class prior. Taddy (2015) uses Bayes formula to compute the probabilities of a document belonging to a sentiment class. Given a document  $d$ , its words  $\{w\}_i$ , label  $y$ , Bayes formula is:

$$p(y|d) = \frac{p(d|y)p(y)}{p(d)}$$

For classification problems, we can ignore  $p(d)$  since  $d$  is fixed.  $p(d|y)$  is estimated by first training `word2vec` on a subset of the corpus with label  $y$ , then using the skipgram objective composite likelihood as an approximation:

$$\log p(d|y) \approx \sum_{s \in d} \sum_{j=1}^{|s|} \sum_{k=1}^{|s|} 1_{1 \leq |k-j| \leq b} \log p(w_k|w_j, y)$$

We estimated  $p(y)$  via class frequencies, i.e. the MLE for the categorical distribution, compared to Taddy (2015), who used the discrete uniform prior.

This model was chosen since it provides a reasonable baseline, and also appears to be independent enough from our neural networks to provide a performance gain in the ensemble. The `word2vec` based model benefits from being

a semi-supervised method, but it also loses ordering information outside a word’s context window, and the prediction of neighboring words also ignores distance to that word. The limited amount of data for each class is also an issue.

## 2.4 Ensemble

If the errors made by each classifier are independent enough, then combining them in an ensemble can reduce the overall error rate. We used soft voting as a method to combine the outputs of the above classifiers. We define soft voting as:

$$y_{\text{vote}} = \sum_i w_i y_i, \text{ s.t. } \sum_i w_i = 1, \forall i : w_i \geq 0$$

where  $y_i$  is the output of classifier  $i$ .

## 3 Topic dependent models

To adapt our neural networks to topic-dependent sentiment classification, in our neural network models, we augmented each embedding vector by concatenating it with a topic embedding. The motivation behind this approach is to allow the model to interpret each word to be within the context of some topic.

Our topic embeddings were obtained by the element-wise average of word embeddings for each word in that topic. We found that empirically, this is a simple yet effective way of achieving a document embedding. When used directly as a feature vector in logistic regression for sentiment analysis, we have found this to outperform methods described in Le and Mikolov (2014).

Word embeddings of dimension  $d = 300$  pretrained over Google News were used directly, without any further tuning. Words in the tweet which were not present in this pretrained embedding were ignored.

## 4 Experiments and evaluation

We evaluated our models on SemEval 2016 Task 4 subtask A, the message-only subtask, and subtask B, the topic-dependent subtask.

### 4.1 Data

Task A consisted of 3 sentiment classes — POSITIVE, NEUTRAL and NEGATIVE — whilst Task B

consisted of 2 sentiment classes — POSITIVE and NEGATIVE. We only managed to download 90% of the entire set of tweets for the 2016 SemEval data, due to tweets becoming “not available”. In addition to the Twitter data for 2016, for Task A we also used training data from SemEval 2016 Task 10. The data is summarized in Table 1.

To pretrain our network using distant learning (described below), we took a random sample of 10M English tweets from a 5.3TB Twitter dataset crawled from 18 June to 4 Dec, 2014 using the Twitter Trending API. We then processed tweets with a regular expression: tweets which contained emoticons like :) were considered POSITIVE, while those which contained emoticons like :( were considered NEGATIVE; tweets which contained both positive and negative emoticons, or others emoticons such as :—, were ignored. We extracted 1M tweets each for the POSITIVE and NEGATIVE classes.

### 4.2 Evaluation

Evaluation consisted of accuracy, macro-averaged  $F_1$  across the POSITIVE and NEGATIVE classes, which we denote  $F^{PN}$ , and macro-averaged recall across the POSITIVE and NEGATIVE classes, which we denote  $\rho^{PN}$ .

### 4.3 Preprocessing

All methods use the same preprocessing. We normalized the tweets by first replacing URLs with `_url` and author methods such as `@Ladi_ibubblezz` with `_author`. Casing was preserved, as the pretrained `word2vec` vectors included casing. The tweets were tokenized using `twokenize`, with `it's` being split into `it` and `'s`.

### 4.4 Training and hyperparameters

#### 4.4.1 Neural networks

For both our models, we initialized  $W_{\text{emb}}$  to word embeddings pretrained using `word2vec`’s skip-gram model (Mikolov et al., 2013) on the Google News corpus, where  $d = 300$ . Unknown words were drawn from  $U[-0.25, 0.25]$  to match the variance of the pretrained vectors. For the CNN model, we also stripped words so all documents had a length  $\leq 56$ .

| Datset             | A total | A used   | B total | B used |
|--------------------|---------|----------|---------|--------|
| Twitter 2016-train | 6000    | 5465     | 4346    | 3941   |
|                    |         | (+11340) |         |        |
| Twitter 2016-dev   | 2000    | 1829     | 1325    | 1210   |
| Twitter 2016-test  | 2000    | 1807     | 1417    | 1270   |

Table 1: Semeval-2016 data. The NEGATIVE : NEUTRAL : POSITIVE split was 16 : 42 : 42 for all of 2016 Task A used. The NEGATIVE : POSITIVE split was 19 : 81 for all of 2016 Task B used.

For our CNN, we used used 3 1-d convolutions, with filter sizes of 3, 4, 5, each with 100 filters. Our dropout rate was 0.5, and our  $\ell_2$  norm restriction was 3. For our LSTM, we used a cell dimension size of 300, and our activations were chosen empirically to be  $\sigma_i = \sigma_f = \sigma_o = \text{sigmoid}$ ,  $\sigma_c = \tanh$ , our gradient cutoff was 100.

To train our neural networks, we used cross entropy loss and minibatch gradient descent with a batch size of 64. For our CNN, we used the adadelta (Zeiler, 2012) gradient descent method with the default settings. For our LSTM, we used the rmsprop gradient descent method with a learning rate of 0.01.

Due to limited training data, we can use distant learning (Severyn and Moschitti, 2015), by initializing the weights of our neural networks by first training them on a silver standard data set (generated using Twitter emoticons which we describe below), then tuning them further on the gold standard data set (Severyn and Moschitti, 2015). However, we did not use this for our topic-dependent models, as there was no performance gain.

We split the distant data into  $10^4$  tweets per epoch, and took the best epoch on the validation set as the initial weights, using  $F^{PN}$  as our scoring metric. We repeatedly iterated over the SemEval data with  $10^3$  tweets per epoch for  $10^2$  epochs, and again took the best epoch on the validation set as the final weights.

#### 4.4.2 word2vec Bayes

Gensim (Řehůřek and Sojka, 2010) was used to train the word embeddings and obtain  $p(d|y)$ . We used the skipgram objective, with a embedding dimension of 100, window size of 10, hierarchical softmax with 5 samples, 20 training iterations, no frequent word cutoff, and a sam-

| Dataset              | $F^{PN}$            |
|----------------------|---------------------|
| Twitter 2013         | 0.687 <sub>7</sub>  |
| Twitter 2014         | 0.706 <sub>7</sub>  |
| Twitter 2015         | 0.650 <sub>4</sub>  |
| Twitter 2016         | 0.617 <sub>3</sub>  |
| Twitter Sarcasm 2014 | 0.449 <sub>11</sub> |
| SMS 2013             | 0.593 <sub>10</sub> |
| LiveJournal 2014     | 0.683 <sub>9</sub>  |

Table 2: Official test scores and ranks for Task A.

| Dataset      | Val metric  | $\rho^{PN}$        | $F^{PN}$           | Acc                |
|--------------|-------------|--------------------|--------------------|--------------------|
| Twitter 2016 | $F^{PN}$    | 0.758 <sub>7</sub> | 0.788 <sub>2</sub> | 0.870 <sub>1</sub> |
| Twitter 2016 | $\rho^{PN}$ | 0.807 <sub>1</sub> | 0.806 <sub>1</sub> | 0.867 <sub>1</sub> |

Table 3: Test scores and ranks for Task B. The official run incorrectly used  $F^{PN}$  as the validation metric.

ple coefficient of 0.

#### 4.4.3 Soft voting

To find  $w_i$ , we first relaxed the sum condition of  $w_i$  by setting  $w_1 = 1$  and noting that  $\max_k y_{vote,i,k}$  is invariant under scaling. We then used the L-BFGS-B algorithm, with initial weights of 1, combined with basin-hopping for 1000 iterations. We optimized for accuracy, since this most-consistently improved results.

## 5 Results

The official evaluation results are shown in Table 2 and Table 3. The results for Task A suggest that our models are overfitting. Our best position was achieved on the Twitter 2016 dataset, and indeed, this is what our parameters were chosen on.

Our own evaluation of our different classifiers, using Twitter 2016-test, is shown in Table 4 and

| Model                  | Accuracy | $F^{PN}$ |
|------------------------|----------|----------|
| soft voting all        | 0.5772   | 0.6000   |
| lstm                   | 0.5379   | 0.5869   |
| soft voting cnn + lstm | 0.5606   | 0.5848   |
| cnn                    | 0.5612   | 0.5841   |
| <b>word2vec Bayes</b>  | 0.5130   | 0.4983   |

Table 4: Results for Task A, sorted by  $F^{PN}$ .

| Model                  | Accuracy  | $\rho^{PN}$ |
|------------------------|-----------|-------------|
| soft voting all        | 0.8008    | 0.7849      |
| soft voting cnn + lstm | 0.7976    | 0.7846      |
| cnn topic              | 0.8047    | 0.7762      |
| lstm topic             | 0.6756    | 0.7494      |
| - - - - -              | - - - - - | - - - - -   |
| cnn                    | 0.8354    | 0.7253      |
| <b>word2vec Bayes</b>  | 0.7654    | 0.7138      |
| lstm                   | 0.8118    | 0.6916      |

Table 5: Results for Task B, sorted by  $\rho^{PN}$ . The dashed line separates topic models from message-only models. The lstm topic model has poorer accuracy due to being optimized on  $\rho^{PN}$ .

Table 5. Taking into account all evaluation metrics, we can see that in both tasks, our CNN outperforms our LSTM, in Task A slightly and in Task B substantially. The **word2vec** Bayes model is worse than both, moreso in Task B.

Soft voting outperforms all classifiers, showing that there is some independence amongst the errors made. In Task A, there appears to be more correlation between the CNN and LSTM classifiers, as excluding the **word2vec** Bayes model reduces the performance. In Task B, the **word2vec** Bayes model appears to perform too poorly to provide a marked benefit.

From Table 5 we can see that the inclusion of topic information provides a substantial boost to both of our neural networks. This shows that our method of incorporating topic information is a useful way of modifying neural networks, and provides a strong baseline for alternative ways of doing this.

## 6 Conclusions

We described our ensemble approach to sentiment analysis both the task of topic-dependent document classification and document classifi-

cation by itself. We gave a detailed description of how to modify our classifiers to be topic-dependent. The results show that ensembles can work for neural nets, and that our way of including topics achieves performance gains, and forms a good basis for future research in this area.

# SentiSys at SemEval-2016 Task 4: Feature-Based System for Sentiment Analysis in Twitter

Hussam Hamdan

Aix-Marseille University

hamdan.hussam@gmail.com

## Abstract

This paper describes our sentiment analysis system which has been built for Sentiment Analysis in Twitter Task of SemEval-2016. We have used a Logistic Regression classifier with different groups of features. This system is an improvement to our previous system Lsislif in Semeval-2015 after removing some features and adding new features extracted from a new automatic constructed sentiment lexicon.

## 1 Introduction

Sentiment analysis in Twitter is different from document level sentiment analysis. Normally, in document level, each document is classified as positive or negative, the document is long enough to obtain a good representation using only the existing words (bag-of-words). For example, in movie reviews we can get f-score of 85% using bag-of-words representation with SVM classifier while in Twitter it is about 60% according to our experiments in previous SemEval workshops. This lower performance in Twitter domain is not surprising if we know the limitations of such task when applied to Twitter:

- The size of a tweet is limited to 140 characters which leads to sparseness where the tweets do not provide enough word co-occurrence.
- The informal language and non-standard expressions.
- The numerous spelling errors.

For dealing with the previous limitations, we have decided to extend the bag-of-words representation. Therefore, many group of features have been extracted. Uni-gram, bi-gram and 3-grams of words features to capture the text of tweet and the context. Negation features to handle the negated context. Sentiment lexicons features can help the classification because it contains positive and negative words which can add a useful information about the polarity of a tweet, they also contain a lot of terms which may not appear in the training data which can be very useful. Semantic features as Brown clusters can also give a rich representation which can be useful for reducing the sparsity.

For evaluating our system, we have participated in SemEval-2016 competition for sentiment analysis in Twitter (message polarity subtask A)<sup>1</sup> (Nakov et al., 2016). Our system has been ranked six over 34, this system is derived from our previous system LsisLif which has been ranked third in SemEval-2015.

The rest of this chapter is organized as follows. Section 2 presents the problem formulation. Section 3 gives an overview of our proposed approach. The features we extracted for training the classifier are presented in Section 4. Our experiments are described in Section 5. The related work is presented in Section 6. The conclusion and future work are presented in Section 7.

## 2 Problem Formulation

Let  $T = t_1, t_2, \dots, t_n$  be a collection of  $n$  tweets. Each tweet  $t_i$  will be represented by a subset of all

---

<sup>1</sup><http://alt.qcri.org/semeval2016/task4/>

possible features  $F = f_1, f_2, \dots, f_m$  that can appear in  $t_i$ . The features can be single words, bigrams, n-grams, stemmed words or other syntactic or semantic features. If a feature  $f_i$  exists in a tweet  $t_j$ , the tweet can be represented as a vector of weighted features  $t_j = (w_1, w_2, \dots, w_m)$  where  $w_i$  is the weight of the feature  $f_i$  in the tweet  $t_j$ .  $w_i$  can represent the presence or absence of the feature or the frequency or any other function of the feature frequency in the tweet.

Let us have three classes  $C = c_1, c_2, c_3$  where  $c_1$  represents the negative class,  $c_2$  the neutral class and  $c_3$  the positive class. Our task is to assign each tweet  $t_j$  to a class  $c_i$ .

### 3 Overview of the Proposed Approach

Our proposed approach for sentiment polarity classification consists of three steps:

1. We tokenize each tweet to get the feature space which contains the words, punctuations and emoticons that appear in the tweets.
2. We extend the feature space by extracting some features using different resources (Sentiment lexicons, Twitter dictionary) and some semantic features.
3. We train a supervised classifier to get a trained model in order to predict the sentiment of the new tweets.

The next section describes the features we have extracted.

### 4 Feature Extraction

Before extracting the features, we should tokenize the tweet. Tokenization is a challenging problem for Twitter text. Happytokenizer<sup>2</sup> is the tokenizer which we used. It can capture the words, emoticons and punctuations. For example, for this tweet:

”RT @ #happyfuncoding: this is a typical Twitter  
tweet :-”

It returns the following terms:

{rt, @, #happyfuncoding, :, this, is, a, typical,  
twitter, tweet, :-)}

---

<sup>2</sup><http://sentiment.christopherpotts.net/tokenizing.html>

We also replaced each web link by the word *url* and each user name by *uuser*. Then, several groups of features have been extracted to improve the bag-of-words representation.

#### 4.1 Word ngrams

Unigram, bigram and 3-gram are extracted for each term in the tweet without any stemming or stop-word removing, all terms with occurrence less than 3 are removed from the feature space. Therefore, for this tweet:

”i’am going to chapel hill on sat. :)”

The feature vector produced by this group of feature will be:

{”i’m”, ‘going’, ‘to’, ‘chapel’, ‘hill’, ‘on’, ‘sat’, ‘..’, ‘:)’, ”i’m going”, ‘going to’, ‘to chapel’, ‘chapel hill’, ‘hill on’, ‘on sat’, ‘sat .’, ‘. :)’, ”i’m going to”, ‘going to chapel’, ‘to chapel hill’, ‘chapel hill on’, ‘hill on sat’, ‘on sat .’, ‘sat . :)’}.

#### 4.2 Negation Features

The rule-based algorithm presented in Christopher Potts’ Sentiment Symposium Tutorial<sup>3</sup> is implemented. This algorithm appends a negation suffix to all words that appear within a negation scope which is determined by a negation key and a punctuation or a connector belonging to [”, “;”, “：“, “!”, “?”, “but”, “—”, “so”]. All the negated words are added to the feature space. For example, for this tweet:

”I’am not happy”

The feature vector generated by the words n-gram features with negation features is:

{”i’am”, ‘not’, ‘happy\_Neg’, ‘happy’, ”i’am not”, ‘not happy’, ”i’am not happy”}

happy\_NEG is added by the negation features while the others are the ngrams features. Obviously, we have chosen to add the negated feature to the vector without removing the original feature *happy*.

#### 4.3 Twitter Dictionary

We constructed a dictionary for the abbreviations and the slang words used in Twitter in order to overcome the ambiguity of these terms which may increase the similarity between two similar tweets written in two different ways. This dictionary maps

---

<sup>3</sup><http://sentiment.christopherpotts.net/lingstruc.html>

certain Twitter expressions and emotion icons to their meaning or their corresponding sentiment. It contains about 125 terms collected from different pages on the Web. Table 1 shows a part of the dictionary.

| Twitter expression | Meaning                                      |
|--------------------|--|
| :)                 | veryhappy                                    |
| :)                 | veryhappy                                    |
| b/c                | Because                                      |
| FWIW               | For what it's worth                          |
| Gr8                | Great  |
| IMHO               | In my honest opinion or in my humble opinion |
| J/K                | Just kidding                                 |
| LOL                | Laughing out loud funny                      |
| OMG                | Oh my God                                    |
| PLZ                | Please                                       |
| ROFL               | Rolling on the floor laughing                |
| RTHX               | Thanks for the retweet                       |
| hahaha             | laughing funny                               |
| wow                | amazing surprised                            |

Table 1: A part of Twitter dictionary.

All terms presented in a tweet and in the Twitter dictionary are mapped to their corresponding terms in the dictionary and added to the feature space. For this tweet: "i'm going to chapel hill on sat. :)”, the term *veryhappy* will be added to the tweet vector because the emoticon :) will be replaced by *veryhappy* as indicated in the dictionary.

#### 4.4 Semantic Features

The semantic representation of a text may bring some important hidden information, which may result in a better document representation and a better classification system. Usually, the semantic features can help to overcome the problem of sparseness in short text. Externally resources may be important to get such representation.

##### 4.4.1 Brown Dictionary Features

From over 56 million English tweets (837 million tokens), 1000 hierarchical clusters have been constructed over 217 thousand words (Owoputi et al., 2013). Table 2 shows an example of five clusters.

| Cluster | Top words (by frequency)   |
|---------|--|
| A1      | lmao lmfao lmaoo lmaooo hahahahaha lol ctfl rofl lmfao lmfaooo lmbolololol     |
| A2      | haha hahaha hehe hahahaha hahah aha hehehe ahaha hab hahahah kk hahaha ahah    |
| A3      | yes yup yup nope yess yessss ofcourse yeap likewise yepp yesh yw yupp yus      |
| A4      | yeah yea nah naw yeahhh nooo yeah nooo yeahaa ikr nvn yeahhhh nahh nooooo      |
| A5      | smh jk #fail #random #fact smfh #smh #winning #realtalk smdh #dead #justsaying |

Table 2: Example Twitter word clusters: we list the most probable words, starting with the most probable, in descending order.

Note that in cluster A1, the term lololol (an extension of lol for “laughing out loud”) is grouped with a large number of laughter acronyms.

Each word in the text is mapped to its cluster in Brown dictionary, 1000 features are added to feature space where each feature represents the number of words in the text belonging to each cluster.

#### 4.5 Sentiment Lexicons

The system extracts four features from the manual constructed lexicons and six features from the automatic ones. For each sentence the number of positive words, the number of negative ones, the number of positive words divided by the number of negative ones and the polarity of the last word are extracted from manual constructed lexicons. In addition to the sum of the positive scores and the sum of the negative scores from the automatic constructed lexicons.

The manual lexicons are: MPQA Subjectivity Lexicon<sup>4</sup> and Bing Liu Lexicon<sup>5</sup>. The automatic ones are: NRC Hashtag Sentiment Lexicon and our lexicon based on natural entropy measure (Hamdan et al., 2015c).

Thus, this feature group adds 20 features to the tweet vector, some of this features are integer numbers others are floats. The lexicons which we used are the following:

##### 4.5.1 Manually Constructed Sentiment Lexicons

Two manual constructed lexicons have been exploited:

###### 1. MPQA Subjectivity Lexicon

Multi-Perspective Question Answering Subjectivity Lexicon is maintained by (Wilson et al., 2005), a lexicon of over 8,000 subjectivity single-word clues, each clue is classified as positive or negative. This is a fragment illustrating this lexicon structure:

| Strength | Length | Word        | Part-of-speech | Stemmed | priorpolarity |
|----------|--------|-------------|----------------|---------|---------------|
| weaksubj | 1      | abandoned   | adj            | n       | negative      |
| weaksubj | 1      | abandonment | noun           | n       | negative      |
| weaksubj | 1      | abandon     | verb           | y       | negative      |

###### 2. Bing Liu Lexicon

A list of positive and negative opinion words or sentiment words for English (around 6800

<sup>4</sup>[http://mpqa.cs.pitt.edu/lexicons/subj\\_lexicon/](http://mpqa.cs.pitt.edu/lexicons/subj_lexicon/)

<sup>5</sup><http://www.cs.uic.edu/~liub/FBS/sentiment-analysis.html#lexicon>

words). This list was compiled over many years starting from this paper (Hu and Liu, 2004a). These are the first three words in each class of this lexicon:

| Positive  | Negative   |
|-----------|------------|
| abound    | abnormal   |
| abounds   | abolish    |
| abundance | abominable |

#### 4.5.2 Automatic Constructed Sentiment Lexicons

Three automatic constructed lexicon have been exploited:

##### 1. NRC Hashtag Sentiment Lexicon

NRC Hashtag Sentiment Lexicon (Mohammad, 2012) contains tweet terms with scores, positive score indicates association with positive sentiment, whereas negative score indicates association with negative sentiment. It has entries for 54,129 unigrams and 316,531 bigrams; the scores were computed using PMI over corpus of tweets. Here are the first and the last three lines of the unigrams NRC lexicon file:

| Term          | Score  | #positive | #negative |
|---------------|--------|-----------|-----------|
| #fabulous     | 7.526  | 2301      | 2         |
| #excellent    | 7.247  | 2612      | 3         |
| #superb       | 7.199  | 1660      | 2         |
| ipad2         | -6.615 | 1         | 1205      |
| #dreadful     | -6.764 | 1         | 1398      |
| #unacceptable | -6.925 | 2         | 3284      |

*Score* is a real number indicates the sentiment score. *#positive* is the number of times the term co-occurred with a positive marker such as a positive emoticon or a positive hashtag. *#negative* is the number of times the term co-occurred with a negative marker such as a negative emoticon or a negative hashtag.

#### 4.6 Our Sentiment Lexicon

PMI metric has been widely used to compute the semantic orientation of words in order to construct the automatic lexicons. Sentiment140 lexicon is constructed using semantic orientation on Sentiment140 corpus (Go et al., 2009), a collection of 1.6 million

tweets that contain positive and negative emoticons<sup>6</sup>. But this corpus is a balanced corpus, it contains the same number of positive and negative tweets. Therefore, semantic orientation can be rewritten as following:

$$SO(w) = PMI(w, +) - PMI(w, -) = \log\left(\frac{p(w,+)}{p(w).p(+)}\right) - \log\left(\frac{p(w,-)}{p(w).p(-)}\right) \quad (1)$$

As  $p(+) = p(-) = 0.5$  in the balanced corpus:

$$So(w) = 1 + \log(p(+|w)) - 1 - \log(p(-|w)) = \log(a/c) \quad (2)$$

where + stands for the positive class, - stands for negative class,  $a$  is the number of documents containing the word  $w$  in the positive class,  $c$  is the number of documents containing the word  $w$  in the negative class. Thus, the semantic orientation is positive if  $a > c$  else it is negative. We should note that the probability of the classes does not affect the final semantic orientation score, therefore we propose another metric which depends on the distribution of the word over the classes which seems more relevant in the balanced corpus.

We constructed a lexicon from sentiment140 corpus, we calculated Natural Entropy (ne) score for each term in this manner:

$$ne(w) = 1 - (- (p(+|w).log(p(+|w)) - p(-|w).log(p(-|w)))) \quad (3)$$

where

$p(+|w)$ : The probability of the positive class given the word  $w$ .

$p(-|w)$ : The probability of the negative class given the word  $w$ .

The more uneven the distribution of documents where a term occurs, the larger the Natural Entropy of this term is. Thus, the entropy of the term can express the uncertainty of the classes given the term. One minus this degree of uncertainty boosts the terms that unevenly distributed between the two classes (Wu and Gu, 2014). *ne* score is always between 0 and 1, and it assigns a high score for the words unevenly distributed over the classes, but it cannot discriminate the positive words from the negative ones. Therefore, we have used the  $a$  and  $c$  for discriminating the positive words from the negative ones; if  $a > c$  then the word is considered positive else it is considered negative.

---

<sup>6</sup><http://help.sentiment140.com/for-students>

Using this lexicon instead of sentiment140 can improve the performance of a state-of-the-art sentiment classifier as shown in (Hamdan et al., 2015c).

## 5 Experiments and Results

### 5.1 Twitter Dataset

Twitter datasets have been provided by SemEval organizers since 2013 for message polarity classification subtask of sentiment analysis in Twitter (Nakov et al., 2013). The participants have been provided with training tweets annotated positive, negative or neutral. In addition to a script for downloading the tweets. After executing the given script, we got the whole training dataset which consists of 9684 tweets. The organizers have also provided a development set containing 1654 tweets for tuning a machine learner. Table 3 shows the distribution of each label in each dataset.

| Data      | All  | Positive | Negative | Neutral |
|-----------|------|----------|----------|---------|
| train     | 9684 | 3640     | 1458     | 4586    |
| dev       | 1654 | 739      | 340      | 575     |
| test-2016 | -    | -        | -        | -       |

**Table 3:** Sentiment labels distribution in the training, testing and development datasets in Twitter.

### 5.2 Experiment Setup

We trained the L1-regularized logistic regression classifier implemented in LIBLINEAR (Fan et al., 2008), we had also tested L2 regularization technique but it gives less performance than L1. The classifier is trained on the training dataset using the features in the previous section with the three polarities (positive, negative, and neutral) as labels. A weighting schema is adapted for each class, we use the weighting option  $-w_i$  which enables a use of different cost parameter  $C$  for different classes. Since the training data is unbalanced, this weighting schema adjusts the probability of each label. Thus, we tuned the classifier in adjusting the cost parameter  $C$  of logistic regression, weight  $w_{pos}$  of positive class and weight  $w_{neg}$  of negative class. We used the development set for tuning the three parameters, all combinations of  $C$  in range [0.1 .. 4] by step of 0.1,  $w_{pos}$  in range [1 .. 8] by step of 0.1,  $w_{neg}$  in range [1 .. 8] by step of 0.1 are tested. The combination

$C=0.3$ ,  $w_{pos}=7.6$ ,  $w_{neg}=5.2$  have given the best F1-score for the development set and therefore it was selected for our experiments on test set 2016.

### 5.3 Results

The evaluation score used by the task organizers was the averaged F1-score of the positive and negative classes. In the SemEval-2016 competition, our submission is ranked six (59.8%) over 34 submissions while it was ranked third in SemEval-2015.

Table 4 shows the results of our experiments after removing a feature group at each run for the four test set 2016.

| Run          | Test-2016 |
|--------------|-----------|
| All features | 59.8      |
| all-lexicons | 56.9      |
| all-ngram    | 58.1      |
| all-brown    | 58.4      |

**Table 4:** The F1 score for each run, All features run exploits all features while the others remove a feature group at each run lexicons, n-gram and brown cluster, respectively.

The results show that the sentiment lexicons features are the most important ones which conforms with the conclusion in different studies (Hamdan et al., 2015c; Mohammad et al., 2013).

## 6 Related Work

There are two principally different approaches to opinion mining: lexicon-based and supervised. The lexicon-based approach goes from the word level in order to constitute the polarity of the text. This approach depends on a sentiment lexicon to get the word polarity score. While the supervised approach goes from the text level and learn a model which assigns a polarity score to the whole text, this approach needs a labeled corpus to learn the model.

### 6.1 Lexicon-Based Approach

Lexicon-based approaches decide the polarity of a document based on sentiment lexicons. The sentiment of a text is a function of the common words between the text and the sentiment lexicons.

Much of the first lexicon-based research has focused on using adjectives as indicators of the seman-

tic orientation of text (Hatzivassiloglou and McKeown, 1997; Hu and Liu, 2004b). (Taboada et al., 2011) proposed another function called SO-CAL (Semantic Orientation CALculator) which uses dictionaries of words annotated with their semantic orientation (polarity and strength), and incorporates intensification and negation.

Thus, the sentiment lexicon is the most important part of this approach. Three different ways can be used to construct such lexicons: Manual Approach, Dictionary-Based Approach and Corpus-Based Approach.

## 6.2 Supervised Approach

The supervised approach is a machine learning approach. Sentiment classification can be seen as a text classification problem (Pang et al., 2002; Liu, 2012).

The research papers in sentiment classification have mainly focused on the two steps: document representation and classification methods.

While some papers have extended the bag-of-word representation by adding different types of features (Pang et al., 2002; Mohammad et al., 2013; Hamdan et al., 2013; Hamdan et al., 2015c), others have proposed different weighting schemas to weight the features such as PMI, Information Gain and chi-square  $\chi^2$  (Martineau and Finin, 2009; Pal-toglu and Thelwall, 2010; Deng et al., 2014). Recently, after the success of deep learning techniques in many classification systems, several studies have learned the features instead of extracting them (Socher et al., 2013; Severyn and Moschitti, 2015).

The work of (Pang et al., 2002) was the first to apply this approach to classify the movie reviews into two classes positive or negative. They tested several classifiers (Naive Bayes, SVM, Maximum entropy) with several features.

Later on, many studies have proposed different features and some feature selection methods to choose the best feature set. Many features have been exploited :

- Terms and their weights: The features are the unigrams or n-grams with the associated frequency or weight given by a weighting schema like TF-IDF or PMI.
- Part of Speech (POS): The words can indicate

different sentiment according to their parts of speech (POS). Some papers treated the adjectives as special features.

- Sentiment Lexicons: The words and expressions which express an opinion have been used to add additional features as the number of positive and negative terms.
- Sentiment Shifters: The terms that are used to change the sentiment orientation, from positive to negative or vice versa such as *not* and *never*. Taking into account these features can improve the sentiment classification.
- Semantic Features: The named entities, concepts and topics have been extracted to get the semantic of the text.

Many systems which have worked on feature extraction have achieved a state-of-the-art performance in many competitions like SemEval<sup>7</sup>. For example, (Mohammad et al., 2013) used SVM model with several types of features including terms, POS and sentiment lexicons in Twitter data set. (Hamdan et al., 2015a; Hamdan et al., 2015c; Hamdan et al., 2015b) have also proved the importance of feature extraction with logistic regression classifier in Twitter and reviews of restaurants and laptops. They extracted terms, sentiment lexicon and some semantic features like topics. And (Hamdan et al., 2013) has proposed to extract the concepts from DBpedia.

Recently, some research papers have applied deep learning techniques to sentiment classification. (Socher et al., 2013) proposed to use recursive neural network to capture the compositionality in the phrases, (Tang et al., 2014) combined the hand-crafted features with learned features. They used neural network for learning sentiment-specific word embedding, then they combined hand-crafted features with these word embedding to produce a state-of-the-art system in sentiment analysis in Twitter. (Kim, 2014) proposed a simple convolutional neural network with one layer of convolution which performs remarkably well. Their results add to the well-established evidence that unsupervised pre-training of word vectors is an important ingredient in deep learning for Natural language processing.

## 7 Conclusion and Future Work

In this paper, we tested the impact of combining several groups of features on the sentiment classification of tweets. A logistic regression classifier with weighting schema was used, the sentiment lexicon-based features seem to get the most influential effect with the combination.

As the sentiment lexicons features seem to be so important in sentiment classification, we think that it is important to orient our future work on this direction. Improving the automatic construction of sentiment lexicons may lead to an important improvement on sentiment classification. For example, taking the context in the consideration may help such process. Another important direction is using deep learning techniques which have recently proved their performance in several studies. Thus, we can learn the features instead of extracting them.

## Abstract

This paper contains the description of our participation at task 4 (sub-task A, Message Polarity Classification) of SemEval-2016. Our proposed system consists mainly of three steps. Firstly, the preprocessing step includes the tokenization and identification of special elements including URLs, hashtags, user mentions and emoticons. The second step aims at selecting and extracting the feature set. Finally, a supervised approach, in particular a Support Vector Machine has been applied to tackle the classification problem.

## 1 Introduction

In the last few years, Twitter has become a source of a huge amount of information which introduces endless possibilities of research in the field of Sentiment Analysis. Sentiment Analysis, also called Opinion Mining, is a research area within Natural Language Processing whose aim is to identify the underlying emotion of a certain document, sentence or aspect (Liu, 2012). As a case in point, Opinion Mining has been applied for recognizing reviews as recommended or not recommended (Turney, 2002) and for generating aspect-based summaries (Hu and Liu, 2004).

The goal of SemEval-2016 task 4 (Nakov et al., 2016) consists of categorizing tweets as positive, negative or neutral concerning the opinion that a user holds with regard to a certain topic. One issue to take into consideration is that the language adopted in Social Media, especially in Twitter, needs to be treated differently than normalized language due to the use

of specific characteristics such as users, hashtags, emoticons and slang as well as some linguistic phenomena including sarcasm and irony.

Our system is closely related to (Giménez et al., 2015). Section 2 describes the proposed method which consists mainly of three steps. Firstly, the preprocessing step includes the tokenization and identification of special elements including URLs, hashtags, user mentions and emoticons. The second step aims at selecting and extracting the feature set. Finally, a supervised approach such as Support Vector Machine (SVM) has been applied to tackle the classification problem. In section 3, the experiments carried out are described. Finally, section 4 discusses the results obtained for the different experiments in the tuning phase and in the official competition.

## 2 System Overview

In this section, we describe the steps carried out in this work to achieve the results obtained in Semeval 2016. In this approach, a matrix of occurrences, in which tweets are represented as rows and features as columns, normalized by tf-idf was used to represent whether a certain feature appears or not in a tweet.

### 2.1 Preprocessing

After fetching all the data from Twitter, our corpus needs to be preprocessed. As Twitter makes an extensive use of emoticons, URLs and concrete elements such as @User mentions and #hashtags, some regex are utilized to substitute these mentioned elements of special interest by labels of the form <URL>, <HASH>, <USER> and <EMOTICON> that let us count the amount of ap-

pearances in a certain tweet. Indeed, after tokenizing the tweet, punctuation and stop words are removed.

## 2.2 Feature Set

In this paper, the following features have been tried out although not all were included for the final submission: see section 4

**N-grams** at word-level were selected ranging from 1-grams to 6-grams. These were combined in the experimentation process.

**Skip-grams** at the word level with 2 words and 1 gap between them. As an example, "What an amazing film" will generate the following list of skip-grams [(“What”, “amazing”), (“an”, “film”)]

**K most frequent Skip-grams.** This feature takes the k-most frequent Skip-grams and discards the other ones which are under the k threshold.

### Lexicons

1. Jeffrey (Hu and Liu, 2004): This lexicon contains two sets of words: a positive and a negative word set. From this lexicon we obtain two scores coming from the addition of the positive words appearing in a tweet and, likewise, from the addition of the negative words.
2. NRC Emotion Lexicon (Mohammad and Turney, 2013): This lexicon contains a set of words and a value (0 or 1) expressing whether a word is associated to a certain emotion such as anger, anticipation, disgust, fear, joy, sadness, surprise and sad.

**Twitter Features.** The way of expressing ideas in Twitter as in other social networks differs from the language used in formal writing. That is why we should capture the peculiarities about this language that could be useful for identifying the polarity of a tweet in certain situations.

- **Elongated Words** We count the number of elongated words. For instance, "I love you sooooo much".
- **ALL CAPS** We count the number of words in upper case.
- **#Hashtags.** We count the number of hashtags in a tweet.

Finally, a **tf-idf** normalization was applied in all the selected features.

## 2.3 Classification

In this work, we classified the tweets polarity using a SVM formalism. An implementation using regularized linear models with stochastic gradient descent (SGD) learning is provided by the scikit-learn toolkit (Pedregosa et al., 2011).

## 3 Experiments

In this section, we expose the experiments carried out. Every experiment applies the preprocessing explained in section 2.1. The dataset used to conduct the experimentation was the one adopted on SemEval-2013 task 2 subtask B (Nakov et al., 2013). Indeed, all the experimentation applies a linear SVM as a classifier. The following lines express the features implemented in the most successful experiments.

### • Experiment 1

- Unigrams and Bigrams
- Jeffrey’s Lexicon.

### • Experiment 2

- 1-6 grams
- Jeffrey’s Lexicon.

### • Experiment 3

- Unigrams
- Jeffrey’s Lexicon.
- Skip-grams

### • Experiment 4

- Unigrams
- Jeffrey’s Lexicon.
- 100-most frequent Skip-grams

### • Experiment 5

- Unigrams and Bigrams
- Jeffrey’s and NRC Emotion Lexicons.

### • Experiment 6

- Unigrams and Bigrams
- Jeffrey’s and NRC Emotion Lexicons.
- All Twitter Features

### • Experiment 7

| Experiment | $F1_{pos}$    | $F1_{neg}$    | $(F1_{pos} + F1_{neg}) / 2$ |
|------------|---------------|---------------|-----------------------------|
| 1          | 0.6913        | 0.5593        | 0.6253                      |
| 2          | 0.6383        | 0.5548        | 0.6180                      |
| 3          | 0.6860        | 0.5458        | 0.6159                      |
| 4          | 0.6851        | 0.5603        | 0.6227                      |
| 5          | <b>0.6973</b> | <b>0.5824</b> | <b>0.6399</b>               |
| 6          | 0.6197        | 0.3516        | 0.4857                      |
| 7          | 0.5906        | 0.3262        | 0.4584                      |
| 8          | 0.5807        | 0.3306        | 0.4556                      |
| 9          | 0.6215        | 0.2840        | 0.4527                      |

**Table 1:** Results. SemEval-2013 Dataset.

- Unigrams and Bigrams

- ALLCAPS

#### • Experiment 9

- Unigrams and Bigrams
- Jeffrey’s and NRC Emotion Lexicons.
- Elongated Words

## 4 Results

This section summarizes the results of the tuning phase. As we can see in Table 1, the best approach is the one used in experiment 5 which uses only unigrams, bigrams and both lexicons. This fact shows the importance of unigrams and bigrams as well as the relevance of using lexicons which can improve considerably a message polarity classification model. Moreover, using n-grams larger than bigrams (6-grams in our experiments) can introduce noise in the model.

As we can see in Table 1, Twitter features decrease the performance of the classification. In experiment 6, we use all Twitter features together which leads us to a decreasing of  $(F1_{pos} + F1_{neg}) / 2$  from 0.6399 to 0.4857. Likewise, the results of experiments 7, 8 and 9 which use Twitter features individually show a diminution of similar magnitude in the evaluation measure  $(F1_{pos} + F1_{neg}) / 2$ .

## 4.1 N-grams vs Skip-grams

In this work, we presented Skip-grams as an alternative to N-grams and we see that N-grams performed slightly better than Skip-grams. However, this difference in the performance is not statistically significant and can vary between different corpora. In addition, experiment 4 includes a variation taking only the one hundred most frequent Skip-grams. The comparison between experiment 3 and 4 shows that using the most frequent Skip-grams leads to better results than using all the Skip-grams generated.

## 4.2 Competition Results

For the competition, the model used in experiment 5 which outperformed the others in the tuning phase was submitted. This model consists of unigrams, bigrams and both lexicons (Jeffrey and NRC emotion lexicon). In the official rank our system achieved the 22nd out of 34 teams.

## Acknowledgments

This work has been partially funded by the project ASLP-MULAN: Audio, Speech and Language Processing for Multimedia Analytics (Spanish MINECO TIN2014-54288-C4-3-R).

## Abstract

This paper describes the system developed at LIF for the SemEval-2016 evaluation campaign. The goal of Task 4.A was to identify sentiment polarity in tweets. The system extends the Convolutional Neural Networks (CNN) state of the art approach. We initialize the input representations with embeddings trained on different units: lexical, part-of-speech, and sentiment embeddings. Neural networks for each input space are trained separately, and then the representations extracted from their hidden layers are concatenated as input of a fusion neural network. The system ranked 2nd at SemEval-2016 and obtained an average F1 of 63.0%.

## 1 Introduction

This paper describes the system developed at LIF for the SemEval-2016 sentiment analysis evaluation task (Nakov et al., 2016). The goal of our participation was to apply approaches developed for the European FP7 project SENSEI<sup>1</sup> based on the study of human conversations according to feelings, opinions, emotions of the participants, in corpora such as transcripts of telephone speech and web comments.

We have participated in Subtask A: sentiment analysis at the message level. It consists in determining the message polarity of each tweet in the test set. The sentiment polarity classification task is set as a three-class problem: positive, negative and neutral.

The sentiment analysis task is often modeled as a classification problem which relies on features ex-

tracted from the text in order to feed a classifier. Recent work has shown that Convolutional Neural Networks (CNN) using word representations as input are well suited for sentence classification problems (Kim, 2014) and have been shown to produce state-of-the-art results for sentiment polarity classification (Tang et al., 2014a; Severyn and Moschitti, 2015). Pre-trained word embeddings are used to initialize the word representations, which are then taken as input of a text CNN.

Our approach consists in learning polarity classifiers for three types of embeddings, based on the same CNN architecture. Each set of word embedding models the tweet according to a different point of view: lexical, part-of-speech and sentiment. A final fusion step is applied, based on concatenating the hidden layers of the CNNs and training a deep neural network for the fusion.

Our contributions are as follows:

- We extend the deep CNN architecture proposed in (Poria et al., 2015) and introduce lexical information similar to (Ebert et al., 2015).
- We introduce **polarity embeddings**, tweet representations extracted from the hidden layer of CNNs with different word embeddings as input.
- We fuse polarity embeddings by concatenating them and feeding them to a neural network trained on the final task.
- The source code of our system, the models trained for the evaluation, and the corpus collected for creating word embeddings are made

<sup>1</sup><http://www.sensei-conversation.eu/>

available to the community to help future research<sup>2</sup>.

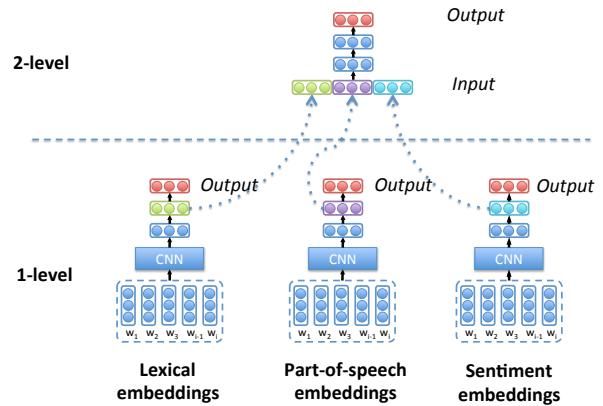

The paper is structured as follows. Section 2 presents the system architecture. Section 3 reviews the implementation details. Then we detail the different word embeddings and other features used in our system (Section 4). Results and discussion appear in Section 5.

## 2 Polarity embeddings

Deep learning models have been shown to produce state-of-the-art performance in various domains (vision, speech, etc...). Convolutional Neural Networks (CNN) represent one of the most used deep learning model in computer vision (LeCun and Bengio, 1995). Recent work has shown that CNNs are also well suited for sentence classification problems and can produce state-of-the-art results (Tang et al., 2014a; Severyn and Moschitti, 2015). The difference between CNNs applied to computer vision and their equivalent in NLP lies in the input dimensionality and format. In computer vision, inputs are usually single-channel (eg. grayscale) or multi-channel (eg. RGB) 2D or 3D matrices, usually of constant dimension. In sentence classification, each input consists of a sequence of words of variable length. Each word  $w$  is represented with a n-dimensional vector (word embedding)  $e_w$  of constant size. All the word representations are then concatenated in their respective order and padded with zero-vectors to a fixed length (maximum possible length of the sentence).

Word embeddings are an approach for distributional semantics which represents words as vectors of real numbers. Such representation has useful clustering properties, since it groups together words that are semantically and syntactically similar (Mikolov et al., 2013). For example, the word “coffee” and “tea” will be very close in the created space. The goal is to use these features as input to a CNN classifier. However, with the sentiment analysis task in mind, typical word embeddings extracted from lexical context might not be the most accurate because antonyms tend to be placed at the same location in the created space. As exemplified in Table 1, “good” and “bad” occur in similar con-

texts, and therefore obtain very similar representations. In addition, the model does not differentiate the senses of a word and creates a representation close to the most used sense in the training data. In order to tackle the representation robustness problem, we propose to extract word embeddings with different training regimes, and fuse their contribution to the system.

**Figure 1:** Overview of the sentiment embedding fusion approach. In a first level, different word representations are used to train CNNs to predict sentiment polarity, in the second level, representations extracted at hidden layers are concatenated and fed to a final classifier.

There are two approaches commonly used for fusion: early and late fusion. Late fusion considers that the different systems are independent by first applying classification separately on each system and then merging the output using a high-level classifier. Unfortunately, the classifier cannot model the correlations among modalities. The early fusion approach tackles this problem by learning features and class relationships to model the interaction between modalities. While late fusion cannot benefit from different system feature correlations, early fusion requires lots of training data.

In previous work (Rouvier et al., 2015), we have proposed a new fusion framework called embedding fusion which consists in concatenating hidden layers of subsystems trained independently, and input them to an other classifier trained to the actual task targets. This embedding fusion approach goes beyond late fusion and overcomes most of the problems linked to early fusion.

In this paper, we apply the embedding fusion to

<sup>2</sup><http://www.github.com/mrouvier/SemEval2016>

| Lexical  |          | Part-of-speech |               | Sentiment |          |

**Table 1:** Closest words to “good” and “bad” according to different regimes for creating word embeddings: lexical, part-of-speech and sentiment (described later in the paper).

the sentiment polarity prediction task, with a two-level architecture (Figure 1). Given a tweet, the first level extracts input representations based different word embeddings. These embeddings are fed to a CNN with n-gram filters (from 1 to 5). The CNN is followed by a series of fully connected hidden layers which are trained to predict the target (sentiment polarity). Three different sets of word embeddings are used: lexical embeddings, joint lexical-part-of-speech embeddings, and joint lexical-sentiment embeddings. The training procedure for the embeddings is explained in the following sections.

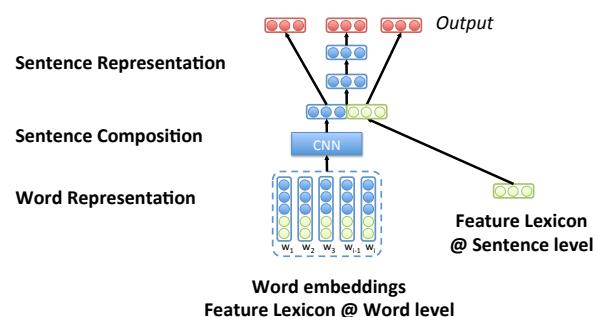

The second level inputs the concatenation of the last hidden layer resulting from each input representation, which we call **polarity embeddings**. This representation is fed to fully connected hidden layers, and also trained to predict the polarity target. This method allows us to take advantage of both early and late fusion at the same time, which brings an improvement in term of performance over merging the decisions of the independent neural networks.

### 3 Implementation details

The proposed architecture relies on word embeddings as word representation as well as sentiment polarity lexicon features, concatenated to the word representation. An alternative to word-level features captured by CNNs is to extract sentence-level features in order to model global evidence in the tweet. In order to incorporate this source of information into the system, a classical MLP with one hidden layer is trained to predict sentiment polarity from a set of sentence-level features and its hidden layer is

concatenated to the other polarity embeddings and fed to the second-level MLP. The CNN and MLP are trained jointly.

The final complete architecture including CNNs and the sentence-level MLP, presented in Figure 2, is based on a single convolutional layer followed by a max-over-time pooling layer (Collobert et al., 2011) and two fully-connected layers. In order to learn this kind of model there are two soft-max fully connected layers. The first one is connected to the pooling layer and the second one at the end of fully-connected layer.

**Figure 2:** Actual CNN architecture: word representations are concatenated with lexicon features, and sentence-level lexicon features are concatenated with the polarity embeddings, and also trained to predict polarity targets on its own.

The parameters of our model were chosen so as to maximize performance on the development set: the width of the convolution filters is set to 5 and the number of convolutional feature maps is 500. We

use ReLU activation functions and a simple max-pooling. The two fully connected hidden-layers are of size 512. For each layer, a standard dropout of 0.4 (40 % of the neurons are disabled in each iteration) is used. The back-propagation algorithm used for training is Adadelta. In our experiments we observed that the weight initialization of the convolution layer can lead to high variation in term of performance. Therefore, we trained 20 models and selected the one that obtained the best results on the development corpus.

In the second part of the system which inputs polarity embeddings and predicts polarity targets, the DNN is composed of two 512-dimensional hidden layers. The non-linearity of the hidden layers is corrected by a ReLU function.

## 4 Input features

### 4.1 Word embeddings

We propose to make use of word embeddings trained under different regimes, in order to capture different aspects of the relation between words so that it might benefit the polarity classifier. Three representations are explored.

**Lexical embeddings:** these embeddings are obtained with the classical skipgram model from (Mikolov et al., 2013). The representation is created by using the hidden layer of a linear neural network to predict a context window from a central word. For a given context  $w_{i-2} \dots w_{i+2}$ , the input to the model is  $w_i$ , and the output could be  $w_{i-2}, w_{i-1}, w_{i+1}, w_{i+2}$ . This method typically extracts a representation which both covers syntax and semantics, to some extent.

**Part-of-speech embeddings:** as stated earlier, the lexical model cannot distinguish between the senses of words and creates a single representation per word form. For example, the word “apple” receives an embedding that is a mixture of its different contextual senses: fruit, company... A lot of sophisticated approaches have been proposed to tackle the problem (Guo et al., 2014; Neelakantan et al., 2015; Huang et al., 2012), by considering senses as latent variables during training, or by conditionning the training documents on topic distributions. In our system we follow a very simple approach which creates joint embeddings for words and their part of speech. Thus, for con-

text  $w_{i-2} \dots w_{i+2}$  tagged with the part-of-speech sequence  $p_{i-2} \dots p_{i+2}$  the input to the model is  $(w_i, p_i)$  and the output is  $(w_{i-2}, p_{i-2}), (w_{i-1}, p_{i-1}), (w_{i+1} : p_{i+1}), (w_{i+2}, p_{i+2})$ .

**Sentiment embeddings:** another problem with the basic skipgram approach (lexical embeddings) is that the model ignores the sentiment polarity of the words. As a result, words with opposite polarity, such as “good” and “bad”, are mapped into close vectors. In (Tang et al., 2014b), the authors propose to tackle this problem so that sentiment information is encoded in the continuous representation of words. They propose to create a neural network that predicts two tasks: the context of the word and the sentiment label of the whole sentence. Since it is expensive to manually label sentences with a polarity label, the authors propose to use tweets that contain emoticons and rely on the polarity of the emoticon to label the sentences. As they report that best performance is obtained by weighting both tasks equivalently, the model is the same as for lexical embeddings, except that the predicted context is formed of (word, sentiment) couples. For example, if  $s$  is the polarity of the sentence where the context  $w_{i-2} \dots w_{i+2}$  is extracted, the model gets  $w_i$  as input and has to predict  $(w_{i-2}, s), (w_{i-1}, s), (w_{i+1}, s), (w_{i+2}, s)$ .

### 4.2 Sentiment lexicon features

Word representations are learned from distributional information of words in large corpora. Although such statistics are semantically informative, they disregard the valuable information that is contained in manually curated sentiment lexicons. In (Ebert et al., 2015), the authors propose to incorporate knowledge from semantic lexicons at the word level. The goal is to extract features based on the overlap between words in the input and sentiment lexicons, and stack these features to the word embedding.

We create two such features per word per lexicon. Both are binary indicators of positive and negative polarity of that word in the lexicons. The lexicons for this feature type are MPQA (Wiebe et al., 2005), Opinion lexicon (Hu and Liu, 2004), and NRC Emotion lexicon (Mohammad and Turney, 2013). The NRC lexicons provide a score for each word instead of just a label. We replace the binary indicators by the scores.

### 4.3 Sentence-level features

The following features are extracted at sentence level and used for training the sentence-level MLP:

- **Lexicons:** frequency of lemmas that are matched in MPQA (Wiebe et al., 2005), Opinion Lexicon (Hu and Liu, 2004) and NRC Emotion lexicon (Mohammad and Turney, 2013).
- **Emoticons:** number of emoticons that are grouped in positive, negative and neutral categories.
- **All-caps:** number of words in all-caps
- **Elongated units:** number of words in which characters are repeated more than twice (for example: loooooool)
- **Punctuation:** number of contiguous sequences of period, exclamation mark and question mark.

## 5 Experiments

### 5.1 Pre-processing

A step of pre-processing is applied to every tweet in the corpus:

- **Character encoding:** every tweet is encoded in UTF-8
- **XML Entities:** all the XML entities are converted back to characters
- **Lowercase:** all the characters are converted in lowercase
- **Lengthening:** character lengthening consists in repeating several times a character in a word. It is used in social media as a method to emphasize a fact. This extension is often correlated with the expression of sentiment. If a character is repeated more than three times, we reduce it to three characters. For example, “loooo” is replaced by “looo”.
- **Tokenization:** tokenization is performed by splitting a sentence in pre-lexical units. We used the tokenizer from the macaon toolchain (Nasr et al., 2011). It is based on a regular grammar that defines a set of types of atoms. A lexical analyzer detects the character sequences (in terms of the grammar) and combines them as a type. We added the atoms for detecting smileys, hashtags and users names (atoms specific to tweets).

- **Map generic words:** The hashtags, numbers and usertags are mapped to generic tokens.

### 5.2 Corpus

We use the train and dev corpora from Twitter’13 to 16 for training and Twitter’16-dev as a development set. Note that we were unable to download all the training and development data because some tweets were deleted or not available due to modified authorization status. The datasets are summarized in Table 3:

| Corpus | Positive | Negative | Neutral | Total  |
|--------|----------|----------|---------|--------|
| Train  | 7.727    | 2.916    | 7.837   | 18.480 |
| Dev    | 884      | 279      | 616     | 1.779  |

**Table 3:** Statistics of the successfully downloaded part of the SemEval 2016 Twitter sentiment classification dataset.

### 5.3 Word embedding training

To train the word embeddings, we have created a unannotated corpus of sentiment bearing tweets in English. These tweets were recovered on the Twitter platform by searching for emotion keywords (from the sentiment lexicons) and unigrams, bigrams and trigrams extracted from the SemEval training corpus. This corpus consists of about 90 million tweets. A sub-corpus of about 20 million tweets containing at least one emoticon is used for training the sentiment embeddings. Both corpora are made available<sup>3</sup>.

In our experiments, lexical embeddings and part-of-speech embeddings are estimated using the word2vec toolkit (Mikolov et al., 2013). Sentiment embeddings are estimated using word2vecf. This toolkit allows to replace linear bag-of-word contexts with arbitrary features. The embeddings are trained using the skipgram approach with a window of size 3 and 5 iterations. The dimension of the embeddings is fixed to 100. Part-of-speech tagging is performed with Tweet NLP (Owoputi et al., 2013; Gimpel et al., 2011).

### 5.4 Results

**Overall performance:** The evaluation metric used in the competition is the macro-averaged F-measure calculated over the positive and negative categories. Table 4 presents the overall performance of our system. It achieved the second rank on the Twitter 2016

data among 34 teams. The system proved to generalize well to other types of short informal texts; it ranked first and third respectively on the two out-of-domain datasets: Live Journal 2014 and SMS 2013.

| Corpus      | SENSEI-LIF | Rank |
|-------------|------------|------|
| Twt2013     | 70.6       | 3    |
| SMS2013     | 63.4       | 3    |
| Twt2014     | 74.4       | 1    |
| TwtSarc2014 | 46.7       | 8    |
| LvJn2014    | 74.1       | 1    |
| Twt2015     | 66.2       | 2    |
| Twt2016     | 63.0       | 2    |

**Table 4:** Overall performance of the SENSEI-LIF sentiment analysis systems.

**Contribution of features:** Table 2 presents the results of ablation experiments on the Twitter 2016 test set. *SENSEI-LIF* is the system which participated to the evaluation campaign. We present the results of three contrastive systems: *Lexical*, *Part-of-speech* and *Sentiment*. These systems are based on the CNN classifier prior to the concatenation of the hidden layers. They use only one set of word embeddings without any kind of fusion.

The different features used in our system are: lexicon features and word embeddings. The ablation of lexicon features removes the lexicon features at the word and sentence level. The ablation of word embeddings feature consists in randomly initializing the word representations.

We observe that the most influential features are word embeddings. They provide a gain of 3.4 points. The main advantage of word embeddings is to learn unsupervised representations on very large corpora which capture general semantic properties. The last most important features are lexicon features. We observe that word level lexicon features are not relevant and tend to degrade the performance of the *SENSEI-LIF* system on the Twitter 2016 dataset.

**Impact of fusion:** Table 5 presents the results us-

ing different kinds of fusion: early, late and embedding fusion. We observe that early fusion obtains the worse results. We think that is due to the small training corpus used. Embedding fusion obtains the bests results on the Twitter 2016 dataset, but more generally late and embedding fusions obtain very close results on the other datasets.

| Corpus      | Early | Late        | Embedding   |
|-------------|-------|-------------|-------------|
| Twt2013     | 69.4  | 70.4        | <b>70.6</b> |
| SMS2013     | 62.6  | <b>63.7</b> | 63.4        |
| Twt2014     | 73.4  | 74.3        | <b>74.4</b> |
| TwtSarc2014 | 46.2  | 44.7        | <b>46.7</b> |
| LvJn2014    | 74.3  | <b>74.4</b> | 74.1        |
| Twt2015     | 64.1  | <b>66.8</b> | 66.2        |
| Twt2016     | 61.6  | 62.8        | <b>63.0</b> |

**Table 5:** Overall performance using different methods of fusion: early, late and embedding fusion.

## 6 Conclusions

This paper describes the LIF participation at SemEval 2016. Our approach consists in learning polarity classifiers for three types of embeddings, based on the same CNN architecture. Each set of word embeddings models the tweet according to a different point of view: lexical, part-of-speech and sentiment. A final fusion step is applied, based on concatenating the hidden layers of the CNNs and training a deep neural network for the fusion. The fusion system ranked 2nd at the SemEval-2016 evaluation campaign.

## Acknowledgments

The research leading to these results has received funding from the European Union - Seventh Framework Programme (FP7/2007-2013) under grant agreement 610916 SENSEI <sup>4</sup>. The Tesla K40 used for this research was donated by the NVIDIA Corporation.

## Abstract

We present our supervised sentiment classification system which competed in SemEval-2016 Task 4: Sentiment Analysis in Twitter. Our system employs a Support Vector Machine (SVM) classifier trained using a number of features including n-grams, synset expansions, various sentiment scores, word clusters, and term centroids. Using weighted SVMs, to address the issue of class imbalance, our system obtains positive class F-scores of 0.694 and 0.650, and negative class F-scores of 0.391 and 0.493 over the training and test sets, respectively.

## 1 Introduction

Social media has evolved into a data source that is massive and growing rapidly. One of the most popular micro-blogging social networks, for example, is Twitter, which has over 645,750,000 users, and grows by an estimated 135,000 users every day, generating 9,100 tweets per second.<sup>1</sup> Users tend to use social networks to broadcast the latest events, and also to share personal opinions and experiences. Therefore, social media has become a focal point for data science research, and social media data is being actively used to perform a range of tasks from personalized advertising to public health monitoring and surveillance (Sarker et al., 2015a). Because of its importance and promise, social media data

has been the subject of recent large-scale annotation projects, and shared tasks have been designed around social media for solving problems in complex domains (e.g., Sarker *et al.* (2016a)) While the benefits of using a resource such as Twitter include large volumes of data and direct access to end-user sentiments, there are several obstacles associated with the use of social media data. These include the use of non-standard terminologies, misspellings, short and ambiguous posts, and data imbalance, to name a few.

In this paper, we present a supervised learning approach, using Support Vector Machines (SVMs) for the task of automatic sentiment classification of Twitter posts. Our system participated in the SemEval-2016 task *Sentiment Analysis in Twitter*, and is an extension of our system for SemEval2015 (Sarker et al., 2015b). The goal of the task was to automatically classify the polarity of a Twitter post into one of three predefined categories—positive, negative and neutral. In our approach, we apply a small set of carefully extracted lexical, semantic, and distributional features. The features are used to train a SVM learner, and the issue of data imbalance is addressed by using distinct weights for each of the three classes. The results of our system are promising, with positive class F-scores of 0.694 and 0.650, and negative class F-scores of 0.391 and 0.493 over the training and test sets, respectively.

## 2 Related Work

Following the pioneering work on sentiment analysis by Pang *et. al.* (2002), similar research has been carried out under various umbrella terms such as: se-

<sup>1</sup><http://www.statisticbrain.com/twitter-statistics/> Accessed on: 23rd December, 2015.

mantic orientation (Turney, 2002), opinion mining (Pang and Lee, 2008), polarity classification (Sarker et al., 2013), and many more. Pang *et al.* (2002) utilized machine learning models to predict sentiments in text, and their approach showed that SVM classifiers trained using bag-of-words features produced promising results. Similar approaches have been applied to texts of various granularities—documents, sentences, and phrases.

Due to the availability of vast amounts of data, there has been growing interest in utilizing social media mining for obtaining information directly from users (Liu and Zhang, 2012). However, social media sources, such as Twitter posts, present various natural language processing (NLP) and machine learning challenges. The NLP challenges arise from factors, such as, the use of informal language, frequent misspellings, creative phrases and words, abbreviations, short text lengths and others. From the perspective of machine learning, some of the key challenges include data imbalance, noise, and feature sparseness. In recent research, these challenges have received significant attention (Jansen et al., 2009; Barbosa and Feng, 2010; Davidov et al., 2010; Kouloumpis et al., 2011; Sarker and Gonzalez, 2014; Sarker et al., 2016b).

### 3 Methods

#### 3.1 Data

Our training and test data consists of the data made available for SemEval 2016 task 4, and additional eligible training data from past Semeval sentiment analysis tasks. Each instance of the data set made available consisted of a tweet ID, a user ID, and a sentiment category for the tweet. For training, we downloaded all the annotated tweets that were publicly available at the time of development of the system. We obtained all the training and devtest set tweets, and also the training sets from past SemEval tasks. In total, we used over 19,000 unique tweets for training. The data is heavily imbalanced with particularly small number of negative instances.

#### 3.2 Features

We derive a set of lexical, semantic, and distributional features from the training data. Brief descriptions are provided below. Some of these features

were used in our 2015 submission to the SemEval sentiment analysis task (Sarker et al., 2015b). In short: we have removed uninformative features such as syntactic parses of tweets, and have added features learned using distributional semantics-oriented techniques.

##### 3.2.1 Preprocessing

We perform standard preprocessing such as tokenization, lowercasing and stemming of all the terms using the Porter stemmer<sup>2</sup> (Porter, 1980). Our preliminary investigations suggested that stop words can play a positive effect on classifier performances by their presence in word 2-grams and 3-grams; so, we do not remove stop words from the texts.

##### 3.2.2 N-grams

Our first feature set consists of word n-grams. A word n-gram is a sequence of contiguous  $n$  words in a text segment, and this feature enables us to represent a document using the union of its terms. We use 1-, 2-, and 3-grams as features.

##### 3.2.3 Synset

It has been shown in past research that certain terms, because of their prior polarities, play important roles in determining the polarities of sentences (Sarker et al., 2013). Certain adjectives, and sometimes nouns and verbs, or their synonyms, are almost invariably associated with positive or non-positive polarities. For each adjective, noun or verb in a tweet, we use WordNet<sup>3</sup> to identify the synonyms of that term and add the synonymous terms as features.

##### 3.2.4 Sentiment Scores

We assign three sets of scores to sentences based on three different measures of sentiment. For the first set of scores, we used the positive and negative terms list from Hu and Bing (2004). For each tweet, the numbers of positive and negative terms are counted and divided by the total number of tokens in the tweet to generate two scores.

For the second sentiment feature, we incorporate a score that attempts to represent the general sentiment of a tweet using the prior polarities of its terms.

---

<sup>2</sup>We use the implementation provided by the NLTK toolkit <http://www.nltk.org/>.

<sup>3</sup><http://wordnet.princeton.edu/>. Accessed on December 13, 2015.

Each word-POS pair in a comment is assigned a score and the overall score assigned to the comment is equal to the sum of all the individual term-POS sentiment scores divided by the length of the sentence in words. For term-POS pairs with multiple senses, the score for the most common sense is chosen. To obtain a score for each term, we use the lexicon proposed by Guerini *et al.* (2013). The lexicon contains approximately 155,000 English words associated with a sentiment score between -1 and 1. The overall score a sentence receives is therefore a floating point number with the range [-1:1].

For the last set of scores in this set, we used the Multi-Perspective Question Answering (MPQA) subjectivity lexicon (Wiebe et al., 2005). In the lexicon, tokens are assigned a polarity (positive/negative), and a strength for the subjectivity (weak/strong). We assign a score of -1 to a token for having negative subjectivity, and +1 for having positive subjectivity. Tokens having weak subjectivity are multiplied with 0.5, and the total subjectivity score of the tweet is divided by the number of tokens to generate the final score.

### 3.2.5 Word Cluster Features

Our past research shows that incorporating word cluster features improve classification accuracy (Nikfarjam et al., 2014). These clusters are generated from vector representations of words, which are learned from large, unlabeled data sets. For our word clusters, the vector representations were learned from over 56 million tweets, using a Hidden Markov Model-based algorithm that partitions words into a base set of 1000 clusters, and induces a hierarchy among those 1000 clusters (Owoputi et al., 2012). To generate features from these clusters, for each tweet, we identify the cluster number of each token, and use all the cluster numbers in a bag-of-words manner. Thus, every tweet is represented with a set of cluster numbers, with semantically similar tokens having the same cluster number. More information about generating the embeddings can be found in the related papers (Bengio et al., 2003; Turian et al., 2010; Mikolov et al., 2013).

### 3.2.6 Centroid Features

We collected a large set of automatically ‘annotated’ sentiment corpus (Go et al., 2009). Using the

negative and positive polarity tweets separately, we generated two distributional semantics models using the Word2Vec tool.<sup>4</sup> We then applied K-means clustering to the two distributional models to generate 100 clusters each. Finally, we compute the centroid vectors for each of the clusters in the two sets.

Two feature vectors are generated from each tweet based on these centroid vectors. For each tweet, the centroid of the tweet is computed by averaging the individual word vectors in the tweet. The cosine similarities of the tweet centroid are then computed with each of the two sets of 100 centroid vectors. The vectors of similarities are then used as features. Our intuition is that these vectors will indicate similarities of tweets with posts of negative or positive sentiments.

### 3.2.7 Structural Features

We use a set of features which represent simple structural properties of the tweets. These include: length, number of sentences, and average sentence length.

## 3.3 Classification

Using the abovementioned features, we trained SVM classifiers for the classification task. The performance of SVMs can vary significantly based on the kernel and specific parameter values. For our work, based on past research on this type of data, we used the RBF kernel. We computed optimal values for the *cost* and  $\gamma$  parameters via grid-search and 10-fold cross validation over the training set. To address the problem of data imbalance, we utilized the weighted SVM feature of the LibSVM library (Chang and Lin, 2011), and we attempted to find optimal values for the weights in the same way using 10-fold cross validation over the training set. We found that  $\text{cost} = 64.0$ ,  $\gamma = 0.0$ ,  $\omega_1 = 1.2$ , and  $\omega_2 = 2.6$  to produce the best results, where  $\omega_1$  and  $\omega_2$  are the weights for the positive and negative classes, respectively.

## 4 Results

Table 1 presents the performance of our system on the training and test data sets. The table presents the

---

<sup>4</sup><https://code.google.com/archive/p/word2vec/>. Accessed Feb-22-2016.

positive and negative class F-scores for the system, and the average of the two scores—the metric that is used for ranking systems in the SemEval evaluations for this task. The training set results are obtained via training on the training set and evaluating on the devtest set. The test results are the final SemEval results.

| Data set | Positive F-score (P) | Negative F-score (N) | $\frac{P+N}{2}$ |
|----------|----------------------|----------------------|-----------------|
| Training | 0.694                | 0.391                | 0.542           |
| Test     | 0.650                | 0.493                | 0.571           |

Table 1: Classification results for the DIEGOLab16 system over the training and test sets.

#### 4.1 Feature Analysis

To assess the contribution of each feature towards the final score, we performed leave-one-out feature and single feature experiments. Tables 2 and 3 show the  $\frac{P+N}{2}$  values for the training and the test sets for the two set of experiments. The first row of the tables present the results when all the features are used, and the following rows show the results when a specific feature is removed or when a single feature is used. The tables suggest that almost all the features play important roles in classification. As shown in Table 3, n-grams, word clusters, and centroids give the highest classification scores when employed individually. Table 2 illustrates similar information, by showing which features cause the largest drops in performance when removed. For all the other feature sets, the drops in the evaluation scores shown in Table 3 are very low, meaning that their contribution to the final evaluation score is quite limited. The experiments suggest that the classifier settings (*i.e.*, the parameter values and the class weights) play a more important role in our final approach, as greater deviations from the scores presented can be achieved by fine tuning the parameter values than by adding, removing, or modifying the feature sets. Further experimentation is required to identify useful features and to configure existing features to be more effective.

| Feature removed  | $\frac{P+N}{2}$ |
|------------------|-----------------|
| None             | 0.542           |
| N-grams          | 0.540           |
| Synsets          | 0.553           |
| Sentiment Scores | 0.540           |
| Word Clusters    | 0.515           |
| Centroids        | 0.527           |
| Other            | 0.541           |

Table 2: Leave-one-out  $\frac{P+N}{2}$  feature scores for the training and test sets.

| Feature          | $\frac{P+N}{2}$ |
|------------------|-----------------|
| All              | 0.542           |
| N-grams          | 0.515           |
| Synsets          | 0.494           |
| Sentiment Scores | 0.472           |
| Word Clusters    | 0.531           |
| Centroids        | 0.535           |
| Other            | 0.254           |

Table 3: Single feature  $\frac{P+N}{2}$  scores for the training and test sets.

## 5 Conclusions and Future Work

Our system achieved moderate performance on the SemEval sentiment analysis task utilizing very basic settings. The F-scores were particularly low for the negative class, which can be attributed to the class imbalance. Considering that the performance of our system was achieved by very basic settings, there is promise of better performance via the utilization of feature generation and engineering techniques.

We have several planned future tasks to improve the classification performance on this data set, and for social media based sentiment analysis in general. Following on from our past work on social media data (Sarker and Gonzalez, 2014; Sarker et al., 2016b), our primary goal to improve performance in the future is to employ preprocessing techniques that can normalize the texts and better prepare them for the feature generation stage. We will also attempt to optimize our distributional semantics models further.

## Abstract

The aim of this paper is to produce a methodology for analyzing sentiments of selected Twitter messages, better known as Tweets. This project elaborates on two experiments carried out to analyze the sentiment of Tweets from SemEval-2016 Task 4 Subtask A and Subtask B. Our method is built from a simple unigram model baseline with three main feature enhancements incorporated into the model: 1) emoticon retention, 2) word stemming, and 3) token saliency calculation. Our results indicate an increase in classification accuracy with the addition of emoticon retention and word stemming, while token saliency shows mixed performance. These results elucidate a possible classification feature model that could aid in the sentiment analysis of Twitter feeds and other microblogging environments.

## 1 Introduction

Twitter is a widely used microblogging environment which serves as a medium to share opinions on various events and products. Because of this, analyzing Twitter has the potential to reveal opinions of the general public regarding these topics. However, mining the content of Twitter messages is a challenging task due to a multitude of reasons, such as the shortness of the posted content and the informal and unstructured nature of the language used. The aim of this study is to produce a methodology for analyzing sentiments of selected Twitter messages, better known as Tweets. This project elaborates on two experiments carried out to analyze the sentiment

of Tweets, namely, Subtask A and Subtask B from SemEval-2016 Task 4 (Nakov et al., 2016).

**Subtask A: Message Polarity Classification.** The goal of this subtask was to predict a given Tweet's sentiment from three classes: 1) positive, 2) neutral, or 3) negative.

**Subtask B: Tweet classification according to a two-point scale.** The goal of this subtask was to classify a given Tweet's sentiment towards a given topic. The sentiments were limited to positive and negative, unlike Subtask A.

## 2 Method

We viewed both tasks as classification problems. We represented the Tweets in a statistical feature matrix and performed the classification using supervised machine learning classification algorithms. Several different feature vectors were experimented with and the same set of feature vectors were applied to both Subtask A and Subtask B.

### 2.1 Feature Vectors

Our methods consume Tweet data and output a matrix where each row represents a Tweet and each column represents a feature. The values in this matrix are the frequency of appearance of a feature in the Tweet. As reference for the rest of the project, please note that *n-grams* are a continuous set of *n* terms in a document. Thus, when *n*=1, we are representing a unigram, or a single word; when *n*=2, we are representing a bigram, or a pair of words, and so on. We evaluated unigram, bigram and trigram models, but discuss only the unigram model. The bigram and trigram models results showed to be less effective.

### **2.1.1 Unigram Model**

As a baseline, a unigram model was used as the primary feature vector. The unigram model consists of several one-state finite automatas, splitting the probabilities of different features in a context. The probability of occurrence for each feature is independent. In our project, each word in a Tweet represents a feature.

For the first step of creating the unigram feature vector, numbers and special characters were removed from each Tweet, since they carry little information when taken out of context. The Tweets were then converted to all lower case to reduce the dimensionality of the data, whereby different users' capitalization does not factor in as a new, separate feature. Next, the Tweets were tokenized by breaking up the messages into single word units that each represent a unique feature. All stop words were then removed from these token sets. Stop words, such as "the" and "a", are the most commonly occurring words in a language and are considered to carry little to no information due to their high frequency of appearance (Yao and Ze-wen, 2011). Their presence in the dataset has the potential of adversely affecting the classification results. The most frequent words in the dataset were then identified based on a specified frequency threshold, filtering out all tokens that appeared less than the threshold. This was done to reduce the size of the resultant feature vector and identify the most general set of terms that represents the dataset.

### **2.1.2 Unigram model with feature reduction through stemming**

In addition to the baseline methodology, we applied a technique known as stemming, which reduces words to their basic forms. This process combines words with similar basic forms, for example the words "running" and "ran" are reduced to the base form of "run," thus reducing the overall feature count and increasing the co-occurrence count.

### **2.1.3 Unigram model with feature enhancement through emoticon retention**

One of the disadvantages of removing special characters from the Tweets was that the emoticons, text representations of emotions, were lost. Emoticons are good indicators of expression and emotion,

and are frequently used in Tweets. We again performed the steps in the previous methods, but before the removal of special characters from the Tweet, we implemented a series of regular expressions to capture a specific set of emoticons and convert them into unique key words.

### **2.1.4 Unigram model with word saliency statistics**

The saliency, or quality, of the terms in the unigram model were calculated using the Term Frequency - Inverse Document Frequency (TF-IDF) score. The values of the matrix were modified to the TF-IDF score through the equations below.

$$TF(Tweet, term) = \frac{\text{frequencyOfTerm}(Tweet)}{\text{totalTerms}(Tweet)} \quad (1)$$

$$IDF(term) = \log \frac{\text{totalDocuments}}{\text{numDocumentsContaining}(term)} \quad (2)$$

$$TF-IDF(Tweet, term) = TF(Tweet, term) \cdot IDF(term) \quad (3)$$

## **3 Classification**

Once the feature vectors were created, the final step of classification was accomplished using supervised machine learning algorithms. In the presented methodology, classification was carried out using single classifiers as well as multiple classifiers. As a reminder, Subtask A is a three class problem, while Subtask B is a two class problem.

### **3.1 Single Classifier**

For this classification method, only a single classifier was used to perform the classification. The feature vector of a Tweet was used as input and the classifier returned the predicted sentiment class for that Tweet.

### **3.2 Multiple Classifiers**

For this classification method, multiple classifiers were utilized to produce the final sentiment class of the Tweet based on a voting system. Each classifier is given a single vote and performs the classification

of the Tweet on its own; casting its vote for which classification should be assigned for that Tweet. The predicted class with the majority of votes is then assigned as the class for that Tweet. We refer to this process as *voting*.

## 4 Data

The SemEval-2016 (Nakov et al., 2016) training datasets were used for both tasks. The datasets consisted of Tweets with pre-labeled sentiments. Table 1 and Table 2 show the class distributions of the training data.

Table 1: Dataset for Subtask A

| # of Tweets | <i>Pos</i>   | <i>Neu</i> | <i>Neg</i> |
|-------------|--------------|------------|------------|
| 705         | 345 (48.93%) | 164        | 196        |

Table 2: Dataset for Subtask B

| # of Tweets | Topics | <i>Pos</i>    | <i>Neg</i> |
|-------------|--------|---------------|------------|
| 3890        | 59     | 3215 (82.64%) | 675        |

## 5 Implementation Specifics

This section discusses the parameters and assumptions made in the implementation of our systems. Our system is freely available for download<sup>1</sup>.

### 5.1 Feature Vector Creation

For the feature vector creation, the stemming process was carried out using the Porter stemmer (Porter, 1997) supplied in the Natural Language Toolkit (NLTK) (Loper and Bird, 2002) platform<sup>2</sup>. The stop word list was manually created and is freely available in our package. The emoticons were retained by converting them to unique tokens using regular expressions. Table 3 shows the emoticons used by the system and their conversion.

For our implementation, we used a frequency threshold of five to filter our features. This parameter was determined during initial development of the system by evaluating several thresholds using 10-fold cross validation over the training data.

### 5.2 Classifiers

Three classifiers were tested for both subtasks. Subtask A utilized the Naive Bayes Multinomial, Naive Bayes, and J48 decision tree classifiers. Similarly,

Table 3: Emoticons

|                    |          |          |
|--------------------|----------|----------|
| smileEmoticon      | :        | )        |
| frownEmoticon      | :        | (        |
| winkEmoticon       | :        | )        |
| tongueEmoticon     | :        | <i>P</i> |
| concernEmoticon    | :        | /        |
| grinEmoticon       | :        | <i>D</i> |
| mirrorGrinEmoticon | <i>D</i> | :        |
| winkGrinEmoticon   | ;        | <i>D</i> |
| surpriseEmoticon   | :        | <i>O</i> |
| tearSmileEmoticon  | :        | )        |
| tearFrownEmoticon  | :        | (        |

Subtask B used the Naive Bayes, J48 decision tree, and Support Vector Machine classifiers. These classifiers were used individually as well as with voting. All classifiers were implemented using the open source, freely available Weka (Hall et al., 2009) data mining package<sup>3</sup>. We used Weka’s default learning parameters in our experiments.

## 6 Results

Table 4 shows the overall accuracies acquired by the different classifiers tested for Subtask A. We chose to use a baseline of a unigram model with the frequency threshold set to one. The Naive Bayes Multinomial classifier produced the highest results for Subtask A from the classifiers tested. Further, the enhancements done to the unigram model did not yield a significant increase of accuracy in our tests. The highest accuracy was achieved with the basic unigram model in conjunction with the Naive Bayes Multinomial classifier. With that being said, the basic unigram model with a frequency threshold of five was able to outperform our selected baseline.

Table 5 illustrates the overall accuracies obtained for Subtask B. We swapped the Naive Bayes Multinomial classifier with the Support Vector Machines classifier due to our use of the Tweet’s topic as categorical data. The SVM classifier produced the highest overall results. Further, all classifiers except for Naive Bayes performed better than the baseline. Voting did not perform as well with the J48 and SVM algorithms, but still outperformed Naive Bayes. Our highest accuracy was achieved using the unigram model with stemming as features into the SVM classifier.

## 7 Discussion and Future Work

In this paper, we present a method to predict the sentiment of Twitter feeds. We evaluated using a unigram model with three feature modifications: (1) stemming, (2) emoticon retention, and (3) word saliency. These modifications were applied to the unigram model and consumed with machine learning algorithms from the Weka datamining package. The results showed that using a unigram model with a frequency threshold of five in conjunction with the Naive Bayes Multinomial classifiers obtained the highest accuracy for Subtask A, and the unigram model with stemming in combination with the Support Vector Machine classifier achieved the highest accuracy for Subtask B.

Analysis of the results showed that the unstructured nature of word spelling may have played a role in our relatively low accuracies, causing multiple features to be seen as unique, when in actuality they should in fact map to the same feature. We also believe that the mixed results from the inclusion of the TF-IDF score is due in part to the heavily skewed nature of the data. In both Subtask A and Subtask B, the training data was mostly comprised of positively tagged sentiments, overwhelming the other classifications.

In the future, we plan to explore incorporating synonym set evaluations, acronym expansion, and spelling correction to aid in feature reduction. Efforts will also be made to include more contextual information, like sentiment lexicon, and to explore other multiple classifier methods, such as co-training.

Università di Pisa

Italy

{attardi,sartiano}@di.unipi.it

## Abstract

The paper describes our submission to the task on Sentiment Analysis on Twitter at SemEval 2016. The approach is based on a Deep Learning architecture using convolutional neural networks. The approach used only word embeddings as features. The submission used embeddings created from a corpus of news articles. We report on further experiments using embeddings built for a corpus of tweets as well as sentiment specific word embeddings obtained by distant supervision.

## 1 Introduction

Up until recently, the typical approaches to sentiment analysis of tweets were based on classifiers trained using several hand-crafted features, in particular lexicons of words with an assigned polarity value. At the SemEval 2015 task 10 on Sentiment Analysis of Twitter (Rosenthal et al., 2015), most systems relied on features derived from sentiment lexicons. Other important features included bag-of-words features, hash-tags, handling of negation, word shape and punctuation features, elongated words, etc. Moreover, tweet pre-processing and normalization were an important part of the processing pipeline.

Quite significantly, the top scoring system in subtask A: Phrase-Level Polarity (Moschitti and Severyn, 2015) was instead based on the use of a convolutional neural network, which used word

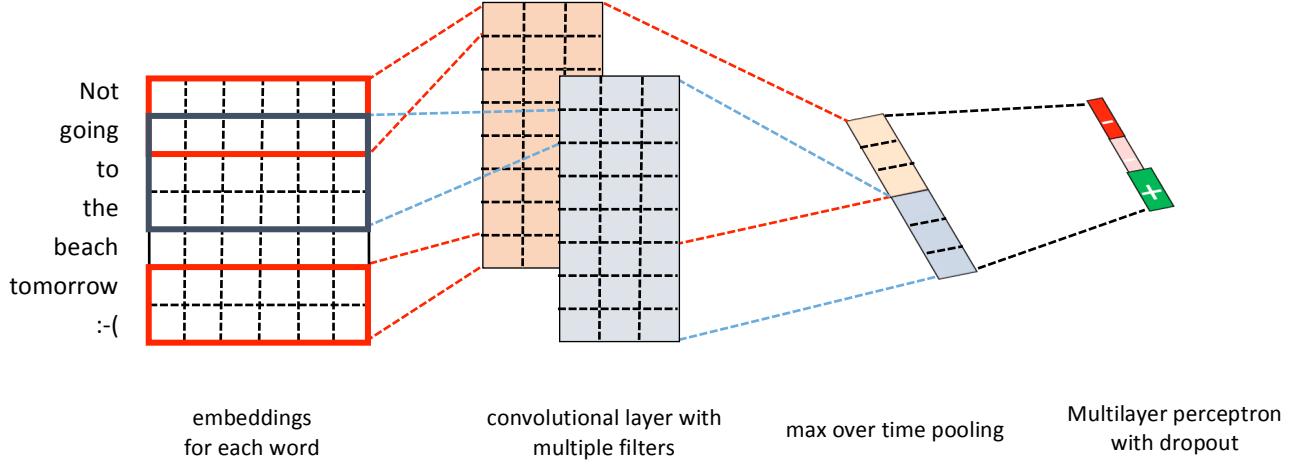

embeddings as its only features. Word embeddings were created by unsupervised learning from a collection of 50 million tweets, using the SkipGram model by Mikolov et al., (2013). The tweets used for training were collected by querying the Twitter API on the presence of a set of emoticons representing positive or negative sentiment. The winning team achieved an F1 of 84.79 on the Twitter2015 test set. The team participated with a similar approach also to subtask B: Message-Level Polarity, achieving the second best score with an F1 of 64.59. The fourth F1 score of 64.17 was achieved also by a system exploiting word embeddings by INESC-ID. The top scoring system instead consisted in an ensemble combining four Twitter sentiment classification approaches that participated in previous editions, with an F1 of 64.84.

We decided to explore a similar approach for tackling SemEval 2016 task 4 on Sentiment Analysis in Twitter (Nakov et al., 2016).

## 2 Approach

The classifier is based on a Deep Learning architecture consisting of the following layers:

1. a lookup layer for word embeddings
2. a convolutional layer with relu activation
3. a maxpooling layer
4. a dropout layer
5. a linear layer with tanh activation
6. a softmax layer

**Figure 1.** Architecture of the Deep Learning classifier.

The architecture is illustrated in Figure 1. The first layer looks up the embedding for words, i.e. vectors in  $\mathbb{R}^d$ . In our experiments we set  $d = 300$ . The convolutional layer consists of multiple convolutional filters of sliding windows of various sizes. These are then combined through a max-pooling layer and then passed through a multilayer perceptron with dropout.

A sentence  $s$  is represented by a sentence matrix  $S$ , where each row  $S_i$  corresponds to the embedding for the  $i$ -th word in a sentence (in the figure the matrix  $S$  is transposed).

A convolution operation involves a filter  $F \in \mathbb{R}^{h,d}$ , which is applied to sliding windows of size  $h$  words to produce a feature map. A feature  $c_i$  is obtained by applying the filter to a window of words  $S_{i:i+h-1}$  as:

$$c_i = f(F \otimes S_{i:i+h-1} + b)$$

where  $\otimes$  is the Frobenius matrix product,  $b \in \mathbb{R}$  is a bias term and  $f$  is a non-linear activation function such as the hyperbolic tangent. The filter is applied to each possible window of words in the sentence to produce a feature map  $c \in \mathbb{R}^{n-h+1}$ , where  $n$  is the length of the sentence (padded as necessary).

Several filters  $F_k$  are used each with its own filter width  $h_k$ .

Max-pooling is applied to the feature maps produced by the filters obtaining a single vector that forms the input to an MLP with a dropout layer. Dropout is used to prevent co-adaptation of hidden units by setting to zero with probability  $p$  a portion of the hidden units during forward propagation.

We preprocessed the tweets using the Tanl pipeline (Attardi, 2010) for performing Sentence Splitting and applying a tweet tokenizer capable of recognizing mentions, hashtags and emoticons. All mentions were replaced by @user, all URL were replaced by http://URL. All sentences are padded to the same length in order to enable processing mini-batches in parallel using CUDA matrix operations.

For training we used the training and development set from SemEval 2013 task 10 and from SemEval 2016.

The code for the DL classifier is written in Theano and is available on GitHub<sup>1</sup>. The implementation is derived from the one developed by Yoon Kim for the paper (Kim, 2014), and provides the ability to configure parameters and settings of the network, as well as to control the use of cross-validation.

The network is implemented by a class `ConvNet` that extends the `MLPDropout` class from <https://github.com/mdenil/dropout>.

Training is done by mean of ASGD with updates performed with Adadelta (Zeiler, 2012).

```
class ConvNet(MLPDropout):
    def __init__(self, U, height,
                 width, filter_ws,
                 conv_non_linear,
                 feature_maps, output_units,
                 batch_size, dropout_rates,
                 activations)
```

**Table 1.** Official results of our submission compared to the top one, and an unofficial run.

where:

U: embedding matrix  
height: sentence length  
width: word vector dimension  
filter\_ws: filter window sizes  
conv\_activation: activation function of the convolutional layer (default relu)  
feature\_maps: number of feature maps (per filter window)  
output\_units: number of output variables  
batch\_size: size of the mini-batches  
dropout\_rates: probability for the dropout layer activations: the activation functions for each layer in the MLP

### 3 Experiments

The settings for the experiment were the following: word embeddings of 300 dimensions from a Google News corpus<sup>2</sup>, filters of size 7,7,7 each with a 100 feature maps, dropout rate 0.5, MLP hidden units 100, batch size 50, adadelta decay 0.95, convolutional layer activation relu, training epochs 25.

For choosing the setting of our single submission, we took into account the suggestion from the experiments carried out by Zhang and Wallace. (2015).

The experiments were run on a linux server with an nVIDIA Tesla K40 accelerated GPU.

### 4 Results

The official submission achieved result presented in Table 1, compared to the top scoring system, as well as with an unofficial run using SWE (Sentiment Specific Word Embeddings) as described later.

A remarkable aspect of the submission is the fact that the accuracy on the 2016 Tweet jumps from the 18<sup>th</sup> position to third place.

<sup>2</sup> <https://code.google.com/archive/p/word2vec/>

In order to analyze this phenomenon, we present the breakdown of score among the three categories.

This is the breakdown of the scores of our official submission:

| UniPI    | Prec. | Rec.  | F1    |
|----------|-------|-------|-------|
| positive | 69.50 | 63.97 | 66.62 |
| negative | 48.77 | 55.73 | 52.02 |
| neutral  | 67.68 | 68.11 | 67.68 |
| Avg F1   |       |       | 59.32 |
| Accuracy |       |       | 64.62 |

**Table 2.** Detailed scores of UniPI official submission.

Details of the evaluation of the top scoring system:

| SwissCheese | Prec. | Rec.  | F1           |
|-------------|-------|-------|--------------|
| positive    | 67.48 | 74.14 | 70.66        |
| negative    | 53.26 | 67.86 | 59.68        |
| neutral     | 71.47 | 59.51 | 64.94        |
| Avg F1      |       |       | <b>65.17</b> |
| Accuracy    |       |       | 64.62        |

**Table 3.** Detailed scores of top submission for Task 4, subtask A.

After submission we performed further experiments, summarized in the following tables, which report the micro average F1 over the whole test set.

The experiments used embeddings from a corpus of 35 million tweets, and the whole training set, including the 10% that was held out for the 10-fold cross validation in the submission. A run with the same hyper-parameters obtained a slight improvement:

| UniPI 2  | Prec. | Rec.  | F1    |
|----------|-------|-------|-------|
| positive | 76.86 | 56.87 | 65.37 |
| negative | 47.70 | 63.07 | 54.32 |
| neutral  | 66.52 | 72.45 | 69.36 |
| Avg F1   |       |       | 59.85 |
| Accuracy |       |       | 65.30 |

**Table 4.** Unofficial run using the full training set and embeddings from a corpus of 35 million tweets.

Using instead a set of filters of sizes 3,5,7,7, improved further, achieving an unofficial best accuracy score:

| <b>UniPI 3</b> | <b>Prec.</b> | <b>Rec.</b> | <b>F1</b>    |
|----------------|--------------|-------------|--------------|
| positive       | 70.88        | 65.35       | 68.00        |
| negative       | 50.29        | 58.93       | 54.27        |
| neutral        | 68.02        | 68.12       | 68.07        |
| Avg F1         |              |             | 61.14        |
| Accuracy       |              |             | <b>65.64</b> |

**Table 5.** Unofficial run using embeddings from tweets and filters of sizes 3,5,7,7.

The good F1 score on the neutral category seems to indicate that there is a certain degree of confusion between the two other categories.

We tested also filters of sizes 3,4,5,6,7,7,7 and 10 filters of size 7, with no overall improvements.

A more interesting experiment was the use of sentiment specific word embeddings (SWE), which encode sentiment information in the continuous representation of words. We incorporated sentiment polarity from the SemEval training corpus into the embeddings built from the corpus of 35 million of tweets, by using the technique by Tang et al. (2014), and implemented in DeepNL<sup>3</sup> (Attardi, 2015). A neural network with a suitable loss function provides the supervision for transferring the sentiment polarity of text (e.g. sentences or tweets) to the embeddings from generic tweets.

Training the same convolutional network with filters of size 3,5,7,7 using these sentiment specific word embeddings, produced an overall improvement that lead to an Avg F1 on Tweets 2016 of 0.595, and in detail:

| <b>UniPI SWE</b> | <b>Prec.</b> | <b>Rec.</b> | <b>F1</b> |
|------------------|--------------|-------------|-----------|
| positive         | 68.87        | 68.38       | 68.62     |
| negative         | 49.49        | 60.02       | 54.25     |
| neutral          | 69.07        | 64.50       | 66.70     |
| Avg F1           |              |             | 61.44     |
| Accuracy         |              |             | 65.18     |

**Table 6.** Run using SWE and filters of size 3,5,7,7.

In order to compare the approach by Moschitti and Severyn (2015), which is quite similar to ours, we tested the code that Severyn kindly provided us. The experiment was run in a similar configuration, using filters of size 3,5,7,7 and also using the sentiment specific embeddings. Contrary to (Moschitti and Severyn, 2015), which used a feature map of a larger size (300), in our experiments we could not see particular benefits in increasing the feature map.

<sup>3</sup> <https://github.com/attardi/deepnl>

Moschitti and Severyn had used their own embeddings, created by distant supervision on a corpus of 50 million tweets that they collected, hence the comparison can only be considered indicative.

| <b>MS-2015</b> | <b>Prec.</b> | <b>Rec.</b> | <b>F1</b> |
|----------------|--------------|-------------|-----------|
| Positive       | 68.03        | 61.73       | 64.73     |
| negative       | 49.29        | 42.06       | 45.39     |
| neutral        | 57.17        | 66.13       | 61.33     |
| Avg F1         |              |             | 55.06     |
| Accuracy       |              |             | 59.85     |

**Table 7.** Test performed using the code by Moschitti&Severyn for SemEval 2015.

## 5 Conclusions

The submission confirmed the effectiveness of convolutional neural networks in the task of tweet sentiment classification. Our systems achieved good precision scores and the third best accuracy score, achieving an overall above average official score.

After submission experiments showed a good ability in separating neutral tweets from the others, with an F1 of 70 on neutral tweets, and a good precision on positive tweets, while the recall on negative tweets was low. The use of sentiment specific word embeddings seems a promising approach for overcoming this problem.

Both the code for the classifier and for computing the sentiment specific embeddings are available on GitHub.

## Acknowledgments

We grateful acknowledge the support of the University of Pisa through project PRA.

We gratefully acknowledge the support by NVIDIA Corporation with a donation of the Tesla K40 GPU used in the experiments.

# IIP at SemEval-2016 Task 4: Prioritizing Classes in Ensemble Classification for Sentiment Analysis of Tweets

Jasper Friedrichs

Infosys Limited

7707 Gateway Boulevard

Newark, CA 94560, USA

jasper\_friedrichs@infosys.com

## Abstract

This paper describes the submission of team IIP in SemEval-2016 Task 4 Subtask A. The presented system is a novel weighted sum ensemble approach for sentiment analysis of short informal texts. The ensemble combines member classifiers that output classification confidence metrics. For the ensemble classification decision the members are combined by weights. In the presented approach the weights are derived to prioritize specific classes in multi-class classification. The presented results confirm that this improves results for the prioritized classes. The official task submission achieved a macro-averaged negative positive F1 of 57.4%. Post submission changes resulted in a F1 score of 60.2%. The evaluation also shows that the system outperforms other ensemble methods.

## 1 Introduction

The SemEval workshops offer the opportunity to compete across a variety of natural language processing tasks. The SemEval-2016 Task 4 Subtask A targets message polarity classification of tweets (Nakov et al., 2016). The polarity can be negative, neutral or positive while the submissions are ranked omitting performance on the neutral class. In practical use cases some classes of a multi-classification problem might be deemed more important than others. For example some work looks explicitly at negative sentiment (Tetlock, 2007).

Combining diverse methods has shown success in sentiment analysis. The combination of machine learners and opinion lexicons has resulted in some of

the best submissions in previous SemEval competitions (Kiritchenko et al., 2014; Miura et al., 2014). Along the line of combining different methods, ensemble approaches have also shown top results in previous runs of this task. Both ensembles of a small number of sophisticated systems (Hagen et al., 2015) as well as large numbers of simpler approaches have been evaluated (Wicentowski, 2015). Ensemble classification with regard to combining different machine learners and feature spaces has previously been evaluated extensively for document level sentiment classification (Xia et al., 2011). In that context, weighted sum ensemble methods have shown the best performance.

This paper describes a weighted sum ensemble that prioritizes some classes in multi-class classification. Results compare the system against two baselines. One baseline is the equivalent approach without prioritizing classes, while the other is an unweighted combination of ensemble members. Naive Bayes and logistic regression classifiers are explored as members across a variety of feature spaces. These classifiers are known to perform differently (Ng and Jordan, 2002). The presented results show:

1. The presented approach successfully prioritizes classes in a multi-class classification problem.
2. The ensemble method outperforms individual members and the baseline ensembles.

The system description will start by a brief outline of the evaluation data. Then the ensemble members are described before the ensemble method is detailed. Finally, the results on all SemEval test sets allow an assessment of the approach and future work.

| Twitter Corpus       | Pos. | Neg. | Neu.  | Total |
|----------------------|------|------|-------|-------|

**Table 1:** SemEval data subsets as well as the full 2016 training set (A), submission (B) and post-submission (C) development data.

## 2 Data

Training data for this approach is constrained to data provided through the SemEval competitions. Table 1 shows the evaluation data used in the approach. This is a subset of the original data, as some tweets were unavailable when querying the Twitter API. The test data corresponds to the data used in the official task ranking (Nakov et al., 2016).

## 3 Ensemble Members

The ensemble members are the basic exchangeable building blocks of this approach. In this work Naive Bayes and logistic regression are chosen as differently performing members.

### 3.1 Naive Bayes

The Naive Bayes classifier is based on the Bayes theorem. The assumption that features are statistically independent might seem too naive. However, this approach often performs surprisingly well. The implementation uses the multinomial Naive Bayes classifier of the datumbox library<sup>1</sup>.

### 3.2 Logistic Regression and Opinion Lexicons

Logistic regression is the second classification approach for ensemble members. Input for this method are text features, as well as scores from five opinion lexicons. Three lexicons have been created automatically from large corpora, namely SentiWordNet (Baccianella et al., 2010), NRC Hashtag Sentiment Lexicon and Sentiment140 Lexicon (Kiritchenko et al., 2014). Bing Liu’s Opinion Lexicon (Hu and

Liu, 2004) was created manually and a fifth lexicon was created automatically and then curated manually. For each lexicon, the two sums over all negative as well as positive opinion scores corresponding to unigrams or lemmas in a message are added as features. The implementation uses the logistic regression classifier available in LIBLINEAR (Fan et al., 2008).

## 3.3 Feature Extraction

User names, URLs and retweet handles are removed before feature extraction. Part-of-speech tags of the CMU ARK Tagger (Owoputi et al., 2013) are used for truecasing if words in a tweet are mostly lowercase or mostly capitalized. ClearNLP (now NLP4J<sup>2</sup>) is used for tokenization, part-of-speech tagging and dependency parsing (Choi and Mccallum, 2013; Choi, 2016). Feature inputs for the classifiers are bag-of-words of unigrams (*uni*), part-of-speech tags (*pos*), bigrams (*bi*), dependency pairs (*dp*) (Xia et al., 2011) and brown clusters (*cl*) (Owoputi et al., 2013). In this work a classifier only ever uses one of the different text feature sets.

## 4 Ensemble

Ensemble methods combine a set of multiple member classifiers. These members can be various classifiers of different methods and different feature sets. Individual classifiers output a classification decision or a classification score for each class.

In the context of this approach classification scores are required for all ensemble members. These scores  $o_{ki} \geq 0$  for every class  $i \in C$  and every member classifier  $k \in M$  are assumed to be normalized,

$$\sum_{i=1}^C o_{ki} = 1. \quad (1)$$

The score  $o_{ki}$  can be interpreted as a probability or confidence measure of classifier  $k$  for class  $i$ .

A basic score based classification method would be to derive the classification decision from the sum over all scores. The highest accumulated class sum would determine the decision, as in

$$\arg \max_{i \in C} \sum_{k=1}^M o_{ki}. \quad (2)$$

<sup>1</sup><https://github.com/datumbox/datumbox-framework>

<sup>2</sup><https://github.com/emorynlp/nlp4j>

Instead the approach uses a weighted sum, with a weight  $w_{ki}$  for every classifier  $k$  and every class  $i$ . Differentiating weights by class represents a finer grained weighting scheme than only differentiating by classifier. The ensemble output is determined by

$$\arg \max_{i \in C} \sum_{k=1}^M w_{ki} o_{ki}, \quad (3)$$

as the class with the highest weighted sum. The essential aspect of a weighed ensemble approach then is how the weights are calculated. The following sections describe optimization conditions that can be used to calculate weights.

#### 4.1 Standard Weight Optimization

A weighted sum ensemble attempts to improve classification by weighing the class scores of individual members. Weights can be calculated based on a gold dataset where the class scores  $o_{ki}$  and the correct gold label  $g$  are known.

The decision function (3) is based on the maximal weighted sum of scores. It is straight forward that a lower difference between weighted sums of different classes is more prone to an erroneous decision through inaccuracies. Thus an intuitive condition for optimal weights could be to maximize the difference between the weighted sum for the correct class and all sums of incorrect classes. For every known gold label  $g$  and the corresponding scores  $o_{kg}$  the conditions would be

$$\sum_{k=1}^M w_{kg} o_{kg} - w_{kj} o_{kj} = |M|, \quad (4)$$

for all labels besides the gold label,  $j \in C \setminus \{g\}$ . The unweighted sum of classification scores was defined equal one for a single classifier (1). This would also be the maximal difference in case of one classifier. Consequently, the conditions for maximal difference between weighted sum scores over the classifier set  $M$  are set equal to the cardinality of the set.

#### 4.2 Prioritizing Weight Optimization

In contrast to the previously introduced weight optimization conditions the following conditions aim to prioritize valid classification of some classes over others. Low priority classes are defined by the set

$L \subseteq C$ . This also defines the priority classes as  $P = C \setminus L$ .

The approach does not aim to improve the ensemble classification across low priority classes  $L$ . For a low priority label  $l \in L$  the weights are fixed to

$$w_{kl} = 1. \quad (5)$$

Based on this, the standard weight conditions (4) for any low priority gold label  $g \in L$  and all priority labels  $p \in P$  are rephrased as

$$\sum_{k=1}^M w_{kp} o_{kp} = -|M| + \sum_{k=1}^M o_{kg} \leq 0. \quad (6)$$

This is problematic because the unweighted sum over scores is positive by definition, since scores can't be negative. However, the derivation shows that the priority weights  $w_{kp}$  would be conditioned to change this sum to negative in favor of low-priority classification decisions. This is a contradiction to the concept of priority classes. The conditions (6) for any low priority gold label  $g \in L$  and all priority labels  $p \in P$  are relaxed to

$$\sum_{k=1}^M w_{kp} o_{kp} = 0. \quad (7)$$

This can be understood as a lower bound for priority weights. Priority weights are also still conditioned to improve priority classification decisions as per the standard conditions (4) for any  $g \in P$ .

Based on the gold dataset the conditions for low priority gold labels (7) and for priority gold labels (4) form an overdetermined system of equations. The solution to this are the priority weights optimized to improve the decision of the ensemble approach. The weights are calculated by solving the conditions as a least squares problem. This requires gold labels from a development dataset different from classifier training data.

## 5 Results

The following section compares results of the introduced approach against the ensemble members and two baseline ensemble methods. The results for Naive Bayes and logistic regression ensemble members on different feature spaces as well as the results for the ensembles are presented in the following.

| Test, weight data | Sum    |           |      | IIP std |           |      | IIP prio    |             |             |
|-------------------|--------|-----------|------|---------|-----------|------|-------------|-------------|-------------|
|                   | uni-bi | uni-bi-cl | all  | uni-bi  | uni-bi-cl | all  | uni-bi      | uni-bi-cl   | all         |
| 2013-test, B      | 55.5   | 56.8      | 55.7 | 55.1    | 55.4      | 53.7 | <b>60.5</b> | <b>60.5</b> | 59.8        |
| 2014-test, B      | 61.6   | 62.9      | 61.3 | 59.5    | 60.5      | 59.4 | 65.3        | <b>65.9</b> | 64.5        |
| 2015-test, B      | 57.4   | 59.4      | 58.3 | 58.5    | 57.6      | 56.8 | <b>63.3</b> | 62.9        | 61.0        |
| 2016-test, B      | 56.1   | 58.0      | 56.6 | 55.0    | 56.0      | 55.4 | 58.3        | <b>58.7</b> | 57.4*       |
| 2013-test, C      | 55.5   | 56.8      | 55.7 | 59.7    | 59.4      | 59.7 | 63.6        | 64.3        | <b>64.6</b> |
| 2014-test, C      | 61.6   | 62.9      | 61.3 | 64.7    | 66.1      | 65.3 | 68.0        | <b>69.9</b> | 68.5        |
| 2015-test, C      | 57.4   | 59.4      | 58.3 | 60.7    | 62.3      | 61.3 | 64.1        | <b>66.2</b> | 65.5        |
| 2016-test, C      | 56.1   | 58.0      | 56.6 | 58.2    | 59.0      | 58.8 | 59.4        | <b>60.2</b> | 59.5        |

**Table 2:** Macro-averaged positive negative F1 [%] for all test data sets across three ensemble methods and three member sets. Set *all* corresponds to all classifier, feature combinations evaluated for 2016-test data in Table 3. Ensemble members were trained on the full 2016 training set (A) while ensemble weights were optimized on 2016 (B) and 2013/2016 development sets (C, Table 1).

| 2016-test | uni  | pos  | bi   | dp   | cl          |
|-----------|------|------|------|------|-------------|
| NB        | 54.5 | 30.3 | 40.7 | 37.6 | <b>54.4</b> |
| LR        | 55.5 | 53.5 | 52.0 | 52.7 | <b>57.6</b> |

**Table 3:** Macro-averaged positive negative F1 [%] for ensemble members of 2016-test on full 2016 training set (A, Table 1).

Table 3 shows the results for Naive Bayes (*NB*) and logistic regression (*LR*) ensemble members. For both classification approaches brown clusters (*cl*) show the best performance.

Table 2 shows results for three ensemble approaches and three sets of members. The *Sum* columns show results for an unweighted sum over contributing classifier scores, as in (2). *IIP std* is a weighted sum approach with standard weight optimization as in (4). *IIP prio* adds the priority condition (7) with positive and negative as priority classes.

The bottom result set for weight optimization on 2013 and 2016 development data shows substantially better results than the top one, where weights were optimized on 2016 development data. While the weighted sum approach is of course unaffected by this, this holds true for all ensemble member sets in the weighted sum ensembles.

Across both result sets the *IIP prio* ensemble always outperforms the other two baseline ensemble methods. The standard ensemble which does not prioritize classes *IIP std* outperforms the sum baseline in the bottom result set but often does not in the top one. For all ensemble approaches the member sets of classifiers for unigram, bigram and cluster feature spaces usually show the best results.

The system for the official submission \* used all members with priority weight optimization, obtain-

ing a macro-averaged F1 of 57.4%. Though this outperforms the equivalent baseline ensembles it performs on a similar level as the best logistic regression member in Table 3. In contrast the best *IIP prio* result used unigram, bigram and cluster members in an ensemble optimized for 2013 and 2016 development data, achieving a macro-averaged F1 of 60.2%.

## 6 Conclusion

This paper presented two methods for weighted sum ensemble classification. The introduced class prioritizing method outperformed the standard method in all evaluations. Furthermore, the results show that the class prioritizing weight ensemble method usually outperformed the basic sum ensemble approach substantially. This shows that combining different classifiers across various feature spaces while prioritizing some classes in multi-class classification works well with the presented system.

The results varied significantly depending on the data used for optimizing weights. Optimization on a more diverse data set showed better performance. Questions of domain dependence and over-fitting need to be explored further. With the modular nature of an ensemble a variety of classifiers and features are left to be evaluated in the context of this approach.

## Acknowledgments

The author is grateful for the opportunity to contribute the implementation of this approach to NLP4J<sup>3</sup>.

## Abstract

This paper presents an alternative approach to polarity and intensity classification of sentiments in microblogs. In contrast to previous works, which either relied on carefully designed hand-crafted feature sets or automatically derived neural embeddings for words, our method harnesses character embeddings as its main input units. We obtain task-specific vector representations of characters by training a deep multi-layer convolutional neural network on the labeled dataset provided to the participants of the SemEval-2016 Shared Task 4 (Sentiment Analysis in Twitter; Nakov et al., 2016b) and subsequently evaluate our classifiers on subtasks B (two-way polarity classification) and C (joint five-way prediction of polarity and intensity) of this competition. Our first system, which uses three manifold convolution sets followed by four non-linear layers, ranks 16 in the former track; while our second network, which consists of a single convolutional filter set followed by a highway layer and three non-linearities with linear mappings in-between, attains the 10-th place on subtask C.<sup>1</sup>

## 1 Introduction

Sentiment analysis (SA) – a field of knowledge which deals with the analysis of people’s opinions, sentiments, evaluations, appraisals, attitudes, and emotions towards particular entities mentioned in discourse (Liu, 2012) – is commonly considered to be one of the most challenging, competitive, but at

<sup>1</sup>The source code of our implementation is freely available online at <https://github.com/WladimirSidorenko/SemEval-2016/>

the same time utmost necessary areas of research in modern computational linguistics.

Unfortunately, despite numerous notable advances in recent years (e.g., Breck et al., 2007; Yessenalina and Cardie, 2011; Socher et al., 2011), many of the challenges in the opinion mining field, such as domain adaptation or analysis of noisy texts, still pose considerable difficulties to researchers. In this respect, rapidly evaluating and comparing different approaches to solving these problems in a controlled environment – like the one provided for the SemEval task (Nakov et al., 2016b) – is of crucial importance for finding the best possible way of mastering them.

We also pursue this goal in the present paper by investigating whether one of the newest machine learning trends – the use of deep neural networks (DNNs) with small receptive fields – would be a viable solution for improving state-of-the-art results in sentiment analysis of Twitter.

After a brief summary of related work in Section 2, we present the architectures of our networks and describe the training procedure we used for them in Section 3. Since we applied two different DNN topologies to subtasks B and C, we make a cross-comparison of both systems and evaluate the role of the preprocessing steps in the next-to-last section. Finally, in Section 5, we draw conclusions from our experiments and make further suggestions for future research.

## 2 Related Work

Since its presumably first official mention by Nasukawa and Yi in 2003 (cf. Liu, 2012), sentiment analysis has constantly attracted the attention of re-

searchers. Though earlier works on opinion mining were primarily concerned with the analysis of narratives (Wiebe, 1994) or newspaper articles (Wiebe et al., 2003), the explosive emergence of social media (SM) services in the mid-2000s has brought about a dramatic focus change in this field.

A particularly important role in this regard was played by Twitter – a popular microblogging service first introduced by Jack Dorsey in 2006 (Dorsey, 2006). The sudden availability of huge amounts of data combined with the presence of all possible social and national groups on this stream rapidly gave rise to a plethora of scientific studies. Notable examples of these were the works conducted by Go et al. (2009) and Pak and Paroubek (2010), who obtained their corpora using distant supervision and subsequently trained several classifiers on these data; Kouloumpis et al. (2011), who trained an AdaBoost system on the Edinburgh Twitter corpus<sup>2</sup>; and Agarwal et al. (2011), who proposed tree-kernel methods for doing message-level sentiment analysis of tweets.

Eventually, with the introduction of the SemEval corpus (Nakov et al., 2013), a great deal of automatic systems and resources have appeared on the scene. Though most of these systems typically rely on traditional supervised classification methods, such as SVM (Mohammad et al., 2013; Becker et al., 2013) or logistic regression (Hamdan et al., 2015; Plotnikova et al., 2015), in recent years, the deep learning (DL) tsunami (Manning, 2015) has also started hitting the shores of this “battlefield”.

In this paper we investigate whether one of the newest lines of research in DL – the use of character-level deep neural networks (charDNNs) – would be a perspective way for addressing the sentiment analysis task on Twitter as well.

Introduced by Sutskever et al. (2011), char-DNNs have already proved their efficiency for a variety of NLP applications, including part-of-speech tagging (dos Santos and Zadrozny, 2014), named-entity recognition (dos Santos and Guimarães, 2015), and general language modeling (Kim et al., 2015; Józefowicz et al., 2016). We hypothesized that the reduced feature sparsity of this approach, its lower susceptibility to informal spellings, and the shift of

the main discriminative classification power from input units to transformation layers would make it suitable for doing opinion mining on Twitter as well.

### 3 Method

To test our conjectures, we downloaded the training and development data provided by the organizers of the SemEval-2016 Task 4 (Sentiment Analysis in Twitter; Nakov et al., 2016b). Due to dynamic changes of this content, we were only able to retrieve a total of 5,178 messages for subtasks B and D (two-way polarity classification) and 7,335 microblogs for subtasks C and E (joint five-way prediction of polarity and intensity).

We deliberately refused to do any heavy-weight NLP preprocessing of these data to check whether the applied DL method alone would suffice to get acceptable results. In order to facilitate the training and reduce the variance of the learned weights though, we applied a shallow normalization of the input by lower-casing messages’ strings and filtering out stop words before passing the tweets to the classifiers.

As stop words we considered all auxiliary verbs (e.g., *be*, *have*, *do*) and auxiliary parts of speech (prepositions, articles, particles, and conjunctions) up to a few exceptions – we kept the negations and words that potentially could inverse the polarity of opinions, e.g., *without*, *but*, and *however*. Furthermore, we also removed hyperlinks, digits, retweets, @-mentions, common temporal expressions, and mentions of tweets’ topics, since all of these elements were *a priori* guaranteed to be objective. An example of such preprocessed microblog is provided below:

#### EXAMPLE 3.1.

**Original:** *Going to MetLife tomorrow but not to see the boys is a weird feeling*

**Normalized:** *but not see boys weird feeling*

#### 3.1 Adversarial Convolutional Networks (Subtasks B and D)

We then defined a multi-layer deep convolutional network for subtasks B and D as follows:

At the initial step, we map the input characters to their appropriate embeddings, obtaining an input matrix  $E \in \mathbb{R}^{n \times m}$ , where  $n$  stands for the length of

---

<sup>2</sup><http://demeter.inf.ed.ac.uk>

the input instance, and  $m$  denotes the dimensionality of the embedding space (specifically, we use  $m = 32$ ).

Next, three sets of convolutional filters – positive (+), negative (−), and shifter (x) convolutions – are applied to the input matrix  $E$ . Each of these sets in turn consists of three subsets: one subset with 4 filters of width 3, another subset comprising 8 filters of width 4, and, finally, a third subset having 12 filters of width 5.<sup>3</sup>

Each subset filter  $F$  forms a matrix  $\mathbb{R}^{w \times m}$  with the number of rows  $w$  corresponding to the filter width and the number of columns  $m$  being equal to the embedding dimensionality as above. A subset of filters  $S_w^p$  for  $p \in \{+, -, x\}$  is then naturally represented as a tensor  $\mathbb{R}^{c \times w \times m}$ , where  $c$  is the number of filters with the given width  $w$ .

We apply the usual convolution operation with max-pooling over time for each filter, getting an output vector  $\vec{v}_{S_w^p} \in \mathbb{R}^c$  for each subset. All output vectors  $\vec{v}_{S_*^p}$  of the same subset are then concatenated into one vector  $\vec{v}_{S^p} = [\vec{v}_{S_3^p}, \vec{v}_{S_4^p}, \vec{v}_{S_5^p}]$  of size  $4 + 8 + 12 = 24$ .

The results of the three sets are subsequently joined using the following equation:

$$\vec{v}_{conv} = \text{sig}(\vec{v}_{S+} - \vec{v}_{S-}) \odot \tanh(\vec{v}_{S^x}),$$

where  $\vec{v}_{S+}$ ,  $\vec{v}_{S-}$ , and  $\vec{v}_{S^x}$  mean the output vectors for the positive, negative, and shifter sets respectively, and  $\odot$  denotes the Hadamard product.

The motivation behind this choice of unification function is that we first want to obtain the difference between the positive and negative predictions (thus  $\vec{v}_{S+} - \vec{v}_{S-}$ ), then map this difference to the range  $[0, 1]$  (therefore the sigmoid), and finally either inverse or dampen these results depending on the output of the shifter layer, whose values are guaranteed to be in the range  $[-1, 1]$  thanks to tanh. Since we simultaneously apply competing convolutions to the same input, we call this layer “adversarial” as all of its components have different opinions regarding the final outcome.

After obtaining  $\vec{v}_{conv}$ , we consecutively use three non-linear transformations (linear rectification, hy-

<sup>3</sup>By simultaneously applying multiple filter sets of different width to the same input, we hoped to improve the precision-recall trade-off, getting more accurate outputs from wider filters while reducing their sparsity with narrower kernels.

perbolic tangent, and sigmoid function) with linear modifications in-between:

$$\begin{aligned}\vec{v}_{relu} &= \text{relu}(\vec{v}_{conv} \cdot M_{relu} + \vec{b}_{relu}), \\ \vec{v}_{tanh} &= \tanh(\vec{v}_{relu} \cdot M_{tanh} + \vec{b}_{tanh}), \\ \vec{v}_{sig} &= \text{sig}(\vec{v}_{tanh} \cdot M_{sig} + \vec{b}_{sig}).\end{aligned}$$

In this equation,  $M_{relu}$ ,  $M_{tanh}$ , and  $M_{sig} \in \mathbb{R}^{24 \times 24}$  stand for the linear transform matrices, and  $\vec{b}_{relu}$ ,  $\vec{b}_{tanh}$ ,  $\vec{b}_{sig} \in \mathbb{R}^{24}$  represent the usual bias terms. With this combination, we hope to first prune unreliable input signals by using a hard rectifying linear unit (Jarrett et al., 2009) and then gain more discriminative power by successively applying tanh and sig, thus funneling the input to increasingly smaller ranges:  $[-1, 1]$  in the case of tanh, and  $[0, 1]$  in the case of sigmoid.

At the last stage, after applying a binomial dropout mask with  $p = 0.5$  to the  $\vec{v}_{sig}$  vector (Srivastava et al., 2014), we compute the final prediction as:

$$y' = \begin{cases} 1, & \text{if } \text{sig}(\sum \vec{v}_{sig} \cdot M_{pred} + \vec{b}_{pred}) \geq 0.5 \\ 0, & \text{otherwise,} \end{cases} \quad (1)$$

where  $M_{pred} \in \mathbb{R}^{24 \times 2}$  and  $\vec{b}_{pred} \in \mathbb{R}^2$  stand for the transformation matrix and bias term respectively, and the summation runs over the two elements of the resulting  $\mathbb{R}^2$  vector.

To train our classifier, we normally define the cost function as:

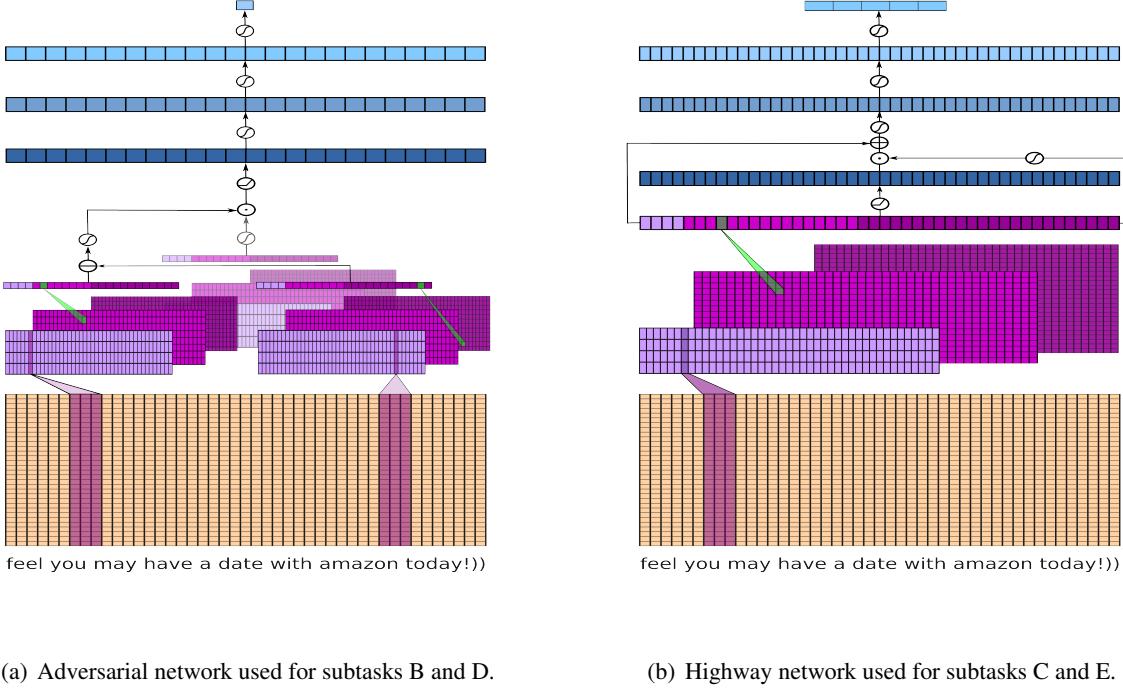

$$\text{cost} = \sum_i y_i * (1 - y'_i) + (1 - y_i) * y'_i, \quad (2)$$

where  $y_i$  denotes the gold category of the  $i$ -th training instance and  $y'_i$  stands for its predicted class, and optimize this function using RMSProp (Tieleman and Hinton, 2012).

### 3.2 Highway Convolutional Networks (Subtasks C and E)

A slightly different model was used for subtasks C and E:

In contrast to the previous two-way classification network, we only use one set of convolutions with 4 filters of width 3, 16 filters of width 4, and 24 filters of width 5, and the number of dimensions of the

(a) Adversarial network used for subtasks B and D.

(b) Highway network used for subtasks C and E.

**Figure 1:** Network architectures.

resulting  $\vec{v}_{conv}$  vector being equal to 44 instead of 24.

After normally computing and max-pooling the convolutions, we pass the output convolution vector through a highway layer (Srivastava et al., 2015) in addition to using relu, i.e.:

$$\begin{aligned}\vec{v}_{hwtrans} &= \text{sig}(\vec{v}_{conv} \cdot M_{hwtrans} + \vec{b}_{hwtrans}), \\ \vec{v}_{hwcarry} &= \vec{v}_{conv} \odot (1 - \vec{v}_{hwtrans}), \\ \vec{v}_{relu'} &= \text{relu}(\vec{v}_{conv} \cdot M_{conv'} + \vec{b}_{conv'}), \\ \vec{v}_{relu} &= \text{sig}(\vec{v}_{relu'} \odot \vec{v}_{hwtrans} + \vec{v}_{hwcarry}).\end{aligned}$$

The rest of the network is organized the same way as in the previous model, up to the final layer. Since this task involves multivariate classification, instead of computing the sigmoid of the sum as in Equation 1, we obtain a softmax vector  $\vec{v}_\sigma \in \mathbb{R}^5$  and consider the argmax value of this vector as the predicted class:

$$\begin{aligned}\vec{v}_\sigma &= \sigma(\vec{v}_{sig} \cdot M_\sigma + \vec{b}_\sigma) \\ y' &= \text{argmax}(\vec{v}_\sigma)\end{aligned}$$

The corresponding cost function is appropriately defined as:

$$cost = \sum_i -\ln \vec{v}_\sigma[y_i] + \ell_2 * \sum_p \|p\|^2 + \ell_3 * (y_i - y'_i)^2,$$

where  $\vec{v}_\sigma[y_i]$  means the probability value for the gold class in the  $\vec{v}_\sigma$  vector,  $\ell_2$  and  $\ell_3$  are constants (we use  $\ell_2 = 1e^{-5}$  and  $\ell_3 = 3e^{-4}$ ),  $p$ 's denote the training parameters of the model, and  $(y_i - y'_i)^2$  stand for the squared difference between the numerical values of the predicted and gold classes.

In this task, we opted for the  $L_2$  regularization instead of using dropout, since we found it working slightly better on the development set, though the differences between the two methods were not very big, and the derivative computation with dropout was significantly faster.

### 3.3 Initialization and Training

Because initialization has a crucial impact on the results of deep learning approaches (Sutskever et al., 2011), we did not rely on purely random weights but used the uniform He method (He et al., 2015) for initially setting the embeddings, convolutional filters, and bias terms instead. The inter-layer transformations were set to orthogonal matrices to ensure their full rank.

Additionally, to guarantee that each preceding network stage came maximally prepared and provided best possible output to its successors, after

adding each new intermediate layer, we temporarily short-circuited it to the final output node(s) and pre-trained this abridged network for 5 epochs, removing the short-circuit connections afterwards. The final training then took 50 epochs with each epoch lasting for 35 iterations over the provided training data.

Since our models appeared to be very susceptible to imbalanced classes, we subsampled the training data by getting  $\min(1.1 * n_{min}, n_c)$  samples for each distinct gold category  $c$ , where  $n_{min}$  is the number of instances of the rarest class in the corpus, and  $n_c$  denotes the number of training examples belonging to the  $c$ -th class. This subset was resampled anew for each subsequent training epoch.

Finally, to steer our networks towards recognizing correct features, we randomly added additional training instances from two established sentiment lexica: Subjectivity Clues (Wilson et al., 2005) and NRC Hashtag Affirmative Context Sentiment Lexicon (Kiritchenko et al., 2014). To that end, we drew  $n$  binary random numbers for each polarity class in the corpus from a binomial distribution  $B(n, 0.1)$ , where  $n$  stands for the total size of the generated training set, and added a uniformly chosen term from either lexica whenever the sampled value was equal to one. In the same way, we randomly (with the probability  $B(m, 0.15)$ , where  $m$  means the number of matches) replaced occurrences of terms from the lexica in the training tweets with other uniformly drawn lexicon items.

## 4 Evaluation

To train our final model, we used both training and development data provided by the organizers, setting aside 15 percent of the samples drawn in each epoch for evaluation and using the remaining 85 percent for optimizing the networks' weights.

We obtained the final classifier by choosing the network state that produced the best task-specific score on the set-aside part of the corpus during the training. For this purpose, in each training iteration, we estimated the *macroaveraged recall*  $\rho^{PN}$  on the evaluation set for subtask B:

$$\rho^{PN} = \frac{\rho^{Pos} + \rho^{Neg}}{2},$$

and computed the *macroaveraged mean absolute error* measure  $MAE^M$  (cf. Nakov et al., 2016a) to

select a model for track C :

$$MAE^M(h, Te) = \frac{1}{|\mathcal{C}|} \sum_{j=1}^{|\mathcal{C}|} \frac{1}{|Te_j|} \sum_{x \in Te_j} |h(x_i) - y_i|$$

The resulting models were then used in both classification and quantification subtasks of the SemEval competition, i.e., we used the adversarial network with the maximum  $\rho^{PN}$  score observed during the training to generate the output for tracks B and D and applied the highway classifier with the minimum achieved  $MAE^M$  rate to get predictions for subtasks C and E.<sup>4</sup> The scores of the final evaluation on the official test set are shown in Table 1.

Since many of our parameter and design choices were made empirically by analyzing systems' errors at each development step, we decided to recheck whether these decisions were still optimal for the final configuration. To that end, we re-evaluated the effects of the preprocessing steps by temporarily switching off lower-casing and stop word filtering, and also estimated the impact of the network structure by applying the model architecture used for subtask B to the five-way prediction task, and vice versa using the highway network for the binary classification. The output layers, costs, and regularization functions of these two approaches were also swapped in these experiments when applied to different objectives.

Because re-running the complete training from scratch was relatively expensive (taking eight to ten hours on our machine), we reduced the number of training epochs by a factor of five, but tested each configuration thrice in order to overcome the random factors in the He initialization. The arithmetic mean and standard deviation (with  $N = 2$ ) of these three outcomes for each setting are also provided in the table.

As can be seen from the results, running fewer training epochs does not notably harm the final prediction quality for the binary task. On the contrary, it might even lead to some improvements for the adversarial network. We explain this effect by the fact that the model selected during the shorter training had a lower score on the evaluation set than the network state chosen during 50 epochs. Nevertheless,

---

<sup>4</sup>We used the official aggregating scripts to generate the results for the quantification tasks.

| Training Configuration        | $\rho^{PN} \wedge$<br>(Subtask B) | $MAE^M \vee$<br>(Subtask C) |
|-------------------------------|-----------------------------------|-----------------------------|
| Adversarial <sup>1/5,cs</sup> | $61.34 \pm 1.24$                  | $1.3 \pm 0.05$              |
| Adversarial <sup>1/5,sw</sup> | $58.64 \pm 0.8$                   | $1.3 \pm 0.05$              |
| Adversarial <sup>1/5</sup>    | $61.9 \pm 0.66$                   | $1.37 \pm 0.03$             |
| Adversarial                   | 61.8                              | n/a                         |
| Highway <sup>1/5,cs</sup>     | $59.87 \pm 0.79$                  | $1.26 \pm 0.01$             |
| Highway <sup>1/5,sw</sup>     | $60.35 \pm 1.5$                   | $1.23 \pm 0.05$             |
| Highway <sup>1/5</sup>        | $62.05 \pm 0.75$                  | $1.3 \pm 0.04$              |
| Highway                       | n/a                               | 1.24                        |

**Table 1:** Results of the adversarial and highway networks with different preprocessing steps on Subtasks B and C. ( $\wedge$  – higher is better;  $\vee$  – lower is better;  $^{1/5}$  – using 1/5 of training epochs; <sup>cs</sup> – preserving the character case; <sup>sw</sup> – keeping stop words)

despite its worse evaluation results, this first configuration was more able to fit the test data than the second system, which apparently overfitted the set-aside part of the corpus.

Furthermore, we also can observe a mixed effect of the normalization on the two tasks: while keeping stop words and preserving character case deteriorates the results for the binary classification, abandoning any preprocessing steps turns out to be a more favorable solution when doing five-way prediction. The reasons for such different behavior are presumably twofold: *a*) the character case by itself might serve as a good indicator of sentiment intensity but be rather irrelevant to expressing its polarity, and *b*) the number of training instances might have become scarce as the number of possible gold classes in the corpus increased.

Finally, one also can see that the highway network performs slightly better on both subtasks (two- and five-way) than its adversarial counterpart when used with shorter training. In this case, we assume that the swapping of the regularization and cost functions has hidden the distinctions of the two networks at their initial layers, since, in our earlier experiments, we did observe better results for the two-way classification with the adversarial structure.

## 5 Discussion and Conclusion

Unfortunately, despite our seemingly sound theoretical assumptions set forth at the beginning, relying on character embeddings as input did not work out in practice at the end. Our adversarial system was only ranked fourth to last on subtask B, and the highway

network attained the second to last place in track C. However, knowing this outcome in advance was not possible without trying out these approaches first.

In order to make a retrospective error analysis, we computed the correlation coefficients between the character n-grams occurring in the training data and their gold classes, also comparing these figures with the corresponding numbers obtained on the test set. The results of this comparison are shown in Table 2.

| 3<br>chars | $\rho_{\text{train}}$ | $\rho_{\text{test}}$ | 4<br>chars |       | $\rho_{\text{train}}$ | $\rho_{\text{test}}$ | 5<br>chars |       | $\rho_{\text{train}}$ | $\rho_{\text{test}}$ |

|            | 0.036                 | 0.055                | 0.036      | 0.036 | 0.067                 | 0.059                | 0.036      | 0.1   | 0.026                 | 0.062                |

**Table 2:** Top-10 character n-grams from the training data and their correlation coefficients with the negative class on the training ( $\rho_{\text{train}}$ ) and test sets ( $\rho_{\text{test}}$ ) of subtask B.

As can be seen from the table, the most reliable classification traits that could have been learned during the training are very specific to their respective topics – in particular, *Trump* and *Turkey* appear to be very negatively biased terms. This effect becomes even more evident as the length of the character n-grams increases. The reason why we did not pre-filter these substrings in the preprocessing was that the respective topics of these messages were specified as *donald trump* and *erdogan*, but we only removed exact topic matches from tweets.

Due to this evident topic susceptibility, as a possible way to improve our results, we could imagine the inclusion of more training data. Applying ensemble approaches, as it was done by the top-scoring systems this year, could also be a perspective direction to go. We would, however, advise the reader from further experimenting with network architectures (at least when training on the original SemEval dataset only), since both the recursive (RNTN, Socher et al., 2012) and recurrent variants (LSTM, Hochreiter and Schmidhuber, 1997) of neural classifiers were found to perform worse in our experiments than the feed-forward structure we described.

## Abstract

We present the INESC-ID system for the 2016 edition of SemEval Twitter Sentiment Analysis shared task (subtask 4-A). The system was based on the Non-Linear Sub-space Embedding (NLSE) model developed for last year’s competition. This model trains a projection of pre-trained embeddings into a small sub-space using the supervised data available. Despite its simplicity, the system attained performances comparable to the best systems of last edition with no need for feature engineering. One limitation of this model was the assumption that a pre-trained embedding was available for every word. In this paper, we investigated different strategies to overcome this limitation by exploiting character-level embeddings and learning representations for out-of-embedding vocabulary words. The resulting approach outperforms our previous model by a relatively small margin, while still attaining strong results and a consistent good performance across all the evaluation datasets.

## 1 Introduction

Pre-trained word embeddings provide a simple means to attain semi-supervised learning in Natural Language Processing (NLP) tasks (Collobert et al., 2011). They can be trained with large amounts of unsupervised data and be fine tuned as the initial building block of a semi-supervised system. However, in domains with a significant number of typos, use of slang and abbreviations, such as social media, the high number of singletons leads to a poor fine tuning of the embeddings. In previous work,

we addressed this by learning a projection of the embeddings into a small sub-space (Astudillo et al., 2015b). This allowed us to attain representations also for Out-Of-Vocabulary (OOV) words, provided that embeddings for those words are available. However, even if the embeddings are estimated from large amounts of unlabeled text, in noisy domains, such as Twitter, a significant number of words will not be seen and therefore will not have an embedding. We refer to those words as the Out-of-Embedding Vocabulary (OOEV).

In this paper, we focus on the problem of obtaining good representations for OOEV words. We experimented with character to word models (C2W) and investigated different strategies for initializing and updating OOEVs from the available training data. The best results were attained by using the labeled data to perform small updates to these representations in the first few epochs of training. The resulting system outperforms that of the previous evaluation, although by a small margin. It ranks fourth in the 2016 evaluation with a consistently high performance in all years.

## 2 NLSE Model Overview

In this section, we briefly review the approach introduced in the 2015 evaluation (Astudillo et al., 2015a). For a particular regression or classification task, only a subset of all the latent aspects captured by the word embeddings will be useful. Therefore, instead of updating the embeddings directly with the available labeled data, we estimate a projection of these embeddings into a low dimensional sub-space. This simple method brings two fundamental advan-

tages. Firstly, the lower dimensional embeddings require fewer parameters fitting the complexity of the target task and the available training data. Secondly, the learned projection can be used to adapt the representations for all words with an embedding, even if they do not occur in the labeled dataset.

Assuming we are given a matrix of pre-trained embeddings, where each column represents a word from a vocabulary  $\mathcal{V}$ , let such matrix be denoted by  $\mathbf{E} \in \mathbb{R}^{e \times |\mathcal{V}|}$ , where  $e$  is the number of latent dimensions. We define the adapted embedding matrix as the factorization  $\mathbf{S} \cdot \mathbf{E}$ , where  $\mathbf{S} \in \mathbb{R}^{s \times e}$ , with  $s \ll e$ . The parameters of matrix  $\mathbf{S}$  are estimated using the labeled dataset, while  $\mathbf{E}$  is kept fixed. In other words, we determine the optimal projection of the embedding matrix  $\mathbf{E}$  into a sub-space of dimension  $s$ . In what follows, we will refer to this approach as Non-Linear Sub-space Embedding (NLSE) model.

The NLSE can be interpreted as a simple feed-forward neural network model (Rumelhart et al., 1985) with one single hidden layer utilizing the embedding sub-space approach. Let

$$\mathbf{m} = [\mathbf{w}_1 \cdots \mathbf{w}_n] \quad (1)$$

denote a message of  $n$  words. Each column  $\mathbf{w} \in \{0, 1\}^{v \times 1}$  of  $\mathbf{m}$  represents a word in one-hot form, that is, a vector of zeros of the size of the vocabulary  $v$  with a 1 on the  $i$ -th entry of the vector. Let  $y$  denote a categorical random variable over  $K$  classes. The NLSE model, estimates the probability of each possible category  $y = k \in K$  given a message  $\mathbf{m}$  as

$$p(y = k | \mathbf{m}; \theta) \propto \exp(\mathbf{Y}_k \cdot \mathbf{h} \cdot \mathbf{1}) \quad (2)$$

with parameters  $\theta = \{\mathbf{S}, \mathbf{Y}\}$ . Here,  $\mathbf{h} \in [0, 1]^{e \times n}$  are the activations of the hidden layer for each word, given by

$$\mathbf{h} = \sigma(\mathbf{S} \cdot \mathbf{E} \cdot \mathbf{m}) \quad (3)$$

where  $\sigma()$  is a sigmoid function acting on each element of the matrix. The matrix  $\mathbf{Y} \in \mathbb{R}^{3 \times s}$  maps the embedding sub-space to the classification space and  $\mathbf{1} \in \mathbb{1}^{n \times 1}$  is a matrix of ones that sums the scores for all words together, prior to normalization. This is equivalent to a bag-of-words assumption. Finally, the model computes a probability distribution over the  $K$  classes, using the *softmax* function.

### 3 Out-of-Embedding Vocabulary Words

Despite the fact that word embeddings are typically estimated from very large amounts of unlabeled data, it is often the case that a number of words appearing on the training or test sets are not present on the unlabeled corpus. These words will not be represented in  $\mathbf{E}$ . This problem is even more significant in social media environments like Twitter, where there is a significant lexical variation and where novel words, expressions and slang can be introduced over time. In Table 1, we show the percentage of OOV and OOEV words on each Twitter dataset.

The naïve way of dealing with this issue, is to simply set the embeddings of unknown words to zero, essentially ignoring them. As will see later, a better approach is to treat these words as model parameters and use the training signal to learn a better representation for them.

#### 3.1 Character-level Embeddings

One natural way of avoiding OOEV in neural network models, is to learn character-level embeddings and define a composition function to combine them into word representations, thus obtaining representations for any given word.

We experimented using *C2W*, a simple compositional model for learning word representations, from character embeddings. Given a word  $w$ , the *C2W* model generates a set of character n-grams  $\{c_1, \dots, c_m\}$ , and projects each n-gram  $c_i$  into a vector  $\mathbf{e}_{c_i} \in \mathbb{R}^d$ , where  $d$  is the number of latent dimensions. The individual character representations are then combined to obtain a fixed-size representation for word  $w$  as  $\mathbf{e}_w = \mathbf{e}_{c_1} \oplus \dots \oplus \mathbf{e}_{c_m}$ , where  $\oplus$  denotes pointwise sum. These word representations can be used as the input to a standard neural language model where the parameters are estimated from unlabeled data by learning to predict words within a context.

#### 3.2 Mapping *C2W* to *SSG* Embeddings

Unfortunately the *C2W* embeddings performed very poorly in our model. Therefore, to have embeddings for all the words we employed an approach similar to (Mikolov et al., 2013). We learn a mapping between the embedding spaces induced by *C2W* and

Table 2: Effect of the improvements on the NLSE model.

Structured Skip-Gram embeddings (*SSG*) (Ling et al., 2015), allowing us compute an approximate *SSG* embedding for all the words. To this end, we first obtained  $\mathcal{C}$ , the set of words present in the two embeddings spaces. Then, we learned a linear map  $\mathbf{T}$  by solving for the following objective:

$$\mathbf{T} \leftarrow \underset{\mathbf{T}}{\operatorname{argmin}} \sum_{w \in \mathcal{C}} \|\mathbf{T} \cdot \mathbf{c}_w - \mathbf{s}_w\|^2 \quad (4)$$

where,  $\mathbf{c}_w$  denotes the *C2W* embedding for word  $w$  and  $\mathbf{s}_w$  denotes the *SSG* embedding for word  $w$ . This mapping, was then used to compute a *SSG* embeddings for each OOEV as  $\mathbf{s}_{w'} = \mathbf{T} \cdot \mathbf{c}_{w'}$ .

### 3.3 Partial Update of Embeddings during Training

Given the small amount of supervised data, directly updating the embeddings with the SemEval train set leads to very poor results. It is however possible to update only the OOEV words present in the training set simultaneously to the computation of the subspace (Astudillo et al., 2015a). To obtain positive results with this approach, it was also necessary to reduce the effect of training by lowering the learning rate to 0.001 and updating the embeddings only in the first two iterations.

## 4 Main Improvements over the 2015 NLSE

One complication with Twitter-based evaluations is the need of the participant to retrieve the tweets themselves, since some of the tweets may no longer be available. The INESC-ID system presented in 2015 employed a train set of 8604 tweets, considerably smaller than the original dataset (with 11328 tweets). For this edition, it was possible to get ahold of the full dataset, as utilized by Severyn and Moschitti (2015). For reproducibility and comparison purposes our systems this year were developed with this dataset.

The system presented in 2015 was very simple both in its structure and the number hyperparameters. Furthermore, tunning and selection of candidate systems was also performed without automatic grid-search. It was therefore expected that our previous setup would outright produce better results by training on a larger dataset. Disappointingly, this was not the case. In fact, the NLSE optimized for the 2015 competition seemed to be sitting on a local optimum that was difficult to come out from. To overcome this problem, we introduced two modifications in the training procedure<sup>1</sup>. The NLSE is trained by minimizing the negative log-likelihood. This cost function is sub-optimal taking into account the evaluation metric, as it weights equally positive, negative and neutral predictions. A simple improvement over this cost is an asymmetric weighting that penalizes the predictions of neutral tweets. This was incorporated as a multiplicative factor on the log-likelihood of values 4/3, 4/3 and 1/3 for the positive, negative and neutral classes, respectively. To reduce the risk of getting trapped into a local minimum, the train data was shuffled before each training epoch. The asymmetric cost and randomization led to a slower, less consistent convergence. For this reason the number of iterations was increased from 8 to 12. The learning rate was changed from 0.01 to 0.005. Table 2 shows the effect of the improvements on the submitted system.

After introducing these two improvements, we investigated different methods to address the problem of OOEV as described in the previous sec-

<sup>1</sup> After paper revision the model in <https://github.com/ramon-astudillo/NLSE> will be updated to reflect the new system.

tion. Namely those exploiting *C2W* embeddings, mapping *C2W* embeddings to *SSG* embeddings and training the embeddings for OOEVs. The results of these strategies are displayed in Table 3.

| <b>System</b>           | <b>2013</b>  | <b>2014</b>  | <b>2015</b>  | <b>2016</b>  |
|-------------------------|--------------|--------------|--------------|--------------|
| baseline                | 0.721        | 0.721        | 0.649        | 0.609        |

Table 3: Comparision of strategies to address the problem of OOEV

## 5 The Submitted System

As mentioned in the previous section, the system submitted is an improvement over our 2015 system (Astudillo et al., 2015b). It therefore shares the same training characteristics as the previous model. The 52 million tweets used by Owoputi et al. (2013) and the tokenizer described in the same work were used to train the word embeddings *Structured Skip-Gram* (*SSG*). For this submission, the *C2W* embeddings were also trained using a publicly available toolkit<sup>2</sup>. For the annotated SemEval training data, the messages were previously pre-processed as follows: lower-casing, replacing Twitter user mentions and URLs with special tokens and reducing any character repetition to at most 3 characters. Following Astudillo et al. (2015a), we used embeddings with 600 dimensions and set the sub-space size to 10 dimensions.

To train the model, the development set was split into 80% for parameter learning and 20% for model evaluation and selection, maintaining the original relative class proportions in each set. The weights were all randomly initialized uniformly with ranges of  $[-0.001, 0.001]$ ,  $[-0.1, 0.1]$  and  $[-0.7, 0.7]$  for the OOEVs, subspace and classification layers respectively. The training procedure entailed minimizing the negative log-likelihood over the training data with respect to the parameters, using standard Stochastic Gradient Descent (Rumelhart et al., 1985) with a fixed learning rate of 0.005 and mini-batch of size 1, i.e., updating the weights after each message was processed. We reshuffled the training

Table 4: Official test-set results for the top five systems in SemEval 2016 Task 4-B. Subscript number indicates position in general ranking.

examples after each training epoch and performed model selection by early stopping after 12 iterations. The candidate for submission was manually selected by observing the performance across 2013, 2014 and 2015 datasets. Priority was given to models that presented a consistent high performance in all the datasets. In retrospect, this was most probably a sub-optimal decision judging from the evaluation results.

Table 4 displays the performance for the top 5 systems in SemEval 2016 task 4-B (Nakov et al., 2016). The NLSE system (labeled INESC-ID) ranks forth with a stable performance across all years. The results are particularly strong for 2013 with a difference of 0.017 points over the next best performing system on the top five. This is consistent with the divide noticed during system selection between performance in 2013 and 2015. High-performing systems in 2014, and particularly in 2013, do not appear to be equally performing in recent years.

## 6 Conclusions

We presented the INESC-ID system for the SemEval 2016 task 4-A, built on top of the successful Non-Linear Subspace Embedding model. We found that training with a larger dataset required a more careful procedure to avoid overfitting. Reproducing the best results obtained in SemEval 2015 required shuffling the data before each training epoch and adapting the cost function to better reflect the evaluation metric.

To address the problem of out-of-embedding words, we tried to introduce character-level embeddings in our model but found these to be detrimental. We obtained better results by learning embeddings for these words during the training. Even though the performance gains were not very pronounced, our system still attained very strong results across all the evaluation datasets.

## Abstract

The paper presents the system developed by the *SentimentalITsts* team for the participation in Semeval-2016 task 4, in the subtasks A, B and C. The developed system uses off the shelf solutions for the development of a quick sentiment analyzer for tweets. However, the lack of any syntactic or semantic information resulted in performances lower than those of other teams.

## 1 Introduction

Slowly but surely, social media replaced the traditional sources of information: people’s need to be constantly updated changed our behavior from buying a newspaper or watching TV, to using a Facebook or Twitter account to visualize, in a customizable manner, the day’s hottest news, with the bonus of being able to also comment on them.

Social media sites gained their popularity due to the “freedom” of expression they induce in people’s mind: being able to post real time messages about your opinions on whatever topic you come across, discuss political and social decisions, complain, express gratitude or exchange impressions about products you use in everyday life.

Texts shared through social media applications offer us the information that we need: for example, the reviews of a product provide us useful information about its advantages and disadvantages, while the text of an advertisement invites us to eat at the new Chinese restaurant in town.

As huge amounts of texts become available through social media, a challenging task concerns the organization and processing of this information to extract knowledge. Natural language processing tools trained on large news corpora have usually problems when applied to unstandardized social media inputs, mainly due to the fact that social media content can appear in various forms (Becker et al., 2012), from photos and video updates to news, offers and literary works, and various informal formats.

Twitter is micro-blogging platform where people can send messages to one or multiple users, follow friends and read messages without much difficulty. Twitter messages, commonly known as tweets, are limited to 140 characters, and frequently include hashtags (labels which should make it easier for users to find messages with similar content), all in one making Twitter analysis charming.

Out of the 5 subtasks of Semeval-2016 task 4, the *SentimentalITsts* participated in subtask A: Message Polarity Classification , subtask B Tweet classification according to a two-point scale and subtask C Tweet classification according to a five-point scale. Subtask A asked to classify a given tweet in three categories: positive, negative or neutral, according to the identified sentiment (Nakov et al., 2016). The tweet was known to be about a specific topic (by topic is meant anything people usually express opinions about on social networks: a product, a political candidate, a policy, an event, etc.) and the topic was given by the task organizers. Subtask B is a two-scale sentiment classification task, where tweets need to be identified as

positive or negative. Subtask C is a refinement of the previous subtasks, demanding a five-point scale: very positive, positive, neutral, negative, very negative. A five-point scale is now ubiquitous in the corporate world where human ratings are involved; e.g., Amazon, TripAdvisor, Yelp, and many others, all use a five-point scale for their reviews.

The remaining of this paper is structured as follow: Section 2 provided an overview of the state of the art applications the team has considered for sentiment analysis of social media, Section 3 presents the method used by the *SentimentalITsts* to develop their own sentiment analyzer, Section 4 offers some not official results used in analyzing the system's performance, before the final section drawing conclusions and further directions.

## 2 State of the art

Specific processing tools (such as POS taggers or anaphora resolution systems), score a higher performance if used on the same text type as the ones they were trained on. In other words, we will have better results if using a POS tagger trained on news corpora to analyze news texts, rather than speech transcripts.

Thus, the short dimension of tweets and their creative informal spelling have raised a new set of challenges to the natural language processing field. How to handle such challenges so as to automatically mine and understand the opinions and sentiments that people are communicating has been the subject of several research (Jansen et al., 2009; Barbosa and Feng, 2010; Bifet and Frank, 2010; Davidov et al., 2010; O'Connor et al., 2010; Pak and Paroubek, 2010; Tumasjen et al., 2010; Kouloumpis et al., 2011; Russell 2013; Pang et el., 2002).

A list of functional applications developed until now on Sentiment Analysis and API's that have a great success over the internet is presented below:

Sentiment140<sup>1</sup> (formerly known as "Twitter Sentiment") allows the discovery of the sentiment associated to a brand, product, or topic on Twitter. The API (Go et al., 2009) uses a maximum entropy classifier, trained on a set of automatically extract-

ed tweets. The training corpus of 1.600.000 tweets is created relying on the use of emoticons (tweets with happy smileys suggest a positive contents, while tweets with sad/anger smileys refer to negative contents). The API lets users classify tweets and integrate sentiment analysis functionality into their own websites or applications, using RESTful calls and responses formatted in JSON.

Werfamous<sup>2</sup> is another webservice offering a sentiment search ability for a user selected term.

**Sentiment Analysis with Python NLTK Text Classification:** It can classify the text introduced on one of three groups: positive, negative or neutral. Using hierarchical classification neutrality is determined first, and sentiment polarity is determined second, but only if the text is not neutral. The NLTK Trainer is used to train classifiers for the sentiments based on twitter sentiment or movie reviews. NLTK<sup>3</sup> (Bird et al., 2009) is a leading platform for building Python programs to work with human language data. It provides easy-to-use interfaces to over 50 corpora and lexical resources such as WordNet, along with a suite of text processing libraries for classification, tokenization, stemming, tagging, parsing, and semantic reasoning, etc.

DatumBox<sup>4</sup>: an OpenSource API that allows users to access the web services offered by DatumBox. This services include Sentiment Analysis on any post using a 3 point scale considering that the topic of the post is given.

AlchemyAPI<sup>5</sup> (Turian, 2013) launched in 2009, is a company that uses machine learning (specifically deep learning) to do natural language processing (specifically semantic text analysis including sentiment analysis) and computer vision (face detection and recognition) for its clients both over the cloud and on-premises.

Lexalytics<sup>6</sup> is a web platform for media monitoring, offering nice visualization tools and powerful document processing capabilities.

For the Semeval-2016 participation, the *SentimentalITsts* team has used a self-trained Naive

Bayes classifiers, combined with the existing Alchemy-API for the cases where the classifier's output score was below an empirically established threshold.

### 3 Architecture

Building a Social Media Monitoring tool requires at least 2 modules: one that evaluates how many people are influenced by the campaign and one that finds out what people think about the brand.

For the second tool, being able to evaluate the opinion of the users is not a trivial matter. Evaluating their opinions requires performing Sentiment Analysis, which is the task of automatically identifying the polarity, the subjectivity and the emotional states of a particular document or sentence. It requires Machine Learning and Natural Language Processing techniques.

The remainder of this section will present a short description of the classes and objects used for the development of the three systems which participated in SemEval subtasks A, B and C. The architecture for the three systems was similar, the main difference being the way Naïve Bayes classifiers were trained: for 2, 3 or 5 classes, respectively. The training instances were obtained from the train and development corpora offered by the organizers of the SemEval-2016 task, and the internal evaluation was performed on the test development data.

- NaiveBayes Class

- o main part of the Text Classifier
- o implements methods such as train() and predict() that are responsible for training a classifier and using it for predictions
- o use external methods to preprocess and tokenize the document before training

- NaiveBayesKnowledgeBase Object

- o output of training which stores all the necessary information and probabilities used by the classifier

- Document Object

- o training and prediction texts in the implementation are internally stored as Document Objects
- o stores all the tokens of the document, their statistics and target classification of the document

- FeatureStats Object

- o stores several statistics that are generated during the Feature Extraction phase.

- FeatureExtraction Class

- o calculates internally several of the statistics that are actually required by the classification algorithm in the later stage, and all these stats are cached and returned in a FeatureStats Object to avoid their recalculation.

- TextTokenizer Class

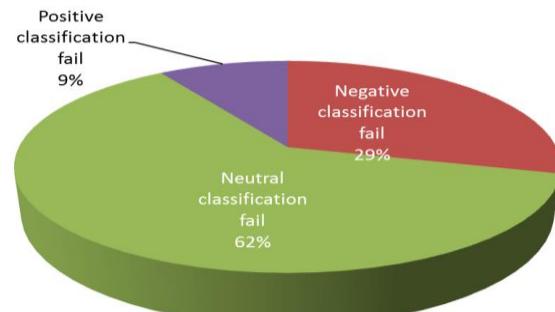

- o simple text tokenization class, responsible for preprocessing: cleaning and tokenizing the original texts, removing special symbols, identifying and annotating hashtags and smileys, standardizing word with repeated letters, and converting them into Document objects.

Similar to (Go et al., 2009 and Pang et al., 2002), the Naïve Bayes classifiers were trained using the following features: tokenized unigrams, emoticons, hashtags.

### 4 Non-official error analysis

In order to check the system's weakness and straightness, an internal evaluation was performed before the official evaluation, for each subtask.

When analyzing the errors found in the classification for subtask A (Fig.1), one can easily note that the system is positive-biased, i.e. it gave too many positive answers. Thus, out of the 29% of negative instances wrongly classified, 77% were classified as positive, while 23 as neutral. Similarly, for the neutral instances in gold which were misclassified, 89% were identified as positive, and 11% as negative.

**Figure 1.** Internal evaluation for three-point scale error cases

For subtask B, the most misclassified category was the negative one. Table 1 presents the confusion matrix for the two categories. It is worth noticing that the system developed for subtask B is significantly better than the one for subtask A, according to our internal evaluation.

|          | Negative | Positive |
|----------|----------|----------|
| Negative | 81,14    | 18,86    |
| Positive | 3,40     | 96,60    |

**Table 1.** Confusion matrix for the five-scale task, evaluated on test development data

For subtask C, the system was biased towards the neutral classification. Thus, in case of doubt or when no other classification goes beyond a confidence score, the neutral classification was selected. The error matrix is presented in table 2.

|           | Very neg. | Very pos. | Pos.  | Neutr. | Neg.  |
|-----------|-----------|-----------|-------|--------|-------|
| Very neg. | 88,31     | 0,00      | 6,68  | 5,01   | 0,00  |
| Very pos. | 0,00      | 65,10     | 32,32 | 2,29   | 0,29  |
| Pos.      | 4,39      | 0,00      | 62,42 | 30,72  | 2,47  |
| Neutr.    | 0,00      | 0,00      | 62,14 | 36,27  | 1,59  |
| Neg.      | 0,00      | 0,00      | 32,73 | 12,90  | 54,37 |

**Table 2.** Confusion matrix for the five-scale task, evaluated on test development data

## 5 Official evaluation and discussions

The official evaluation placed the *SentimentalITsts* on the 32nd place for subtask A (see table 3 for details of performances on each dataset). For subtask B, the team was placed 15<sup>th</sup> out of 19<sup>th</sup>, and for subtask C the official classification was at rank 9 out of 11 (see for details Nakov et al., 2016).

| SentimentalITsts | 2013  |      | 2014  |               |              | 2015 tweet | 2016 Tweet |
|------------------|-------|------|-------|---------------|--------------|------------|------------|
|                  | Tweet | SMS  | Tweet | Tweet sarcasm | Live Journal |            |            |
|                  | 0.33  | 0.23 | 0.39  | 0.28          | 0.32         | 0.34       | 0.33       |

**Table 3.** Official results for the SentimentalITsts team, task A

In this version of the system, no syntactic or semantic information was used. Similarly, hashtags or smileys, although they seemed useful in initial tests, ultimately showed that they bring more noise

than relevant information, and were thus removed from the message files.

## **Abstract**

*Minions*, a team formed of first year students in the Master of Computational Linguistics, started the participation at Semeval-2016 as a semester project, aiming to build a model for analyzing and classifying “tweets” into positive, neutral and negative, according to the evoked sentiment, while getting familiar with Natural Language Processing tools and methods. Therefore, the backbone of our sentiment analyzer consists in several off-the-shelf, freely available resources, enhanced with a classifier trained on the SemEval-2016 data.

## **1 Introduction**

Texts live around us just as we live around them. At any instant, there are texts that people write, share, use to get informed, etc. (starting with an advertisement heard on the radio every morning and finishing with the contract of sale signed before a notary). Combining this with the concept of language economy (or the principle of least effort) – a tendency shared by all humans – consisting in minimizing the needed amount of effort to achieve the maximum result, it is no wonder why the social media, with its short, informal and context-dependent texts, achieved such a high popularity.

SemEval-2016 task 4 had several subtasks, but since our team consists mainly of members beginning to learn about Natural Language Processing, we only felt comfortable in participating in Subtask A. This subtask involved the classification of a message polarity, i.e. classify a given

tweet in three categories: positive, negative or neutral, according to the identified sentiment (Nakov et al., 2016).

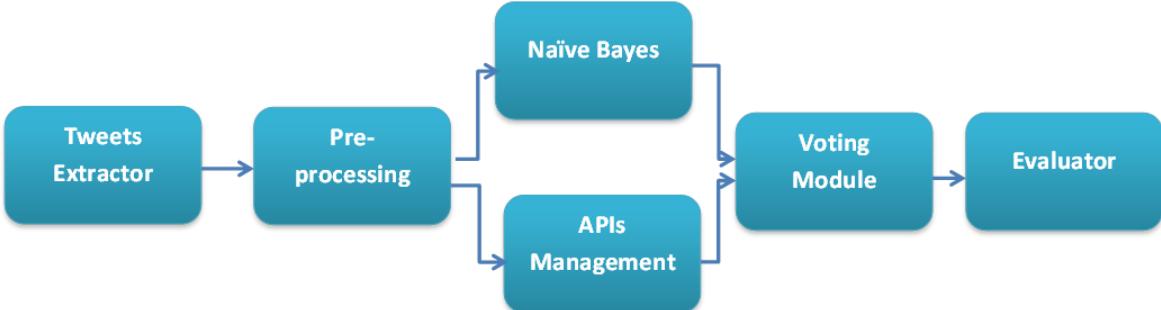

The remaining of this paper is structured as follows: Section 2 provides an overview of available online applications for analyzing social media sentiments; Section 3 presents our own sentiment analyzer, before the final section presenting the evaluation of the system and drawing some conclusions.

## **2 State of the art**

Specific processing tools (such as POS taggers or anaphora resolution systems), score a higher performance if used on the same text type as the ones they were trained on. In other words, we will have better results if using a POS tagger trained on news corpora to analyze news texts, rather than speech transcripts.

Thus, the short dimension of tweets and their creative informal spelling have raised a new set of challenges to the natural language processing field. How to handle such challenges while automatically mining and understanding the opinions and sentiments that people are communicating has been the subject of several research (Jansen et al., 2009; Barbosa and Feng, 2010; Bifet and Frank, 2010; Davidov et al., 2010; O’Connor et al., 2010; Pak and Paroubek, 2010; Tumasjan et al., 2010; Kouloumpis et al., 2011).

We have investigated existing online applications for sentiment extraction of social media from Twitter, briefly discussed below, and integrated some of them in our sentiment analyzer.

**Figure 1.** Diagram of our tweet sentiment analyzer

Trackur<sup>1</sup> is an online application, allowing the display of opinions on a particular search criterion, trained on datasets from various social networks such as Facebook, Google Plus, Instagram, etc.

Social Mention<sup>2</sup> application monitors over 100 social networks, blogs or forums such as Twitter, Facebook, Youtube, Digg, Google, etc. in an attempt to identify emerging hot topics.

AlchemyAPI<sup>3</sup> (Turian, 2013), provider of artificial intelligence cloud services, offers multiple modes of sentiment analysis: document-level, entity-level, and keyword-level sentiment mining is provided, in addition to support for advanced features such as negation handling, sentiment amplifiers / diminishers, slang, and typos, all based on the company's deep-learning classifier, trained on an impressive social media corpus.

Sentiment140<sup>4</sup> (formerly known as "Twitter Sentiment") allows the discovery of the sentiment associated to a brand, product, or topic on Twitter. It uses a maximum entropy classifier, trained on a set of automatically extracted tweets. The training corpus of 1.600.000 tweets was created relying solely on the use of emoticons (tweets with happy smileys suggest a positive contents, while tweets with sad/anger smileys refer to negative contents). The API lets users classify tweets and integrate sentiment analysis functionality into their own websites or applications, using RESTful calls and responses formatted in JSON.

NLTK<sup>5</sup> (Bird et al., 2009) is a platform for building Python programs to work with human language data. It provides easy-to-use interfaces to over 50 corpora and lexical resources (including WordNet), along with a suite of text processing libraries for classification, tokenization, stemming, tagging, parsing, and semantic reasoning, etc.

After analyzing the available applications for sentiment analysis, we decided to build our own analyzer based on several existing services (Alchemy, Sentiment 140 and NLTK's Sentiment analyzer), enhanced with a Naïve Bayes classifier trained on the SemEval-2016 data.

### 3 System Architecture

The system developed for SemEval-2016 can be divided in the following modules:

1. **Tweets Extractor:** a module which extracts tweets based on a list of ID's provided by the task organizers;
2. **Pre-processing:** cleaning operations needed to remove from tweets symbols unsupported by the sentiment analysis services;
3. **APIs Management:** development of a web service able to manage the calls to the three sentiment analysis APIs: Alchemy, Sentiment 140, NLTK;
4. **Naïve Bayes Classifier:** trains a Naïve Bayes classifier from the NLTK toolkit for identification of positive, negative and neutral sentiments.

<sup>1</sup> <http://www.trackur.com/about-trackur>

<sup>2</sup> <http://socialmention.com/>

<sup>3</sup> <http://www.alchemyapi.com/>

<sup>4</sup> <http://help.sentiment140.com/home>

<sup>5</sup> <http://www.nltk.org/>

5. **Voting Module** receives sentiment scores from the three APIs and decides, in case of mismatch, which one to further obey;
6. **Evaluator:** Analysis the output file and creates statistics used to improve the system's performances.

The system's architecture is presented in figure 1 above and the modules are discussed in more details in the next subsections.

### 3.1 Tweet Extractor

This module receives as input a set of tweets IDs and extracts the text of tweets using Twitter API. One of the challenges with regard to this module was to overcome the limitations set by the Twitter API (a limit of 100 tweets in a response for any request). Therefore, the tweet extractor has a parameter that allows us to specify the frequency of crawling. We found that an interval of 2 minutes is a reasonable polling parameter.

Several tweet IDs returned errors when processing, the content of the tweets being no longer available. For example, for the train data, out of the 6000 ID's, 632 were not found.

### 3.2 Pre-processing

After obtaining the texts from tweets, a cleaning phase was performed, in order to standardize the data. Thus, regular expressions have been built to: convert the texts to lowercase, discard words shorter than two characters, remove special diacritic signs, URLs, as well as symbols unsupported by the sentiment analyzers' APIs (such as "?"). Users often include Twitter usernames in their tweets in order to direct their messages, using the @ symbol before the username (e.g. @radut), therefore a regex replaces all words that start with the @ symbol. Another modification proved to significantly reduce feature space, inspired by (Pang et al., 2002), is removing duplicated vowels in the middle of the words (e.g. coooooool). Any letter occurring more than two times in a row is replaced with exactly two occurrences.

### 3.3 APIs Management

This module was intended to manage the calls to the sentiment analysis APIs used in this project:

Alchemy, Sentiment 140 and NLTK's Sentiment analyzer.

### 3.4 Naïve Bayes Classifier

Similar to (Go et al, 2009 and Pang et al., 2002), we trained a Naïve Bayes classifier, using the NLTK's training facility, with the following features: tokenized unigrams, emoticons, hashtags. We used the train and development data made available by the SemEval-2016 organizers for training.

Ultimately, our internal evaluation on test development data from the SemEval-2016 competition revealed the fact that our Naïve Bayes classifier was introducing more errors than correct cases, most probably due to a bug. We therefore introduced a parameter allowing us to run the system with a customized series of analyzers. For the submitted runs, we only considered the outputs of the three sentiment analysis APIs.

### 3.5 Voting Module and Evaluator

These modules are used to analyze the output of the sentiment analysis APIs aiming to identify, in case different labels are issued, which sentiment analyzer is most reliable. The Evaluator outputs a set of statistics using the test development data provided by the SemEval-2016 organizers.

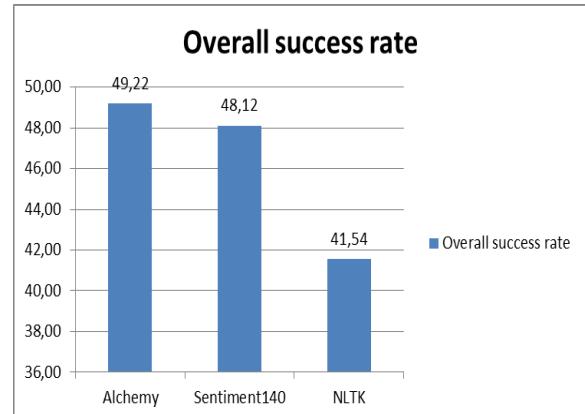

Figure 2. Comparison between the three sentiment identification services

Thus, this module checks how many agreements/disagreements are found in the results offered by different sentiment analyzers (see figure 2 for an overview and figure 3 for a detailed analysis of matched labels). We found that in

only 14.9% of the cases, all three services gave the same good result. For 9.4% of the cases, the three services gave similar label, but failed to find the good one. Out of these situations, almost 14% were mislabeled negative cases, and only 1.5% mislabeled positive tweets.

However, in 30.6% of the cases, two of the services gave the same label, the good one and in 78% of cases at least one classifier gave the right answer.

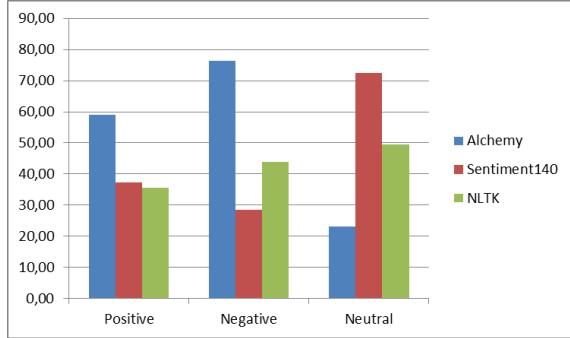

Figure 3. Percentage of correctly identified sentiments on SemEval-2016 training data

These analyses lead us to the decision to implement a simple voting module, which is based on the following empirically derived rules:

- If at least two services give the same label, this label is chosen;
- Otherwise, based on the internal evaluation (see figure 3), the priority was given as follows:
  - o if Alchemy gives a negative result, select it;
  - o else if Sentiment140 gave a neutral result, select it;
  - o otherwise, if Alchemy gave a positive result, select it,
  - o otherwise select the neutral label.

#### 4 Official evaluation and discussions

The official evaluation (Nakov et al., 2016), presented in table 1, placed our system on the 28th place (out of 34 places).

| Minions | 2013  |      | 2014  |                  |                 | 2015<br>tweet | 2016<br>Tweet |  |  |
|---------|-------|------|-------|------------------|-----------------|---------------|---------------|--|--|
|         | Tweet | SMS  | Tweet | Tweet<br>sarcasm | Live<br>Journal |               |               |  |  |
|         |       |      |       |                  |                 |               |               |  |  |
|         | 0.48  | 0.52 | 0.55  | 0.42             | 0.47            | 0.48          | 0.41          |  |  |

Table 1 Official results for the Minions team

In this version of the system, we did not use part-of-speeches, since initial tests showed that in this configuration, they bring more noise than relevant information, conclusion shared (for part-of-speeches) also by (Pang et al., 2002). However, as further improvements, we intend to lemmatize the tweets before feeding them to our classifier, and use an external dictionary of sentiment valences in the voting module, to enhance our system's performance.

## Abstract

Sentiment analysis of tweets has attracted considerable attention recently for potential use in commercial and public sector applications. Typical sentiment analysis classifies the sentiment of sentences into several discrete classes (e.g., positive and negative). The aim of Task 4 subtask C of SemEval-2016 is to classify the sentiment of tweets into an ordinal five-point scale. In this paper, we present a system that uses word embeddings and recurrent convolutional networks to complete the competition task. The word embeddings provide a continuous vector representation of words for the recurrent convolutional network to use in building sentence vectors for multi-point classification. The proposed method ranked second among eleven teams in terms of micro-averaged MAE (mean absolute error) and eighth for macro-averaged MAE.

## 1 Introduction

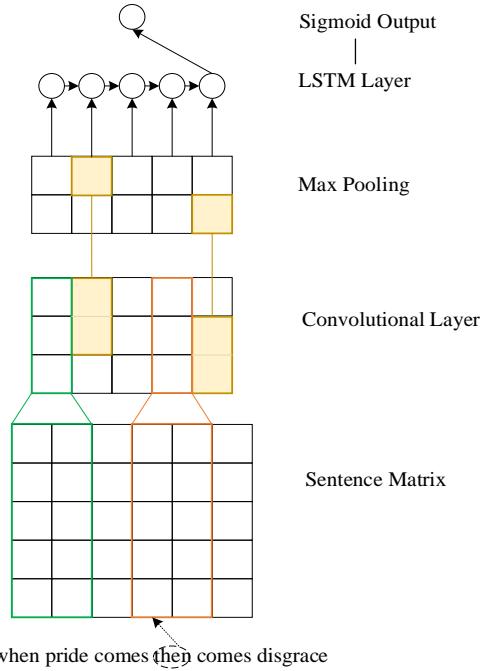

Sentiment analysis seeks to detect and analyze sentiment within texts. Following the rapid increase of user generated content in the form of social media, sentiment analysis has attracted considerable interest. Typical approaches to sentiment analysis classify the sentiment of a sentence into several discrete classes such as positive and negative polarities, or six basic emotions: anger, happiness, fear, sadness, disgust and surprise (Ekman, 1992). Based on this representation, various techniques have been investigated including supervised learn-

ing and lexicon-based approaches. Supervised learning approaches require training data for sentiment classification (Go et al., 2009; Yu et al., 2009; Saif et al., 2016), while lexicon-based approaches do not require training data but use a sentiment lexicon to determine the overall sentiment of a sentence (Liu, 2010; Hu et al., 2013).

A five-point scale (Nakov et al., 2016) is also a popular way to evaluate sentiment. Many companies, such as Amazon, Google, and Alibaba all use a multi-point scale to evaluate product or APP reviews. Unlike typical classification approaches, ordinal classification can assign different ratings (e.g., *very negative*, *negative*, *neutral*, *positive* and *very positive*) according to sentiment strength (Taboada et al., 2011; Li et al., 2011; Yu et al., 2013; Wang and Ester, 2014).

Task 4 subtask C of SemEval-2016 seeks to classify the sentiment of tweets into an ordinal five-point scale. This paper presents a system that uses word embeddings (Mikolov et al., 2013) and recurrent convolutional networks to this end. The word embeddings can capture both semantic and syntactic information of words to provide a continuous vector representation of those words. These word vectors are then used to build sentence vectors through a recurrent convolutional neural network. For multi-point classification, we discretize the continuous sentiment intensity to a five partitions of equal intervals.

The proposed recurrent convolutional network consists of two parts: a convolutional neural network (CNN) (LeCun et al., 1990) on the bottom to reduce the dimension of a sentence matrix, fol-

**Figure 1:** System architecture of the proposed CNN-LSTM model.

lowed by a long short-term memory (LSTM) (Hochreiter et al., 1997) layer to form the sentence representation, and a linear regression layer on the top to fit the sentiment intensity of sentences. The details of the CNN, LSTM and their combination are described in the following section.

## 2 Combining LSTM and CNN for Ordinal Classification

Ordinal classification of sentiment aims at classifying the sentence into ordinal discrete values according to their sentiment intensity. Figure 1 shows the system architecture of the proposed CNN-LSTM model for ordinal classification. In the bottom layer, the word vectors of vocabulary words are first trained from a large corpus using word embeddings. For each given sentence, a sentence vector is then built based on the word vectors of words in the sentences, which is further transformed into a matrix representation. The sentence matrix is sequentially passed through a convolutional layer and max pooling layer for multi-point classification. Unlike a conventional LSTM model which directly uses word embeddings as input, the proposed model takes uses outputs from a single-layer CNN with max pooling.

### 2.1 Convolutional Neural Network

In our model, the input of the LSTM layer is an output from the CNN. CNNs have achieved the state-of-the-art results in computer vision applications, and also have been shown to be effective for various NLP applications (Krizhevsky et al., 2012; Kim, 2014; Ma et al., 2015). The CNN architecture used for our tasks is described as follows.

Let  $V$  denote the vocabulary of words, while  $d$  denotes the dimensionality of word vectors, and  $S \in R^{d \times n}$  denotes the sentence matrix built by concatenating the word vectors occurring in the sentences. Suppose that the sentence  $T$  is made up of a sequence of words  $[d_1, d_2, \dots, d_n]$ , where  $n$  is the length of sentence  $T$ . Then the representation of  $T$  is given by the matrix  $S^T \in R^{d \times n}$ , where the  $j$ -th column corresponds to the embeddings for word  $d_j$ . Note that for batch processing we zero-pad sentence matrix  $S^T$  so that the number of columns is a constant (equal to the max length of sentences) for all sentences in the corpus.

We apply a narrow convolution between  $S^T$  and a filter  $F \in R^{d \times w}$  of a width  $w$ . We then add a bias term and apply a nonlinearity function to obtain a feature map  $f^T \in R^{n-w+1}$ . The  $i$ -th element of  $f^T$  is given by:

$$f^T[i] = \text{relu}(\langle S^T[:, i:i+w-1], F \rangle + b) \quad (1)$$

where  $S^T[:, i:i+w-1]$  is the  $i$ -to- $(i+w-1)$ -th column of  $S^T$  and  $\langle A, B \rangle = \text{Trace}(A \cdot B^T)$  is the Frobenius inner product.

The feature maps are input into a max pooling layer to capture the most salient feature (i.e., the one with the highest value) for a given filter. Filter operation is useful for determining the n-grams, where the size of the n-gram corresponds to the filter length.

The above description uses just one filter matrix to generate one feature. In practice, the proposed convolutional layer uses multiple filters in parallel to obtain the feature vectors.

### 2.2 Recurrent Neural Network

A recurrent neural network (RNN) architecture particularly suited for modelling sequence phenomena (Sak et al., 2014; Zhou et al. 2015). At each time step  $t$ , the RNN takes the input vector  $x_t$

| Name         | # Tweets released | # Tweets used | # Topics | Avg. Length |
|--------------|-------------------|---------------|----------|-------------|
| Gold Train   | 6,000             | 5,346         | 60       | 19.49       |
| Gold Dev     | 2,000             | 1,795         | 20       | 19.58       |
| Gold Devtest | 2,000             | 1,781         | 20       | 19.69       |
| Test         | 20,632            | 20,632        | 100      | 19.62       |

**Table 1:** Summary of data statistics.

and the hidden state vector  $h_{t-1}$  to produce the next hidden state  $h_t$  by applying the following recursive operation:

$$h_t = f(Wx_t + Uh_{t-1} + b) \quad (2)$$

Here  $W$ ,  $U$ ,  $b$  are the parameters of an affine transformation and  $f$  is an element-wise nonlinearity function. In theory, the RNN can summarize all historical information up to time  $t$  with the hidden state  $h_t$ . In practice, however, a vanilla RNN has difficulty learning long-term dependencies due to the vanishing gradient problem, as the gradient decreases exponentially with the number of network layers and the front layer trains very slowly.

Approaches have been developed to deal with vanishing gradient problem, and certain types of RNNs (like LSTM, GRU) are specially designed to get around them. LSTM (Hochreiter et al., 1997) addresses the problem of learning long-term dependencies by augmenting the RNN with a gating mechanism. To illustrate this, the following formulas show how a LSTM calculates a hidden state  $h_t$ .

$$\begin{aligned} i_t &= \sigma(W^i x_t + U^i h_{t-1} + b^i) \\ f_t &= \sigma(W^f x_t + U^f h_{t-1} + b^f) \\ o_t &= \sigma(W^o x_t + U^o h_{t-1} + b^o) \\ g_t &= \tanh(W^g x_t + U^g h_{t-1} + b^g) \\ c_t &= f_t \circ c_{t-1} + i_t \circ g_t \\ h_t &= o_t \circ \tanh(c_t) \end{aligned} \quad (3)$$

Here  $\sigma(\cdot)$  and  $\tanh(\cdot)$  are the element-wise sigmoid and hyperbolic tangent functions,  $\circ$  is the element-wise multiplication operator, and  $i_t$ ,  $f_t$ ,  $o_t$  are called the *input*, *forget* and *output* gates respectively. All the gates have the same dimension  $d_s$ , which is equal to the size of hidden state, and  $c_0$ ,  $h_0$  are initialized to zero vectors at  $t=1$ .  $c_t$  is the internal memory of the unit, which could be regarded as

| Name         | # (-2) | # (-1) | # (0) | # (1) | # (2) |
|--------------|--------|--------|-------|-------|-------|
| Gold Train   | 87     | 668    | 1654  | 3154  | 437   |
| Gold Dev     | 43     | 296    | 675   | 933   | 53    |
| Gold Devtest | 31     | 233    | 583   | 1005  | 148   |

**Table 2:** Distributions of sentiment ratings. # ( $n$ ) denotes the number of tweets annotated with a rating of  $n$  in the range of [-2, -1, ..., 2], corresponding to *Strongly Negative*, *Negative*, *Negative or Neutral*, *Positive*, *Strongly Positive*, respectively.

how we want to combine previous memory and the new input.

The gating mechanism allows LSTM to model long-term dependencies. By learning the parameters  $W^j$ ,  $U^j$ ,  $b^j$  for  $j \in \{i, f, o, g\}$ , the network learns how its memory cells should behave.

### 3 Experiments and Evaluation

**Dataset.** We evaluated the proposed CNN-LSTM model by submitting the results to the SemEval-2016 Task 4 subtask. The statistics of the dataset used in this competition are summarized in Table 1. As the original tweets may be removed by Twitter users themselves, we can just download a part of the data in gold training, gold development, and gold development-test dataset. The distribution of sentiment labels shown in Table 2 shows data imbalance. Most of the data were annotated in [-1, 0, 1] labels, and only a few were annotated *Very Negative* (-2) or *Very Positive* (2).

**Implementation details.** As mentioned earlier, the proposed method consists of word embeddings and a recurrent convolutional network. Both parts may have their own parameters for optimization. For word embeddings, we used popular pre-trained word vectors from GloVe (Pennington et al., 2014). GloVe is an unsupervised learning algorithm for learning word representation. Training is performed on aggregated global word co-occurrence statistics from a large corpus, and the resulting representation showcases interesting linear substructures in the word vector space. They provide pre-trained word vectors trained on 840B tokens from common crawls and have a length of 300.

Although the pre-trained word embeddings can capture important semantic and syntactic in-

|        | $MAE^{\mu}$ | $MAE^M$ |
|--------|-------------|---------|
| Scores | 0.588       | 1.111   |
| Rank   | 2           | 8       |

**Table 3:** Results of the proposed CNN-LSTM model for SemEval-2016 Task 4 Subtask C.

formation of words, they are not sufficient to capture sentiment behaviors in texts. To further improve word embeddings to capture sentiment information, we trained our recurrent convolutional network using an additional dataset from the Vader corpus (Hutto et al., 2014). It contains 4,000 tweets pulled from Twitter’s public timeline, independently annotated by 20 human raters with sentiment ratings in a range of [-4, 4]. We discretized the continuous human-assigned ratings of [-4, 4] to discrete numbers [-2, -1, ..., 2] to make them compatible with the task context.

The hyper-parameters of the network are chosen based on the performance on the development-test data. We use: rectified linear units (ReLU), filter windows ( $w$ ) of 3 with 64 feature maps, dropout rate ( $p$ ) of 0.25, pool length of 2, and mini-batch size of 16. *Adagrad* update rule is used to automatically tune the learning rate, and micro-averaged  $MAE$  is used as the loss function. Early stop mechanism is used to avoid overfitting. The activation function in the top layer is a sigmoid function, which scales each sentiment intensity to the range 0 to 1. These continuous intensity scores are transformed into a five-point scale through the cut-offs: [0, 0.2], (0.2, 0.4], (0.4, 0.6], (0.6, 0.8], (0.8, 1.0] for strongly negative, negative, negative or neutral, positive, strongly positive, respectively.

**Evaluation metrics.** SemEval-2016 Task 4 subtask C published the results for all participants using both macro-averaged mean absolute error ( $MAE^M$ ) and micro-averaged mean absolute error ( $MAE^{\mu}$ ) (Nakov et al., 2015). The  $MAE^M$  is defined as:

$$MAE^M(h, Te) = \frac{1}{|C|} \sum_{j=1}^{|C|} \frac{1}{|Te_j|} \sum_{X_i \in Te_j} |h(X_i) - y_i| \quad (4)$$

where  $y_i$  denotes the true label of  $X_i$ ,  $h(X_i)$  denotes the predicted label, and  $Te_j$  denotes the set of test documents whose true class is  $c_j$ . The  $MAE^{\mu}$  is defined as:

|          | Devtest Set |         | Test Set    |         |
|----------|-------------|---------|-------------|---------|
|          | $MAE^{\mu}$ | $MAE^M$ | $MAE^{\mu}$ | $MAE^M$ |
| CNN      | 0.656       | 0.992   | 0.534       | 0.939   |
| CNN-LSTM | 0.590       | 0.974   | 0.588       | 1.111   |

**Table 4:** Results of CNN-LSTM and CNN alone.

$$MAE^{\mu}(h, Te) = \frac{1}{|Te|} \sum_{X_i \in Te} |h(X_i) - y_i| \quad (5)$$

Compared to the micro-averaged  $MAE^{\mu}$ , the macro-averaged  $MAE^M$  is more appropriate to measure the classification robustness of systems for imbalanced data.

**Results.** A total of eleven teams participated in subtask C. Table 3 shows the results of the proposed CNN-LSTM model for both  $MAE^{\mu}$  and  $MAE^M$ . The proposed method ranked second for  $MAE^{\mu}$  and eighth for  $MAE^M$ . The results of  $MAE^{\mu}$  and  $MAE^M$  are inconsistent because we used a standard  $MAE$  as the loss function for model training and did not consider the imbalanced sentiment labels. Therefore, our model yielded better performance on  $MAE^{\mu}$  than on  $MAE^M$ .

Table 4 shows the experimental results after the release of test set ratings. We found that the CNN-LSTM achieved better performance on the development test set than the test set. Conversely, the CNN alone yielded better performance on the test data than the development-test set.

## 4 Conclusions

This study presents a deep learning approach to classifying tweets into a five-point scale. The proposed model combines the convolutional neural networks and long short-term memory networks. To better capture the sentiment aspect of words, we further tuned our model using an additional sentiment corpus. Experimental results show that the proposed method archived good performance on the micro-averaged  $MAE$ .

Future work will focus on exploring more effective features and machine learning methods to improve classification performance for both micro- and macro-averaged  $MAE$ .

## Abstract

This paper reports our submissions to Task 4, i.e., Sentiment Analysis in Twitter (SAT), in SemEval 2016, which consists of five subtasks grouped into two levels: (1) sentence level, i.e., message polarity classification (subtask A), and (2) topic level, i.e., tweet classification and quantification according to two-point scale (subtask B and D) or five-point scale (subtask C and E). We participated in all these five subtasks. To address these subtasks, we investigated several traditional Natural Language Processing (NLP) features including sentiment lexicon, linguistic and domain specific features, and word embedding features together with supervised machine learning methods. Officially released results showed that our systems rank above average.

## 1 Introduction

In recent years, with the emergence of social media, more and more users have shared and obtained information through microblogging websites, such as Twitter. As a result, a huge amount of available data attracts a lot of researchers. SemEval 2016 provides such a universal platform for researchers to explore in the task of Sentiment Analysis in Twitter (Nakov et al., 2016) (Task 4), which includes five subtasks grouped into two levels, i.e., sentence level and topic level. Subtask A is a sentence level task aiming at sentiment polarity classification of the whole tweet. The other four subtasks are at topic level, i.e., given one topic, the sentiment polarity of tweets are classified or assigned by a two-point scale (i.e., subtask

B and D) and by a five-point scale (i.e., subtask C and E). Specifically, subtask B is to identify the sentiment polarity label (i.e, *Positive* and *Negative*) of tweets with respect to the given topic while subtask D aims at estimating the sentiment distribution of tweets with respect to the given topic. Both subtask B and D are on a two-point scale. The purposes of subtask C and E are similar with that of subtask B and D, except for using a five-point scale, that is, the class labels are of 5 values, i.e, 2, 1, 0, -1 and -2 representing *Very Positive*, *Positive*, *Neutral*, *Negative* and *Very Negative*.

Given the character limitations on tweets, sentiment orientation classification on tweets can be regarded as a sentence-level sentiment analysis. Many researchers focus on feature engineering to improve the performance of SAT. For example, (Turian et al., 2010; Liu, 2012; Zhang et al., 2006) showed that one-hot representation on  $n$ -gram features is a relatively strong baseline. Furthermore, (Mohammad et al., 2013) proposed a state-of-the-art model which implemented several sentiment lexicons and a variety of manual features. Apart from the traditional methods, more and more researchers have paid their attention to use deep learning methods. Word embedding is one of such methods, where each word is represented as a continuous, low-dimension vector and has been applied into NLP tasks as a critical and fundamental step. Commonly, there are several types of word embedding models, e.g., Bengio proposed a *Neural Probabilistic Language Model (NNLM)* in (Bengio et al., 2003) to learn distributed representation for each word and Mikolov simplified the structure of *NNLM* and presented t-

wo efficient log-linear models in (Mikolov et al., 2013). Moreover, (Zhang and Lan, 2015; Tang et al., 2014) further proposed learning sentiment-based word embeddings to settle SAT. Meanwhile, topic-based opinion always adheres on certain words or phrases rather than whole tweet. To address topic-based SAT, (Wang et al., 2011) used the hashtag information, (Lin and He, 2009) utilized the topic model to extract topic information from tweets and (Zhang et al., 2015) picked out related words rather than all words in whole tweet as pending words for consequential feature extraction.

Previous work showed that feature engineering has a significant impact on this task. Thus, in this work, we presented multiple types of traditional NLP features to perform SAT, e.g., sentiment lexicon features (e.g., *MPQA*, *IMDB*, *Bing Liu opinion lexicon*, etc), linguistic features (e.g., negations, *n*-gram at the word level and character level, etc) and tweet specific features (e.g., emoticons, capital words, elongated words, hashtags, etc.). Besides, the word embedding features were adopted. We also performed a series of experiments to select effective feature subsets and supervised machine learning algorithms with optimal parameters.

The rest of this paper is organized as follows. Section 2 describes our system framework including preprocessing, feature engineering, evaluation metrics, etc. The experiments are reported in Section 3. Finally, this work is concluded in Section 4.

## 2 System Description

### 2.1 Data Preprocessing

With the aid of approximate 5,000 abbreviations and slangs collected from Internet, we converted the informal writing into regular forms, e.g., “*asap*” replaced by “*as soon as possible*”, “*3q*” replaced by “*thank you*”, etc. And we recovered the elongated words to their original forms, e.g., “*soooooo*” to “*so*”. Finally, the processed data was performed for tokenization, POS tagging and parsing by using *C-MU Parsing tools* (Owoputi et al., 2013).

### 2.2 Feature Engineering

We used four types of features, i.e, linguistic features (e.g., negations, *n*-gram, etc), tweet specific features (e.g., emoticons, all-caps, hashtags, etc),

sentiment lexicon features (the score calculated from eight sentiment lexicons) and word embedding features.

#### 2.2.1 Linguistic Features:

- *Character n-grams*: The character-level *n*-grams are used, where  $n = \{3, 4, 5\}$ .
- *Word n-grams*: The word-level *unigrams*, *bigrams*, *trigrams* and *4-grams* are adopted.
- *POS*: The absolute frequency of each part-of-speech tag is recorded.
- *Negation*: Negation in a message always reverses its sentiment orientation. We collected 29 negations from Internet and recorded the frequency of negations in the whole tweet.
- *Cluster*: The *CMU TweetParser tool* provides 1,000 token clusters produced with the Brown clustering algorithm on 56 million English language tweets. We recorded the existence of tokens in tweets with respect to these 1,000 clusters.
- *Dependency triple*: The dependency tree is generated by *Stanford Parser tool* and each tweet contains several dependency triples (e.g., *relation(government, dependent)*). We used a binary feature to record if a dependency triple is present or absent in a tweet.

#### 2.2.2 Tweet Specific Features:

- *Punctuation*: Punctuation marks (e.g, exclamation mark (!) and question mark (?) ) usually indicate the strength of sentiment. Therefore, we recorded the numbers of these marks in isolation and in combination. Besides, the position of punctuation in tweet is also an important clue for sentiment, thus we used a binary feature to indicate whether it is the last token of tweet.
- *All-caps*: The number of words in uppercase is recorded.
- *Hashtag*: We recorded the number of hashtags in the tweet.

- *Emoticon*: We collected 67 emoticons from Internet and this feature type records the number of positive and negative emoticons respectively. Moreover, two binary values are to record whether the last token is a positive or negative emoticon respectively.
- *Elongated*: It indicates the number of elongated words in the raw text of tweet.

### 2.2.3 Sentiment Lexicon Features (SentiLexi):

We employed the following eight sentiment lexicons to extract sentiment lexicon features: *Bing Liu lexicon*<sup>1</sup>, *General Inquirer lexicon*<sup>2</sup>, *AFINN*<sup>3</sup>, *IMDB*<sup>4</sup>, *MPQA*<sup>5</sup>, *NRC Emotion Sentiment Lexicon*<sup>6</sup>, *NRC Hashtag Sentiment Lexicon*<sup>7</sup>, and *NRC Sentiment140 Lexicon*<sup>8</sup>. Generally, we transformed the scores of all words in all sentiment lexicons to the range of -1 to 1, where the positive number indicates positive sentiment and the minus sign denotes negative sentiment.

The following six scores are calculated on the whole data for each sentiment lexicon: (1) the ratio of positive words to all words, (2) the ratio of negative words to all words, (3) the maximum sentiment score, (4) the minimum sentiment score, (5) the sum of sentiment scores, and (6) the sentiment score of the last word in tweet. If a word does not exist in one sentiment lexicon, its corresponding score is set to 0.

### 2.2.4 Word Embedding Features:

In this work, we employed three different types of word vectors. The general word vectors are trained by Google on huge amount of News, which is a different domain from Twitter. The other two sentiment word vectors are both trained on tweets but using different methods. The purpose of this feature

type is to examine the effects of word embedding and sentiment word embedding on performance.

- *General Word Vector (GeneralW2V)*: We adopted the *word2vec* tool<sup>9</sup> to obtain word vectors with the dimensionality of 300 (i.e., *GeneralW2V*), trained on 100 billion words from Google News.
- *Sentiment Word Vector (SWV)*: (Zhang and Lan, 2015) proposed a *Combined-Sentiment Word Embedding Model* to learn sentiment word vectors (*SWV*) for sentiment analysis task. In this work, we learn *SWV* on *NRC140 tweet corpus*(Go et al., 2009), where the corpus is made up of 1.6 million tweets (0.8 million positive and 0.8 million negative). The vector dimension is set as 100.
- *Sentiment-specific Word Embedding (SSWE)*: Similar with *SWV*, the sentiment-specific word embedding model proposed by (Tang et al., 2014) used a multi-hidden-layers neural network to train *SSWE* with dimensionality of 50.

To convert the above word vectors into a sentence vector, we simply adopted the *min*, *max* and *average* operations. Obviously, this combination strategy neglects the word sequence in tweet but it is simple and straightforward. As a result, the final sentence vector  $V(s)$  was concatenated by  $V_{min}(s)$ ,  $V_{max}(s)$  and  $V_{average}(s)$ .

## 2.3 Evaluation Metrics

For subtask A, we used the macro-averaged  $F$  score of positive and negative classes (i.e.,  $F_{macro} = \frac{F_{pos} + F_{neg}}{2}$ ) to evaluate the performance. Subtask B and D just contain positive and negative labels. The official metric for subtask B is *macro-averaged recall* among positive and negative (i.e.,  $R_{macro} = \frac{R_{Pos} + R_{Neg}}{2}$ ). As for subtask D, it is *Kullback-Leibler Divergence* (KLD) among distributions of two classes (i.e.,  $KLD(pos, neg) = \sum_{c_j \in pos, neg} P(c_j) \cdot \log \frac{P(c_j)}{\hat{P}(c_j)}$ , where  $P$  denotes the probability of predicted label and  $\hat{P}$  is the probability of gold label). There are 5 classes existing in subtask C and E, and

the organizers adopted *Macroaveraged Mean Absolute Error* (i.e.,  $MAE^M$ ) and *Earth Mover’s Distance* ( $EMD$ ) among 5 predefined classes for two subtasks respectively, where the detail information of two metrics for evaluation is described in the official document available on the website<sup>10</sup>.

### 3 Experiments

#### 3.1 Datasets

Since only tweet IDs are provided by organizers, different participants may collect different numbers of tweets due to missing tweets or system errors. Subtask B and D are of the same data set. And subtask C and E share one common data set. The statistics of all datasets for these subtasks are shown in Tables 1, 2, and 3, respectively.

For subtask A, the training data set consists of four parts which are shown in Table 1, i.e., 2013train, 2013dev, 2016train and 2016dev. The data set 2013train means SemEval-2013 Task 2 training data set (Nakov et al., 2013), and the following data sets are named in the same way. Actually, in consideration of the difference of polarity distribution between data set 2016devtest and 2013&2014test, we just adopted 2016devtest as development data. For subtask B, C, D and E, the data is divided into many topic sets.

| dataset | Positive   | Negative   | Neutral     | Total  |
|---------|------------|------------|-------------|--------|
| train   | 3,250(37%) | 1,276(15%) | 4,151(48%)  | 8,677  |
|         | 575(35%)   | 340(20%)   | 739(46%)    | 1,654  |
|         | 2,839(51%) | 787(14%)   | 1,892(34%)  | 5,518  |
|         | 772(42%)   | 359(20%)   | 702(38%)    | 1,833  |
| dev     | 886(49%)   | 287(16%)   | 626(35%)    | 1,799  |
|         | 5,078(40%) | 2,142(16%) | 5,580(44%)  | 12,800 |
| test    | 7,059(34%) | 3,231(16%) | 10,342(50%) | 20,632 |

**Table 1:** Statistics of data sets in training (train), development (dev), test (test) data for subtask A.

| dataset | Positive   | Negative   | Total  |
|---------|------------|------------|--------|
| train   | 4,191(81%) | 997(19%)   | 5,188  |
| dev     | 1,027(81%) | 238(19%)   | 1,265  |
| test    | 8,212(78%) | 2,339(22%) | 10,551 |

**Table 2:** Statistics of data sets in training, development, test data for subtask B and D.

#### 3.2 Experiments on Training Data

In order to improve the performance of sentiment analysis, we performed feature selection experi-

| dataset | 2       | 1          | 0           | -1         | -2      | Total  |
|---------|---------|------------|-------------|------------|---------|--------|
| train   | 475(6%) | 3,815(50%) | 2,295(30%)  | 906(12%)   | 120(2%) | 7,611  |
| dev     | 123(7%) | 900(50%)   | 535(30%)    | 211(12%)   | 29(1%)  | 1,798  |
| test    | 382(2%) | 7,830(38%) | 10,081(49%) | 2,201(10%) | 138(1%) | 20,632 |

**Table 3:** Statistics of data sets in training, development, test set for subtask C and E.

ments on all subtasks and the optimum feature sets are shown in Table 4. From Table 4, it is interesting to find that: (1) Negation features and tweet specific features such as emoticon and all-caps make contributions to almost all subtasks. (2) The feature set with the best performance of subtask B is not quite beneficial for subtask D even though they have the same data set, perhaps because of the essential difference between binary classification and binary quantification: in the latter, errors of different polarity compensate each other. The similar observation is found in subtask C and E. (3) The sentiment lexicon features make contributions to performance improvement of subtask A, B and C, but are not quite useful for subtask D and E. A possible reason is that the latter two subtasks focus on quantification analysis while the sentiment lexicon only contains sentiment orientation rather than sentiment strength. (4) The word embedding features are not as effective as expected. It maybe because we obtained sentence vectors by the simplest combination method described above, which does not take into account contextual information and semantic relations among words.

Besides, since subtask B, C, D and E focus on topic-level sentiment analysis, we tried to extract features from related words rather than whole tweet. But the preliminary experimental results showed that extracting features from related words underperformed the latter strategy for extracting features. The possible reason is that in many cases a tweet only has one single sentiment polarity. Thus the sentiment polarity of sentence can always represent that of topic and extracting features from the related words may drop important information.

#### 3.3 Learning Algorithm

For these subtasks, we examined several supervised machine learning classification algorithms with different parameters (e.g., Logistic Regression with  $c=\{0.1, 1\}$ , Support Vector Machine with  $kernel=\{linear, rbf\}$ ,  $c=\{0.01, 0.1, 1\}$ , Random

**Table 4:** Results of feature selection experiments for subtask A, B, C, D and E in terms of the corresponding evaluation metrics on the training data, where ✓ indicates this feature was employed in the corresponding subtask system.

Forest with  $n=\{20, 50, 100, 400, 1000, 2000\}$ , SGD with  $loss=\{hinge, log\}$ , etc). Finally, Logistic Regression with  $c=1$  implemented in *Liblinear*<sup>11</sup> was adopted for all five subtasks for its good performance in preliminary experiments.

### 3.4 Results on Test Data

Based on the optimum feature sets shown in Table 4 and configuration of classifiers described above, we trained separate models for each subtask.

| Subtask | System      | Score     |
|---------|-------------|-----------|
| A       | ECNU        | 0.585(10) |
|         | SwissCheese | 0.633(1)  |
|         | SENSEI-LIF  | 0.630(2)  |
| B       | ECNU        | 0.768(4)  |
|         | Tweester    | 0.797(1)  |
|         | LYS         | 0.791(2)  |
| C       | ECNU        | 0.806(2)  |
|         | twise       | 0.719(1)  |
|         | PUT         | 0.860(3)  |
| D       | ECNU        | 0.121(10) |
|         | finki       | 0.034(1)  |
|         | LYS         | 0.053(2)  |
| E       | ECNU        | 0.341(5)  |
|         | QCRI        | 0.243(1)  |
|         | finki       | 0.316(2)  |

**Table 5:** Performance of our systems and the top-ranked systems on all five subtasks. The numbers in the brackets are the official ranking.

Table 5 shows the results of our systems and the top-ranked systems on all five subtasks. Our systems ranked 10th out of 34 submissions for sub-

<sup>11</sup><https://www.csie.ntu.edu.tw/~cjlin/liblinear/>

task A, 4th/19 for subtask B, 2nd/11 for subtask C, 10th/14 for subtask D and 5th/10 for subtask E. Compared with the top ranked systems, there is much room for improvement in our work. Although word embedding features were adopted in this work, we used the simplest combination method to convert word vectors to sentence vectors. The effective convolution method is expected to be able to improve the performance of sentiment analysis.

## 4 Conclusion

In this paper, we extracted several traditional NLP features(e.g., linguistic features, tweet specific features, etc) and word embedding features from whole tweet and constructed classifiers using supervised machine learning algorithms to accomplish sentiment analysis towards sentence level(i.e., subtask A) and topic level(i.e., subtask B, C, D and E). Word embedding features are not as effective as expected since the way of using these features are quite simple and naive, thus it is too hasty to make a conclusion that the word embedding features make marginal contribution. In future work, we consider to focus on developing advanced convolution neural network to model sentence with the aid of sentiment word vector.

## Abstract

Sentiment analysis has become a well-established task in Natural Language Processing. As such, a high variety of methods have been proposed to tackle it, for different types of texts, text levels, languages, domains and formality levels. Although state-of-the-art systems have obtained promising results, a big challenge that still remains is to port the systems to the “real world” – i.e. to implement systems that are running around the clock, dealing with information of heterogeneous nature, from different domains, written in different styles and diverse in formality levels. The present paper describes our efforts to implement such a system, using a variety of strategies to homogenize the input and comparing various approaches to tackle the task. Specifically, we are tackling the task using two different approaches: a) one that is unsupervised, based on dictionaries of sentiment-bearing words and heuristics to compute final polarity of the text considered; b) the second, supervised, trained on previously annotated data from different domains. For both approaches, the data is first normalized and the slang is replaced with its expanded version.

## 1 Introduction

Sentiment analysis is the task in Natural Language Processing (NLP) that deals with classifying opinions according to the polarity of the sentiment they express. Due to the large quantities of user-

generated online contents available on different Internet sites (forums, social networks, blogs, review sites, microblogs, etc.) and the possible value they can have for different domains (Marketing, e-Rulemaking, Political Science, etc.), Sentiment Analysis has become a very popular task in the field in the past decade.

As such, a high variety of methods have been proposed to tackle it, for different types of texts, text levels, languages, domains and formality levels. Although state of the art systems have obtained promising results (most of all in priory defined datasets – domains, languages, styles, formality levels), a big challenge that still remains is to port the systems to the “real world” – i.e. systems that are running around the clock, dealing with information of heterogeneous nature, from different domains, written in different styles and diverse in formality levels.

The present paper describes our efforts to build such a system. The challenge is not straightforward to tackle, as this entails building a system that is: a) on the one hand, robust enough to obtain similar levels of performance across domains, languages, text types and formality levels; b) on the other hand, flexible enough to treat all these types of texts. Further on, this entails that such a system must have components to treat the input to make it as homogeneous as possible, so as it can be treated in an equal way (POS-tagging, lemmatizing, syntactic parsing, etc.). The methods employed have to be general enough so that they can be used for as many different languages as possible. This is especially difficult, since there are languages that are under-resourced and have little tools available (i.e. it is not possible to perform accurate syntactic

parsing in all languages, lemmatizing is more difficult for some languages than others, etc.).

In order to address these issues, we proposed two approaches, which we plan to eventually combine in a unique system. The first approach is based on knowledge, taken from dictionaries of sentiment-bearing words. A variant of this system is implemented in-house to compute the tonality of entity mentions in the news. The second is based on supervised learning and is implemented in a system we are currently running in-house to classify the sentiment of tweets on different subjects. A model is trained on a set of input data and is subsequently used to classify new examples. The next sections detail on the implementation of the two methods.

## 2 State of the art and related approaches.

As far as tweet processing and sentiment analysis in tweets is concerned, Go et al. (2009) pioneered research proposing the use of emoticons (e.g. “:)”, “(.”, etc.) as markers of positive and negative tweets. Read (2005) employed this method to generate a corpus of positive tweets, with positive emoticons “:)”, and negative tweets with negative emoticons “:(”. Pak and Paroubek (2010) also generated a corpus of tweets for sentiment analysis, by selecting positive and negative tweets based on the presence of specific emoticons. These approaches employed different supervised approaches for sentiment analysis, using n-grams as features. Zhang et al. (2011) employ a hybrid approach, combining supervised learning with the knowledge on sentiment-bearing words, which they extract from the DAL sentiment dictionary (Whissell, 1989). The authors conclude that the most important features are those corresponding to sentiment-bearing words. Finally, (Jiang et al., 2011) classify sentiment expressed on previously-given “targets” in tweets adding the context of the tweet to increase the text length.

The approaches employed are based on the system we developed in (Balahur et al., 2010) and (Balahur, 2013).

## 3 OPAL: Approaches in SemEval 2016 Task 4 A and B

The OPAL system participated in SemEval in Task 4, subtasks A and B.

In subtask A, the method employed was based on sentiment dictionaries and rules to compute the final polarity of the tweets.

In subtask B, the system was trained on the training data provided by the organizers using SVM and uni- and bigrams.

Before applying each of the two approaches, the texts were pre-processed in order to be transformed from informal to formal language, to be treated by traditional text processing methods. Additionally, the words are matched against our in-house (Balahur et al., 2010)<sup>1</sup> sentiment and modifier dictionaries.

In the next subsections, we detail the steps, methods and resources employed.

### 3.1. Text Pre-processing

- **Multiple punctuation sign identification.** In the first step of the preprocessing, we detect repetitions of punctuation signs (“.”, “!” and “?”). Multiple consecutive punctuation signs are replaced with the labels “multistop”, for the fullstops, “multiexclamation” in the case of exclamation sign and “mult question” for the question mark and spaces before and after. The entire context before the punctuation sign, up until the previous punctuation sign, is marked as “intensifier”.
- **Emoticon replacement.** In the second step of the preprocessing, we employ the annotated list of emoticons from SentiStrength<sup>2</sup> and match the content of the tweets against this list. The emoticons found are replaced with their polarity score from this resource.
- **Lower casing and tokenization.** Further on, the tweets are lower cased and split into tokens, based on spaces and punctuation signs.
- **Slang replacement.** In order to be able to include the semantics of the expressions frequently used in Social Media, we employed the list of slang expressions from the Urban Dictionary<sup>3</sup> and other two slang dictionaries dedicated sites<sup>4</sup>.
- **Word normalization.** In the next step, we match the tokens against entries in Roget’s Thesaurus. If no match is found, repeated letters are sequentially reduced to two or one until a match is found in the dictionary (e.g. “greeeat” becomes “greet”, “greet” and finally “great”). The words used in this way are replaced with “intensifier” plus original word as matched from Roget’s Thesaurus.

<sup>1</sup> The dictionaries were obtained by mixing three existing resources that have proven to be most precise, although with less recall as others: General Inquirer, LIWC and MicroWNOp.

<sup>2</sup> <http://sentistrength.wlv.ac.uk/>

<sup>3</sup> <http://www.urbandictionary.com/>

<sup>4</sup> [www.noslang.com/dictionary](http://www.noslang.com/dictionary), [www.smsslang.com](http://www.smsslang.com)

- **Affect word matching.** Further on, the tokens in the tweet are matched against the in-house produced lexicon based on three different sentiment dictionaries: General Inquirer, LIWC and MicroWNOp and split into four different categories (“positive”, “high positive”, “negative” and “high negative”). Matched words are replaced with their sentiment label - i.e. “positive”, “negative”, “hpositive” and “hnegative”.
- **Modifier word matching.** Similar to the previous step, we employ a list of expressions that negate, intensify or diminish the intensity of the sentiment expressed to detect such words in the tweets. If such a word is matched, it is replaced with “negator”, “intensifier” or “diminisher”, respectively.
- **User and topic labeling.** Finally, the users mentioned in the tweet, which are marked with “@”, are replaced with “PERSON” and the topics which the tweet refers to (marked with “#”) are replaced with “TOPIC”.

### 3.2. OPAL Task 4 A

In subtask A, the participating systems were supposed to classify a set of tweets in three classes, according to the polarity of the sentiment they conveyed: positive, negative or neutral.

To tackle this task, we used an unsupervised method, based on the identified sentiment words and modifiers. Each of the sentiment words was mapped to four categories, which were given different scores: positive (1), negative (-1), high positive (4) and high negative (-4). The dictionaries have been previously built and the process is described by Balahur et al. (2010). It is based on *WordNet Affect* (Strapparava and Valitutti, 2004), *SentiWordNet* (Esuli and Sebastiani, 2006), *MicroWNOp* (Cerini et al, 2007) and an in-house built resource entitled *JRC Tonality*. This resource has also been used to create the multilingual tonality dictionaries described by Steinberger et al. (2011) and are also implemented in the Europe Media Monitor system. Subsequently, in a window of 6 words around the identified sentiment-bearing token, the following rules were applied:

- When an “intensifier” was present, the value was multiplied with 1.5.
- When a “diminisher” was identified, the value was multiplied with 0.5.
- When a “negator” was identified, the value was multiplied with -1.

Finally, the partial scores obtained for the sentiment contexts were added and normalized by the number of contexts. A positive score led to the text being classified as “positive”, a negative score to its being classified as “negative” and a score of 0 labeled as “neutral”.

### 3.3. OPAL Task 4 B

In subtask B, the participating systems were tasked to classify a set of tweets in two classes: positive or negative.

In this task, we employed supervised learning using Support Vector Machines Sequential Minimal Optimization (Platt, 1998) with a binomial kernel, employing boolean features - the presence or absence of unigrams and bigrams determined from the training data (tweets that were previously preprocessed as described above) that appeared at least twice. Bigrams are used especially to spot the influence of modifiers (negations, intensifiers, diminishers) on the polarity of the sentiment-bearing words. We trained and tested the approach using the Weka data mining software<sup>5</sup>, on the data provided for training by the organizers.

## 4 Evaluation

In the SemEval 2016 Task 4, the OPAL system obtained the following results (Nakov et al., 2016):

In subtask A, 0.50521 average F1, 0.56020 average Recall and 0.54122 accuracy.

In subtask B, OPAL scored 0.61617 average Recall, 0.63316 average F1 and 0.79215 accuracy.

## 5 Conclusions and Future Work

In this paper, we presented the two approaches to classify tweets according to their polarity, being simple enough to be ported to different languages, domains and deal with documents written in different styles and diverse in formality levels. The performance levels are promising given the simplicity of the implementations. As such, our next challenge resides in adding and evaluating new and simple processing components that can be added for specific languages and domains, in order to increase the classification performance while at the same time keeping the wide usability and reliability of the system.

## Abstract

This paper describes our participation in SemEval-2016 Task 5 for Subtask 1, Slot 2. The challenge demands to find domain specific target expressions on sentence level that refer to reviewed entities. The detection of target words is achieved by using word vectors and their grammatical dependency relationships to classify each word in a sentence into *target* or *non-target*. A heuristic based function then expands the classified target words to the whole target phrase. Our system achieved an F1 score of 56.816% for this task.

## 1 Introduction

Nowadays, modern technologies allow us to collect customer reviews and opinions in a way that changed the sheer amount of information available to us. For that matter the requirement to extract useful knowledge from this data rose up to a point where machine learning algorithms can help to accomplish this much faster and easier than humanly possible. Natural language processing (NLP) emerges as an interfacing tool between human natural language and many technical fields such as machine learning and information extraction.

This article describes our approach towards Opinion Target Expression (OTE) extraction as defined by Task 5 for Subtask 1, Slot 2 of the SemEval-2016 (Pontiki et al., 2016) challenge. The core goal behind Slot 2 in Subtask 1 of Task 5 is to extract consecutive words which, by means of a natural language, represent the opinion target expression. The opinion target expression is that part of a sentence

which stands for the entity towards which an opinion is being expressed. An example could be the word “*waitress*” in the sentence “*The waitress was very nice and courteous the entire evening.*”.

The evaluation for Slot 2 fell into evaluation phase A, where provided systems were tested in order to return a list of target expressions for each given sentence in a review text. Each target expression was an annotation composed of the index of the starting and end character of the particular expression as well as its corresponding character string.

For our system we decided to used word vectors (Mikolov et al., 2013a; Mikolov et al., 2013b). Word vectors (Bengio et al., 2003) are distributed representations which are designed to carry contextual information of words if their training meets certain criteria. We also used typed grammatical dependencies to extract structural information from sentences. Furthermore we used a sentiment parser to determine the polarity of words.

## 2 External Resources

Our system uses Stanford dependencies (Chen and Manning, 2014) and utilizes the Stanford Sentiment Treebank (Socher et al., 2013) for sentiment word detection.

## 3 System for Slot 2: Opinion Target Extraction

For the Opinion Target Extraction (OTE) task, in order to extract different features, we followed a supervised approach. We train and test different combinations of these features first at the word level and

following on the provided training data<sup>1</sup> on sentence level before using our classifier for the final evaluation. There are two essential steps performed by our system to correctly annotate opinion target expressions.

1. Classify each word of a sentence as either *target* or *non-target*
2. Given each *target* word, find the full target phrase

For classification we use a L2-regularized L2-loss support vector dual classification<sup>2</sup> provided by the LIBLINEAR (Fan et al., 2008) library. In the second step we use heuristics, based on observations and statistical information we extracted from the training data. The key observation is that target expressions are usually composed of noun phrases and/or proper nouns. In all trials we allow only certain Part of Speech (PoS) tags for target words which are NN, NNS, NNP, NNPS and FW from the Penn Treebank (Marcus et al., 1993) listed in Table 1.

| PoS-Tag | Name                   |
|---------|------------------------|
| NN      | Noun, singular or mass |
| NNS     | Noun, plural           |
| NNP     | Proper noun, singular  |
| NNPS    | Proper noun, plural    |
| FW      | Foreign word           |

**Table 1:** Used PoS-Tags and their meaning according to the Penn Treebank.

## 4 Features

In this section we describe the different set of features we evaluated and how they can be extracted.

### 4.1 Token

We obtain tokens by using the Stanford Parser and extract all tokens from the available reviews used for training. We are then able to use tokens as a feature for the classifier.

### 4.2 Word Vector Feature

As another feature for words we are using the pre-trained word vectors of Google News dataset<sup>3</sup>. Each

<sup>1</sup>Using the English data set

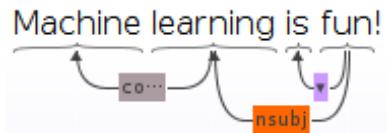

<sup>2</sup>Implementation of a Support Vector Regression Machine

<sup>3</sup><https://code.google.com/archive/p/word2vec/>

word vector is a 300-dimensional, real-valued vector.

### 4.3 Combined Typed Dependencies Feature

Using Stanford dependencies, we extract for each word in a sentence its typed dependencies to other words in the sentence.

**Figure 1:** Shown are typed dependencies from Stanford dependencies visualized with grammarscope.

Given the sentence “*Machine learning is fun!*”, the feature for “*learning*” is *compound; nsubj* which are the present relations for this word. We extract all typed dependency combinations from all provided words in the training set and use these in a Bag of Words (BoW) sparse vector model. In order to normalize this feature we order the relations alphabetically and remove duplicates. For example *det; amod; amod* gets normalized to *amod; det*.

### 4.4 Individual Typed Dependencies Feature

Another approach is to look at the dependencies individually. We use the set of present grammatical relations as feature vector and set corresponding fields to 1 if the word does own such a relation and 0 otherwise. We are testing the two possible options of *directed* and *undirected* dependencies to see if this additional information has an impact on the end result. A short overview of a textual representation of these features can be seen in Table 2.

#### 4.4.1 Undirected

In the undirected approach we extract the relations of each word from the data and use the resulting set of *present* relations as feature vector. From the training set we extracted 105 different undirected relations. Here the directional information of the grammatical dependency is lost.

#### 4.4.2 Directed

For the directed approach we preserve the direction in terms of *incoming* or *outgoing* relations for each grammatical relation. As an example, the word

“learning” from Figure 1 has an outgoing relation compound+ and an incoming relation nsubj– where + depicts the outgoing relation and – the incoming respectively. This way we found 164 different relations in the training set.

| Typed Dependency Features |          |                   |
|---------------------------|----------|-------------------|
| Directed                  | Word     | Feature           |
| no                        | learning | coumpund; subj;   |
| yes                       | learning | coumpund-; subj+; |

**Table 2:** The table shows two example of *undirected* and *directed* typed dependency features for the word “learning” in the sentence “Machine learning is fun.”.

#### 4.5 Sentimend Dependency Feature

For a given word we determine whether it has a grammatical relation to a sentiment word. A sentiment word is a word that can have a positive or negative meaning for example “breathtaking” in “The food was breathtaking!”. We are not considering a directional approach which makes this a binary feature.

### 5 Results

This section describes the results we achieved on the restaurant domain of the SemEval-2016 aspect based sentiment analysis (ABSA) on Task 5, Slot 2. It also explains how we trained and tested our system only on the provided training data.

#### 5.1 Word-Level Feature Evaluation

We determine how well our different features are performing by splitting the train data available and using 80% training and 20% test data. In Table 3 the performance on the *target-word* class of the individual features are shown depicting the performance of classifying single words as targets or non-targets.

The results for the similarly token-based approach outperforms the other approaches. The weighted average for *Token* settles at 0.696 and very similar *Token + combined typed dependencies* at 0.697. None of the word vector approaches outperforms these two.

#### 5.2 Testing Features

To test our features we use the same training/testing split of the SemEval-2016 training data and utilize

| Evaluation class: target-word |       |       |                      |
|-------------------------------|-------|-------|----------------------|
| Feature                       | Prec. | Rec.  | F1 score<br>wt. avg. |
| Token                         | 0.649 | 0.749 | 0.696                |
| + comb. typed dep.            | 0.657 | 0.741 | 0.697                |
| w2v                           | 0.595 | 0.649 | 0.621                |
| + comb. typed dep.            | 0.610 | 0.696 | 0.650                |
| + indiv. typed dep.           |       |       |                      |
| <i>undirected</i>             | 0.595 | 0.587 | 0.591                |
| <i>undir. + sentiment</i>     | 0.587 | 0.598 | 0.592                |
| <i>directed</i>               | 0.568 | 0.674 | 0.617                |
| <i>dir. + sentiment</i>       | 0.574 | 0.679 | 0.622                |

**Table 3:** The resulting F1 scores for the *target-word* class using different features on word-level over a 80/20 training/test split of the provided training data.

it to train the classifier and run the SemEval-2016 evaluation tool respectively. In order to annotate the Opinion Target Expressions (OTE) our system first classifies single tokens of a sentence into *target* or *non-target* and further tries to complete the target expression. The completion of the target expression is heuristic based and looks at existing incoming or outgoing *compound* relations using Stanford dependencies (Chen and Manning, 2014). Each compound relation is added to the target phrase and correspondingly extended.

| Feature                   | Prec. | Rec.  | F1 score |
|---------------------------|-------|-------|----------|
| Token                     | 0.498 | 0.488 | 0.493    |
| + comb. typed dep.        | 0.460 | 0.433 | 0.446    |
| w2v                       | 0.484 | 0.598 | 0.535    |
| + comb. typed dep.        | 0.498 | 0.520 | 0.509    |
| + indiv. typed dep.       |       |       |          |
| <i>undirected</i>         | 0.482 | 0.550 | 0.513    |
| <i>undir. + sentiment</i> | 0.466 | 0.552 | 0.505    |
| <i>directed</i>           | 0.465 | 0.623 | 0.532    |
| <i>dir. + sentiment</i>   | 0.465 | 0.625 | 0.533    |

**Table 4:** Shown are evaluation F1 scores given by the SemEval-2016 evaluation tool for different features and feature combinations used for training on a 80/20 training/test split of the provided training data.

In Table 4 we can see the results for the evaluation. It shows that despite having a better result on word-level, the token-based approach falls behind the word vector approach. It is interesting to see, that adding the *undirected* grammatical relations as feature does not improve the F1 score but performs even worse than the pure *w2v* approach. However,

taking *directed* dependencies into account does improve the results again. We can see that for directed dependencies the recall improves but in contradiction the precision declines resulting in a higher miss-classification rate and thus in a lower F1 score than we were hoping to see.

### 5.3 Official Evaluation Results: Restaurant domain

Our submitted system is using the individual (directed) typed dependencies and the sentiment information combined with word vectors as features. The official results for participating *unconstrained* systems for Slot 2: Opinion Target Extraction can be seen in Table 5. The table shows the F1-score for all participating *unconstrained* systems. Our system was able to outperform the baseline and a few others. Considering only unconstrained systems, Know-Center reached rank 6 out of 10 (excluding the baseline results).

| System             | F1 score       |
|--------------------|----------------|
| NLANGP             | 72.340%        |
| AUEB.              | 70.441%        |
| UWB                | 67.089%        |
| GTI                | 66.553%        |
| bunji              | 64.882%        |
| <b>Know-Center</b> | <b>56.816%</b> |
| BUAP               | 50.253%        |
| Baseline           | 44.071%        |
| IHS-R.             | 43.808%        |
| IIT-T.             | 42.603%        |
| SeemGo             | 34.323%        |

**Table 5:** Shown are the official evaluation results for Subtask 1, Slot 2 of Task 5 from the SemEval-2016 challenge for the Restaurant domain. The table shows only results for *unconstrained* systems.

## 6 Conclusions and Future Work

In this paper, we presented our approach for SemEval-2016 Task 5 for Subtask 1, Slot 2 in order to introduce ourselves to this particular evaluation task. Our solution might have potential for improvement and might be able to reach a much better ranking than what it achieved in the course of this challenge. Therefore, we will continue our work by focusing on finding the correct target phrase annotation given one or more target words. A drawback

of our solution is the heuristic based selection of the *full* target phrase and we are curious about how we can improve our results with more sophisticated techniques for target phrase labelling.

## Abstract

This paper describes our participation in the SemEval-2016 task 5, Aspect Based Sentiment Analysis (ABSA). We participated in two slots in the sentence level ABSA (Subtask 1) namely: aspect category extraction (Slot 1) and sentiment polarity extraction (Slot 3) in English Restaurants and Laptops reviews. For Slot 1, we applied different models for each domain. In the restaurants domain, we used an ensemble classifier for each aspect which is a combination of a Convolutional Neural Network (CNN) classifier initialized with pre-trained word vectors, and a Support Vector Machine (SVM) classifier based on the bag of words model. For the Laptops domain, we used only one CNN classifier that predicts the aspects based on a probability threshold. For Slot 3, we incorporated domain and aspect knowledge in one ensemble CNN classifier initialized with fine-tuned word vectors and used it in both domains. In the Restaurants domain, our system achieved the 2<sup>nd</sup> and the 3<sup>rd</sup> places in Slot 1 and Slot 3 respectively. However, we ranked the 8<sup>th</sup> in Slot 1 and the 5<sup>th</sup> in Slot 3 in the Laptops domain. Our extended experiments show our system could have ranked 2<sup>nd</sup> in the Laptops domain in Slot 1 and Slot 3, had we followed the same approach we followed in the Restaurants domain in slot 1 and trained each domain separately in Slot 3.

## 1 Introduction

Due to the increasing numbers of user generated reviews written every day within e-commerce websites, a great interest has been shown in the sentiment analysis research community to build intelligent systems that can accurately tackle the task of sentiment analysis in these reviews.

In this context, the SemEval-2016 ABSA, task 5<sup>1</sup>, Subtask 1 addresses a number of research problems related to this topic, including building systems that are able to extract aspect categories (Slot 1) and determine the sentiment polarity towards each aspect in each sentence (Slot-3) which were the two slots in which we participated.

The best results for Slot 1 in SemEval-2015 (Pontiki et al., 2015), were achieved by the NLANGP team (Toh and Su, 2015). The team tackled the problem by modeling it as a multi-class classification problem with binary classifiers for each aspect. They used a neural network with one hidden layer and features based on word n-grams, brown and k-means word clusters from Amazon and Yelp datasets and parsing features. For Slot 3, the best results were achieved by the Sentiae team (Saias, 2015) who used a Maximum Entropy classifier with domain and aspect features and features based on word n-grams, lemmas, negation terms, exclamation and question marks, sentiment lexicons, and POS tags.

---

<sup>1</sup> <http://alt.qcri.org/semeval2016/task5/>

This year, when addressing Slot 1, we participated with a system that can extract aspects in English reviews in the two domains that the task provided test sets for, namely: restaurants (REST) and laptops (LAPT). For the restaurants domain we treated the problem as a multi-class classification problem using an ensemble binary classifier for each aspect which is a combination of a Support Vector Machine (SVM) (Cortes and Vapnik, 1995) classifier and a Convolutional Neural Network (CNN). While the SVM classifier features were based on a Bag of words model, the CNN classifier was initialized with pre-trained word vectors based on the architecture proposed by Kim (2014). For the Laptops domain, we used one CNN classifier that outputs probability scores for each aspect, then a threshold was applied so that only outputs with scores higher than that threshold were predicted as aspects.

For Slot 3, we incorporated domain and aspect information in one ensemble classifier consisting of three CNNs trained using the whole training data provided in both domains and initialized with word vectors that were fine-tuned using training examples collected in a semi supervised way by the same CNN architecture as in an earlier phase.

The rest of this paper is organized as follows: section 2, describes the system architecture and settings, while section 3, presents and discusses our system performance and evaluation. Finally, section 4 concludes the paper and presents some ideas for potential future work.

## 2 System Details

To train our models, we depended mainly on the official training data provided by the SemEval-2016 task organizers. Furthermore, for choosing the best parameters and architectures, we used the SemEval-2015 (Pontiki, et al., 2015) training set for training and SemEval-2015 test set as a validation set. The validation set was used to choose the best model for each domain and to tune the network hyperparameters. In aspect category extraction (Slot 1), we used only the training data, however we considered our submission as an unconstrained one because we initialized our models using pre-trained publicly available word vectors<sup>2</sup> trained on a subset of Google news using the word2vec model (Mikolov,

et al., 2013). For polarity extraction (Slot 3), we used additional external examples for training and fine-tuning the word vectors from the Yelp Academic Dataset<sup>3</sup> and Amazon electronics reviews (Jo, 2011).

In the next subsections, we discuss the used CNN architecture as it's involved in all of our models. Then we discuss each model in detail.

### 2.1 Convolutional Neural Network architecture

Our CNN implementation is based on the architecture proposed by Kim (2014). In this model, each sentence is represented as a concatenation of all its word vectors which can be described using Equation (1),

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus \dots \mathbf{x}_n \quad (1)$$

where  $\mathbf{x}_i \in \mathbb{R}^k$  is a  $k$  dimensional word vector for the  $i^{th}$  word in the sentence,  $\oplus$  is the concatenation operator, and  $\mathbf{x}_{1:n}$  is the model input vector, which is the concatenated word vectors of the sentence from the first word to the  $n^{th}$  word, where  $n$  is the number of words in the sentence.

A convolution filter  $\mathbf{w}$  of width  $h$  words is then applied to the input vector to produce new features by simply taking the dot product between the filter and the corresponding input vector slice, then adding a bias factor  $b$ , and finally applying the non-linearity function  $f$ . The filter is then shifted by one word and applied again to produce the next feature until we reach the end of the input vector. This operation is clarified in Equation (2),

$$\mathbf{c}_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b) \quad (2)$$

where  $\mathbf{c}_i$  is the generated feature resulting from applying the filter  $w$  on the input vector slice from the start of word  $i$  to the end of word  $i + h - 1$ .

As a result of the convolution operation, a feature map  $\mathbf{c} \in \mathbb{R}^{n-h+1}$  is generated where:

$$\mathbf{c} = [\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_{n-h+1}] \quad (3)$$

A max-pooling operation (Collobert et al., 2011) is then applied to the feature map vector  $\mathbf{c}$  by only taking the maximum value  $\hat{c} = \max\{\mathbf{c}\}$  and considering it as a hidden layer feature generated from the corresponding convolution filter.

Since one feature is not enough to represent the needed knowledge, the process is repeated several

<sup>2</sup> <https://code.google.com/archive/p/word2vec/>

<sup>3</sup> [https://www.yelp.com/dataset\\_challenge/](https://www.yelp.com/dataset_challenge/)

times using different filters and different filter widths. These features form a hidden layer, which is followed by a Softmax layer that outputs prediction probabilities for each output class.

To prevent overfitting to the training data, we employed ‘dropout’ on the hidden layer and constrained its weights by  $l_2$ -norms (Hinton, et al., 2012). This was done by randomly dropping some of the hidden layer units by a probability rate  $p$  while training to prevent over adaptation to certain units. We also applied a constraint on the  $l_2$ -norms, by rescaling the weights connecting the hidden layer and the output layer such that they are limited by an upper limit  $s$  after each update step.

For training, the backpropagation algorithm (Rumelhart, et al., 1986) was applied and the network weights were updated using mini-batch stochastic gradient descent with the Adadelta update rule (Zeiler, 2012), which considers a separate adaptive update rate for each weight. As will be detailed in the following subsections, we have mostly employed Static-CNN, where initialized input vectors are kept as is. However, there were cases where we also employed Dynamic-CNN. In Dynamic-CNN, input vectors are updated for optimizing the network.

For choosing the CNN hyperparameters, we started by using the ones which were validated by Kim (2014) and then we tried different values on our validation set. We ended up by choosing convolution filter window widths ( $h$ ) of 3, 4, and 5 with 100 feature maps for each width. We used the rectified linear units as a non-linearity activation function, which simply outputs the maximum of zero and the input value. We set the dropout rate ( $p$ ) to 0.5 and the  $l_2$  maximum value ( $s$ ) to 3. We set the number of optimization iterations over the whole data (epochs) and the mini-batch size to 25 except for the official Laptops aspect extraction model (LAEM), where the values were set to 100 and 50 accordingly.

## 2.2 Restaurants Aspect Extraction Model (RAEM)

To extract aspect categories for the restaurants domain, we dealt with the problem as a multi-class classification problem where we have a binary ensemble classifier for each of the 12 aspects, trained

on the aspect data against all other aspects’ data (one vs all strategy).

This ensemble classifier is a combination of two classifiers; one Static-CNN classifier initialized using the Google news word vectors, and one SVM classifier which was trained using word unigram counts weighted by the inverse word frequencies in the training data (IDF) (Salton and Buckley, 1988). Vectors for words that had no corresponding entry in the Google news vectors, were set to zeros. The model predicts the aspect if any of the two classifiers predicts it.

The SVM classifier had a high precision on the validation set but a very low recall. Using it as part of our ensemble thus increased the total F-Score on the validation set.

## 2.3 Laptops Aspect Extraction Model (LAEM)

To extract aspects from laptop reviews, we used a Static-CNN classifier with 81 output nodes representing all the aspects found in the Laptops training set. At test time, the classifier predicts the aspect if its output nodes’ probability score exceeds a certain threshold.

To choose the best threshold, we tried different values on our validation set and found out that a threshold value of 0.18 performed best, followed by 0.16 which was slightly less in terms of the total F-Score. We preferred to use 0.16 as a threshold to prevent choosing a value resulting from overfitting on the validation set.

We chose to use this model for the laptops domain as using the alternative one vs all strategy needed 81 classifiers to be trained which is computationally slower during training and testing. The one classifier model also performed slightly better on the validation set at the chosen threshold. As we show in the extended experiments section (section 3.2), this was not the best strategy in approaching this problem.

## 2.4 The Sentiment Extraction Model (SEM)

For Slot 3, an ensemble model was used for both domains. This model counts votes from three classifiers and predicts the class which has the maximum number of votes from the three classes namely: the positive (Pos), the negative (Neg), and the neutral (Neu).

| Data Domain      | Positive Sentences | Negative Sentences |
|------------------|--------------------|--------------------|
| Amazon Dataset   | 50,000             | 18,326             |
| Yelp Restaurants | 50,000             | 50,000             |
| Yelp Computers   | 1974               | 2230               |
| Yelp Electronics | 3478               | 2226               |

Table 1: Fine-tuning data distribution.

| Data Domain              | Neutral Example | Negative Examples |
|--------------------------|-----------------|-------------------|
| Amazon Dataset           | 22              | 2                 |
| Yelp Restaurants Dataset | 78              | 24                |

Table 2: Hand labeled data distribution.

We adopted this voting criterion as it yielded slightly better results on the validation set. Each one of the three classifiers is similar to the one which was discussed in section 2.1 with a slight variation resulting from incorporating domain and aspect knowledge into the CNN model. This incorporation was done by introducing new binary features to the hidden layer of the CNN. The new features indicate the presence or the absence of a certain aspect or domain in a given sentence.

The problem with a word vector is that it represents a word by its semantic meaning captured through its context while the sentiments are not captured directly. To tackle this problem, we trained a Dynamic-CNN on sentences tokenized from the Yelp academic dataset reviews in restaurants, computers and electronics domains as well as data obtained from electronics and laptop reviews from Amazon. We employed a distant supervision method where five star review sentences are considered to be positive, while the one star ones are considered to be negative. We could not apply the same method for getting neutral sentences because we noticed that the three stars reviews can be mainly a combination of positive and negative sentences rather than neutral ones. Using these reviews could simply introduce more noise. A number of sentences were then sampled randomly from these reviews and used for fine-tuning the word vectors. Domain features were added when possible, otherwise they were set to zeros. The distribution of this collected dataset over the polarity labels and domains is clarified in Table 1.

| Model            | Do-main | P     | R     | F     |
|------------------|---------|-------|-------|-------|
| RAEM (Official)  | REST    | 72.69 | 73.08 | 72.88 |
| RAEM without SVM | REST    | 76.76 | 68.91 | 72.62 |
| LAEM (Official)  | LAPT    | 44.25 | 50.56 | 47.19 |
| RAEM             | LAPT    | 59.44 | 45.3  | 51.42 |
| RAEM without SVM | LAPT    | 63.27 | 39.67 | 48.76 |

Table 3: Results for Slot 1 in terms of precision, recall, and F-Score.

| Model               | Do-main | Pos-F | Neg-F | Neu-F | Acc.  |
|---------------------|---------|-------|-------|-------|-------|
| SEM (Official)      | REST    | 91.63 | 75.44 | 32.73 | 85.44 |
| Domain Specific SEM | REST    | 91.25 | 74.94 | 32.73 | 85.09 |
| SEM (Official)      | LAPT    | 83.55 | 72.95 | 8.00  | 77.40 |
| Domain Specific SEM | LAPT    | 84.85 | 73.65 | 11.76 | 78.65 |

Table 4: Results for Slot 3 in terms of positive, negative, neutral F-Score and accuracy.

After tuning the word vectors, three Static-CNNs with incorporated domain and aspect features were initialized with them, with random weights initializations, and trained on the whole training data from both domains in addition to 310 hand labeled examples which we added as an attempt to balance the training set label distribution across the two tackled domains (REST and LAPT) and to increase the number of the neutral labels as there were very few of them in the official training set compared to the other two polarities. The distribution of the hand labeled examples is shown in Table 2.

### 3 Evaluation and Results

In this section we discuss our official scores in the SemEval-2016 ABSA task. Furthermore, we present other experiments that were not officially submitted, but which provide insights regarding the adopted models as well as better performance for the laptops domain, than what was submitted.

### 3.1 Official Participations

For the aspect category extraction task (Slot 1), our RAEM model achieved the 2<sup>nd</sup> place out of 30 teams in the restaurants domain, with an F-Score of 72.886 which is only 0.145 less than what was achieved by the best performer. In the laptops domain, our LAEM model ranked the 8<sup>th</sup> amongst the 22 participating teams with an F-Score of 47.196. The detailed results in terms of precession, recall, and F-Score are shown in Table 3.

For the sentiment extraction task (Slot 3), we ranked 3<sup>rd</sup> and 5<sup>th</sup> in the restaurants and the laptops domains with accuracy scores of 85.448 and 77.403 respectively. The official evaluation accuracies and the per-class F-Scores are shown in Table 4. It can be deduced from the F-Scores that the number of training examples per class matters as the positive F-Score is always the best, followed by the negative and the neutral is always the worst which is a real reflection of the bias of the official training data distribution and the fine-tuning data.

### 3.2 Extended Experiments

In addition to the official submissions, we ran some additional experiments that were evaluated using the official scripts provided by the task organizers.

For Slot 1, given that the RAEM model achieved a good result in the restaurants domain, we decided to train this model on the laptops data. The resulting model achieved an F-score of 51.42 which would have put the system in 2<sup>nd</sup> place. We also experimented using the RAEM model without using the SVM classifier and reported that in Table 3 which shows that it contributed to enhancing the recall especially in the laptops domain. However, the RAEM system on its own, seems to perform relatively well even without the help of the SVM.

For Slot 3, we conducted two other experiments in which we used the fine-tuned word vectors to initialize two different ensemble classifiers like the one which was described in the SEM. However, here we separated the data so that there is one classifier per domain. This provided better results in the laptops domain which would have ranked as the 2<sup>nd</sup> best performer, but decreased the accuracy slightly in the restaurants domain as shown in Table 4 as Domain Specific SEM.

## 4 Conclusions

In this paper, we presented models for extracting aspects and their corresponding sentiment polarities from user reviews in SemEval-2016, task 5. The proposed models achieved comparable scores to state of the art results on the test set without any feature engineering efforts.

Our experiments show that the best performance in the aspect category extraction task can be achieved by using one binary classifier per aspect following the one vs all strategy. For the sentiment extraction task, our results show that after fine tuning the word vectors, it is better to train a separate classifier for each domain.

We believe that bigger and more class balanced training and fine-tuning datasets can boost the results as it was clear that the classes' distributions are reflected in the testing results. We used fine-tuned word vectors for training the CNN model used for sentiment determination, initializing its weights randomly. In the future we plan investigating using the weights of the CNN that was used to fine tune the word vectors to initialize the second CNN used for sentiment classification. We expect that this might have a positive impact on the performance of the classifier, but this remains to be tested.

## Abstract

This paper presents our contribution to the SemEval 2016 task 5: Aspect-Based Sentiment Analysis. We have addressed Subtask 1 for the restaurant domain, in English and French, which implies opinion target expression detection, aspect category and polarity classification. We describe the different components of the system, based on composite models combining sophisticated linguistic features with Machine Learning algorithms, and report the results obtained for both languages.

## 1 Introduction and Related Work

Sentiment Analysis is an important topic in natural language processing, and Aspect Based Sentiment Analysis (ABSA), i.e. detection of sentiments expressed on different aspects of a given entity, constitute a very interesting but quite challenging task (Liu, 2012; Ganu et al., 2009). ABSA is a task first introduced at SemEval in 2014 (Pontiki et al., 2014), continued in 2015 (Pontiki et al., 2015) and now, in 2016 (Pontiki et al., 2016). Our team has participated to the first edition, with good results on the restaurant domain (Brun et al., 2014) and decided to reiterate the participation in 2016, on the same domain but on English and French, as the challenge has become multilingual. While relatively similar, the task has evolved since 2014: aspect targets and categories are annotated together instead of separately; only opinionated terms (Opinion Target Expressions, OTE) are annotated, and aspect categories are finer grained (12 classes instead of 5), which makes the subtasks even more challenging.

In the previous challenges, most systems, including ours, use state-of-the art machine learning algorithms such as SVMs (Wagner et al., 2014; Kiritchenko et al., 2014; Brun et al., 2014; Brychcín et al., 2014) or CRFs (Toh and Wang, 2014; Hamdan et al., 2015), with lexical information, bigrams and POS as features. In 2014, (Kiritchenko et al., 2014) had particularly good results on aspect category and aspect polarity detection, using SVMs combined with rich linguistic features including dependency parsing. In 2015, the system presented by (Saias, 2015) reported the best result for polarity classification, using a maximum entropy classifier, having bag-of-words, lemmas, bigrams after verbs, and punctuation based features, along with sentiment lexicon-based features. Our system shares with these ones the use of syntactic features to address the different ABSA tasks.

For the present challenge, we addressed subtask 1, which implies target terms detection, aspect category and polarity classification. In the remaining of the paper, we describe the different components of our system which combine rich linguistic features and machine learning algorithms (CRF, Ensemble models for classification). We then present and discuss our results on the different subtasks. We finally conclude and propose future directions.

## 2 System Description

We present here the different components of our system, dedicated to linguistic feature extraction, sequence labeling and classification.

## 2.1 Linguistic Feature Factory

We use a robust syntactic parser (XIP (Ait-Mokhtar et al., 2002)) as one of the fundamental components of our system. This parser provides a full processing chain including tokenization, morpho-syntactic analysis, POS tagging, Named Entity Detection, chunking and finally, extraction of dependency relations such as subject, object and modifiers. This robust parser has been already used for the Aspect Based Sentiment Analysis of SemEval 14 (Brun et al., 2014). We have designed and adapted a semantic extraction component that extracts semantic information about aspect targets and their polarities on top of the parser described before. For this task, syntactic dependencies, lexical information about word polarities and semantic classes, sub-categorization information are all combined within the parser to extract semantic relations associated to aspect targets. We already have developed a component that extracts sentiment relations (see (Brun, 2011) for the complete description of this component), taking into account contexts and scope of the polar predicates. This semantic component makes use of a polar lexicon associating polarities (only positive and negative) to words, and a semantic lexicon associating lexical semantic features (FOOD, DRINK, AMBIENCE, SERVICE, RESTAURANT, PRICE, STYLE) to words. For the present challenge, we used the English and French version of the grammars, and complemented the existing domain lexicons with lexical information extracted from the training corpus.

We use this parser as a “feature factory”, that outputs linguistic features which can feed the various Machine Learning algorithms we applied to the ABSA tasks<sup>1</sup>, that are described afterwards.

## 2.2 Domain Term detection using CRF

Conditional Random Fields (CRF) (Lafferty et al., 2001) is a popular class of statistical modelling for sequence labeling, which can be applied to term detection. For this specific task, we used CRFsuite<sup>2</sup> (Okazaki, 2007), which provides a cross-validation

<sup>1</sup>**Important note:** as we use this proprietary parser for our experiments, and for reproducibility concerns, we have released our feature datasets both for train and test, on English and French, for the different slots at this url: <http://semeval2016.xrce.xerox.com/>

<sup>2</sup><http://www.chokkan.org/software/crfsuite>

mechanism, to detect the terms and categories in the different sentences. The CRF model was trained with some traditional features such as POS, lemma, surface form, and the presence of uppercase letters for instance. However, we also used the output of the XIP parser to detect if a word was in a particular syntactic construction such as attribute, coordination or object dependencies. The parser also supplies lexico-semantic information, for instance if a given noun phrase is related to food or to service, also integrated into the list of features. Finally, we used as feature whether a word was detected as being part of a sentiment analysis structure. We then combined the features from the three previous and the three next words in order to train our system within a window of seven words. Thus, the CRF model was trained over a mixture of word forms and syntax. Since CRFsuite provides a cross-validation scheme, we applied a 10 fold cross validation, which displayed a consistent F-measure of 85 over the English training set and the French training set.

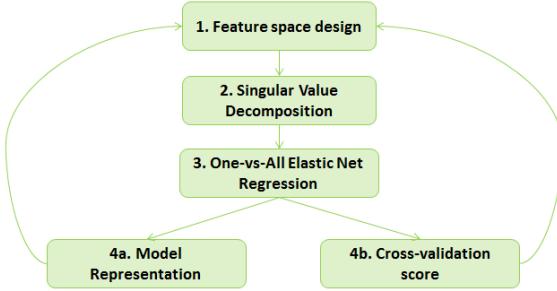

## 2.3 Inference models

In this section, the different aspects of the decision model are presented. Based on the rich linguistic representation produced for the different tasks, a feedback loop of classification has been developed. Indeed, in order to highlight the most efficient linguistic features, we developed a simple framework of feedback generation for assisting feature definition and selection.

### 2.3.1 Feedbacked Ensemble Models

In order to address aspect category and polarity classification, an interactive feedbacked ensemble method pipeline has been designed to cope with the strong sparsity nature of the data. Indeed, figure 1 details the overall dynamic of the model. First, the feature set associated with the considered term is defined. Then, in order to cope with sparsity truncated singular value decomposition (Hansen, 1986) can be performed on the original set of features then a one-versus-all Elastic Net regression model (Zou and Hastie, 2003) is used to infer the target concept, in our case category and polarity. The advantage of Elastic Net is that it explicitly defines a trade-off between L1-norm and L2-norm type of regularization. As an output of the model learning task, a model rep-

resentation and cross-validation scores are provided in order to allow for improvement of the feature set used as decision support, enabling a formal error analysis of such model. As feedbacked interaction, statistics informing of the relevance of the sentence features estimated during crossvalidation but also recurrent errors occurring in crossvalidation have been used as evidence in order to enhanced the linguistic representation of the sentences.

**Figure 1:** Ensemble Modeling Process for ABSA

This pipeline is applied to the different classification tasks described below.

### 2.3.2 Aspect Category Classification

For the restaurant domain, 12 semantic categories are covering the aspects (food#quality, food#style\_options, food#prices, drinks#quality, drinks#style\_options, drinks#prices, location#general, restaurant#general, restaurant#misc, restaurant#prices, service#general and ambience#general), into which explicit and implicit aspect targets have to be classified. Classification into aspect categories is done in two steps: the first step classifies aspect terms (explicit targets), which have been detected by the CRF model presented in section 2.2 into one or more aspect category; then a second classification step is applied to classify sentences into aspect categories, to cover the cases of implicit targets (i.e. “NULL” targets).

(1) Aspect term classification into aspect categories: to achieve this task we used a precise extraction of features that are relevant for a given term in a given sentence, knowing that several terms can be present in the same sentence. We apply a term centric feature extraction, i.e. for a given term, features are: lexical semantic features associated to the term by the parser (FOOD, SERVICE); bigrams and

trigrams involving the term; all syntactic dependencies (subject, object, modifier, attribute,...) involving the term. In other words, a term, i.e. a node in the dependency graph, is represented by the information captured by the arcs connecting this specific node to other nodes of the graph. The classification models presented in section 2.3.1 output the list of aspect categories together with their probabilities: we systematically associate the class of highest probability to a term detected by the CRF, and then associate additional categories whenever this probability is above a certain threshold; the threshold for these additional categories for a term was selected by cross-validation on the training corpora.

(2) Sentence classification into aspect categories: for this purpose, we used the same set of features as previously but at sentence level (i.e. not restricted to a given term). The classification models associate the potential sentence level aspect categories together with their probabilities; we annotate at sentence level (i.e. NULL annotation) if and only if the probability is above a given threshold, also calculated by cross-validation on the training corpora.

### 2.3.3 Polarity Classification

Opinion has to be classified with the three following polarities: positive, negative or neutral. We applied a similar strategy as for the aspect categories classification, i.e. classify the detected terms using a term-centric feature representation and then classify the sentences. We use the same pipeline as previously but in this case, we associate the highest polarity probability to the term or the sentence, ignoring the few cases presenting a mixed polarity (i.e. both positive and negative). Features are extracted the same way, but we add the aspect category detected previously as a feature for polarity classification. We also delexicalized the features, replacing a term by its generic aspect category (e.g. “staff” is replaced by “SERVICE”, “sushi” is replaced by “FOOD”, etc.), since our parser associates lexical semantic information to the domain terms.

## 3 Evaluation

Tables 1 and 2 report the results obtained on the 4 slots for English and French.

Our system performs target term classification, using a term centric representation, which proba-

|                      | XRCE          | Baseline | Rank  |
|----------------------|---------------|----------|-------|
| S1: Categories (F-1) | 68.701        | 59.928   | 7/29  |
| S2: Targets (F-1)    | 61.98         | 44.071   | 10/18 |
| S12: Tuples (F-1)    | 48.891        | 37.795   | 2/14  |
| S3: Polarity (Acc.)  | <b>88.126</b> | 76.484   | 1/28  |

**Table 1:** Results on English for the restaurant domain

|                      | XRCE          | Baseline | Rank |
|----------------------|---------------|----------|------|
| S1: Categories (F-1) | <b>61.207</b> | 52.609   | 1/5  |
| S2: Targets (F-1)    | 65.316        | 45.455   | 2/2  |
| S12: Tuples (F-1)    | 47.721        | 33.017   | 1/1  |
| S3: Polarity (Acc.)  | <b>78.826</b> | 67.4     | 1/5  |

**Table 2:** Results on French for the restaurant domain

bly explain the relatively good results we get on slot 12, <categories,target> tuples. It also explains the less good results on slot 1 for English, for which a sentence level classification would probably have been a better strategy. Results of the CRF on slot 2 are somehow disappointing, but analyzing the errors shows that we may have used a too large feature window (-3, +3) that could have resulted to an overfitting behaviour. Reducing the window to (-2, +2) improves the results: for slot 2, the F-1 reaches 67.883 for English and 68.533 for French; for slot 12, the F-1 reaches 53.364 for English, and 49.182 for French.

There are significant differences in term of performances between the two languages: for aspect category detection, the lower results for French are partly due to the smaller coverage of the lexical semantic information in the lexicon. For aspect polarity, most of the errors we've detected on English and French are misclassification of neutral utterances. This is due to the limited proportion of neutral cases in the training corpus (4% in English and 6% in French), and also to the fact that our polarity lexicons focus primarily on positive and negative vocabulary. This has a greater impact on the results for French, since the test corpus has a more balanced repartition of polarities.

In conclusion, the most encouraging result is that the system ranked first on polarity detection both for French and English. It tends to show that the combination of term-oriented and sentence-oriented classification performs well for polarity inference.

## 4 Conclusion

In this paper, we present a composite method based on ensemble modelling combined with rich linguistic features including lexical semantic information and syntactico-semantic dependencies to address aspect based category and polarity classification. We have also designed a target term recognizer using CRFs. Classification is performed at two levels : term level, for which we extract a set of term-centric features and sentence level, for which we extract sentence-based features, to address the cases where there is no explicit mention of a term (i.e. "NULL"). We have participated to the SemEval 2016 ABSA subtask 1, for English and French, in the restaurant domain, on slots 1, 2, 12, and 3. The system obtained very satisfying results for category detection in French (slot 1), and for slot 12 in English. But the best performances are achieved on polarity detection, since the system ends up first for both languages on slot 3: first among 28 submissions for English, and first among 5 submissions for French. Further directions of investigation will focus on two aspects. On one hand, we plan to investigate methods to decrease the level of supervision of the system (Broß, 2013), and on the other hand, we plan to extend to other languages and domains, via domain adaptation methods.

## Acknowledgements

We would like to warmly thank the SemEval 2016 Task 5 organizers and the French dataset support team for their support.

## Abstract

This paper describes our system submitted to Aspect Based Sentiment Analysis Task 5 of SemEval-2016. Our system consists of two components: binary classifiers trained using single layer feedforward network for aspect category classification (Slot 1), and sequential labeling classifiers for opinion target extraction (Slot 2). Besides extracting a variety of lexicon features, syntactic features, and cluster features, we explore the use of deep learning systems to provide additional neural network features. Our system achieves the best performances on the English datasets, ranking 1st for four evaluations (Slot 1 for both restaurant and laptop domains, Slot 2, and Slot 1 & 2).

## 1 Introduction

Sentiment analysis and opinion mining have gained increasing interests in recent years due to the continuous growing of user-generated content on the Internet. Traditionally, the primary focus of the research has been on the detection of the overall sentiment of a sentence or paragraph. However, such approach is unable to handle conflicting sentiment for different aspects of the same entity. Hence, a more fine-grained approach, known as Aspect-Based Sentiment Analysis (ABSA), is proposed. The goal is to correctly identify the aspects of entities and the polarity expressed for each aspect.

The SemEval-2016 Aspect Based Sentiment Analysis (SE-ABSA16) task is a continuation of the same task in 2015 (Pontiki et al., 2015). Besides sentence-level ABSA (Subtask 1), it provides

datasets to allow participants to work on text-level ABSA (Subtask 2). In addition, additional datasets in languages other than English are available (Pontiki et al., 2016).

We participate in Subtask 1 of SE-ABSA16, where we submitted results for Slot 1 (aspect category classification), Slot 2 (opinion target extraction), and Slot 1 & 2 (assessing whether a system correctly identifies both Slot 1 and Slot 2) for the English datasets.

Our work is based on our previous machine learning system described in Toh and Su (2015), enhanced using additional features learned from neural networks. For Slot 1, we treat the problem as a multi-class classification problem where aspect categories are predicted via a set of binary classifiers. The one-vs-all strategy is used to train a binary classifier for each category found in the training data. Each classifier is trained using a single layer feed-forward network. We enhance the system by adding neural network features learned from a Deep Convolutional Neural Network system. For Slot 2, we treat the problem as a sequential labeling task, where sequential labeling classifiers are trained using Conditional Random Fields (CRF). The output of a Recurrent Neural Network system is used as additional features. To generate Slot 1 & 2 predictions, the predictions of Slot 1 and Slot 2 are combined.

The remainder of this paper is organized as follows. In Section 2, the features used in our system are described. Section 3 presents the detailed machine learning approaches. Section 4 and Section 5 show the official evaluation results and feature ablation results respectively. Finally, Section 6 summa-

rizes our work.

## 2 Features

Our system used a variety of features which are briefly described in the following subsections. Most of the features used are the same as the features used in Toh and Su (2015).

### 2.1 Word

Each word in a sentence is used as a feature. Additional word context is used for different slots: for Slot 1, all word bigram context found in a sentence are also used; for Slot 2, the previous word and next word context are also used.

### 2.2 Name List

Two name lists of opinion targets are generated from the training data of the restaurant domain. One list contains opinion targets that frequently occur in the training data. The other list contains words that often occur as part of an opinion target in the training data.

### 2.3 Head Word

For each word, the head word is extracted from the sentence parse tree and is used as a feature.

### 2.4 Word Embeddings

Word embeddings have shown previously to be beneficial to opinion target extraction, requiring only minimal feature engineering effort (Liu et al., 2015). We trained word embeddings from two unlabeled datasets: the Multi-Domain Sentiment Dataset containing product reviews from Amazon (Blitzer et al., 2007)<sup>1</sup>, and the user reviews found in the Yelp Phoenix Academic Dataset<sup>2</sup>. Additional word embeddings are also generated from the concatenation of the above two datasets.

Two different approaches are used to train the word embeddings. The first approach uses the gensim<sup>3</sup> implementation of the word2vec tool (Mikolov et al., 2013)<sup>4</sup>. We experiment with different vector sizes, window sizes, minimum occurrences and subsampling thresholds.

<sup>1</sup><http://www.cs.jhu.edu/~mdredze/datasets/sentiment/>

<sup>2</sup>[http://www.yelp.com/dataset\\_challenge/](http://www.yelp.com/dataset_challenge/)

<sup>3</sup><https://radimrehurek.com/gensim/>

<sup>4</sup><https://code.google.com/archive/p/word2vec/>

The second approach uses the GloVe tool (Pennington et al., 2014)<sup>5</sup>. By varying the minimum count, window size and vector size, different embedding files are generated. The best embedding files to use are selected using 5-fold cross validation.

### 2.5 Word Cluster

We further processed the embedding files described in Section 2.4 by generating K-means clusters from them. Specifically, the K-means clusters are generated using the K-means implementation of Apache Spark MLLib<sup>6</sup>. Different cluster sizes are tried out and the best cluster files are selected using 5-fold cross validation.

### 2.6 Double Propagation Name List

Besides using the training data to generate name lists, we used the unsupervised Double Propagation (DP) algorithm (Qiu et al., 2011) to generate candidate opinion targets and collect them into a list. We adjust the logical rules stated in Liu et al. (2013) to derive our own propagation rules written in Prolog. The SWI-Prolog<sup>7</sup> is used as the solver. One issue with our rules is that it can only identify single-word targets. Thus, we check each identified target and include any consecutive noun words right before the target.

## 3 Approaches

This section describes our approaches used to generate the predictions for the different slots. The machine learning system is based on our previous work (Toh and Su, 2015) and is extended to use additional neural network features.

### 3.1 Aspect Category Classification (Slot 1)

For each category found in the training data, a binary classifier is trained using the Vowpal Wabbit tool<sup>8</sup>, which provides the implementation of the single layer feedforward network algorithm that we use.

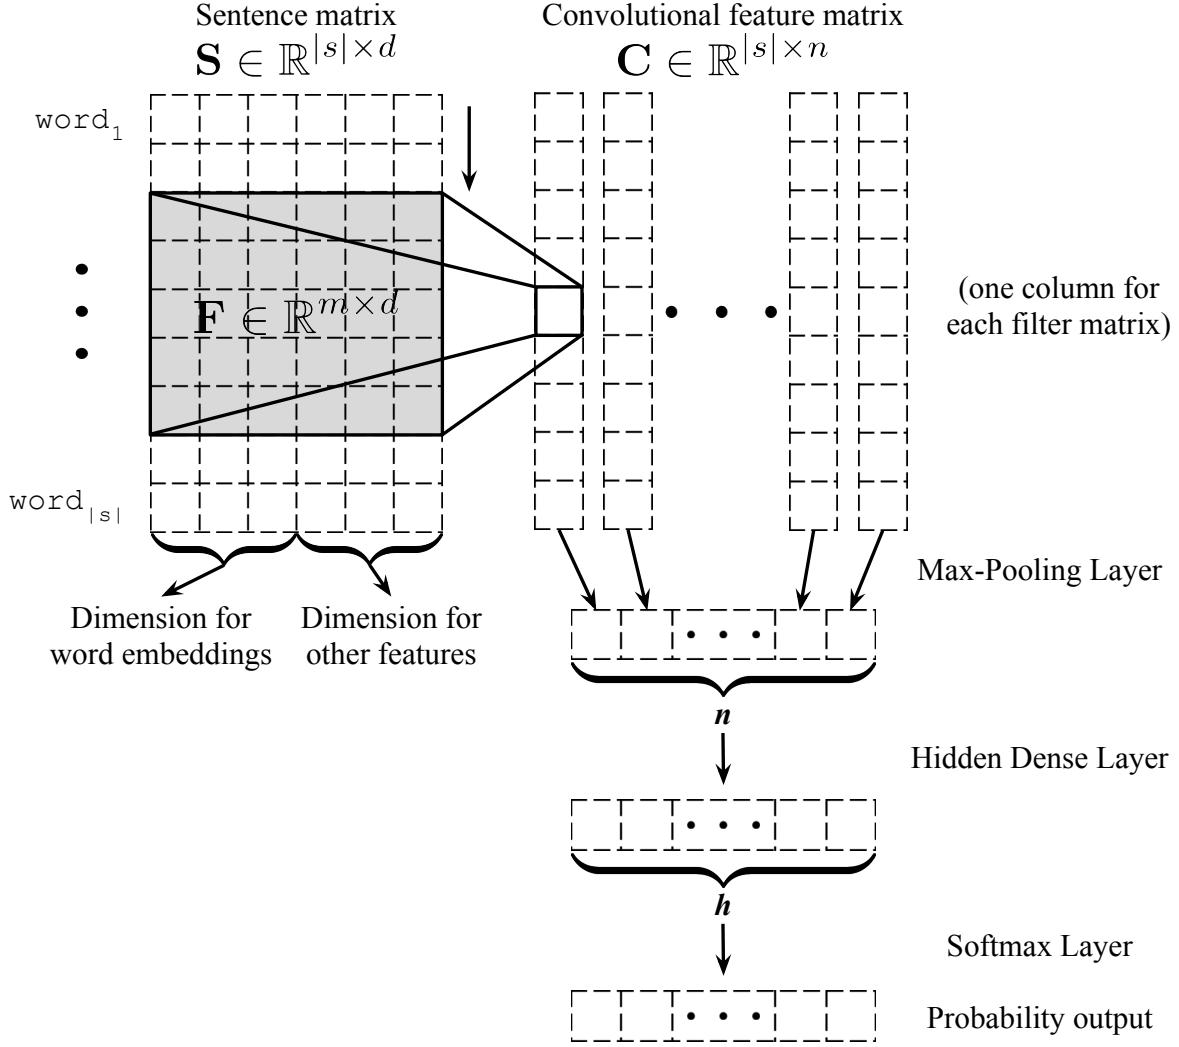

Besides using the features reported previously, we enhance our existing system by using additional features from a deep learning system described below.

<sup>5</sup><http://nlp.stanford.edu/projects/glove/>

<sup>6</sup><http://spark.apache.org/mllib/>

<sup>7</sup><http://www.swi-prolog.org/>

<sup>8</sup>[https://github.com/JohnLangford/vowpal\\_wabbit/wiki](https://github.com/JohnLangford/vowpal_wabbit/wiki)

**Figure 1:** The architecture of our Convolutional Neural Network.

The deep learning system is based on the Deep Convolutional Neural Network (CNN) architecture described in Severyn and Moschitti (2015). The architecture we use is shown in Figure 1.

A sentence matrix  $\mathbf{S} \in \mathbb{R}^{|s| \times d}$  is built for each input sentence  $s$ , where each row  $i$  is a vector representation of the word  $i$  in the sentence. The sentence length  $|s|$  is fixed to the maximum sentence length of the dataset so that all sentence matrices have the same dimensions. (Shorter sentences are padded with row vectors of 0s accordingly.) Each row vector of the sentence matrix is made up of columns corresponding to different input features (e.g. word embedding feature, name list feature, etc.) concatenated together<sup>9</sup>.

nated together<sup>9</sup>.

The input sentence matrix  $\mathbf{S}$  is then passed through a series of network layer transformations, described in the following subsections.

### 3.1.1 Convolutional Layer

We apply a convolution operation between the input sentence matrix  $\mathbf{S}$  and a filter matrix  $\mathbf{F} \in \mathbb{R}^{m \times d}$  of context window size  $m$ , resulting in a column vector  $\mathbf{c} \in \mathbb{R}^{|s|}$ . The filter matrix  $\mathbf{F}$  will slide (with a stride of 1) along the row dimension of  $\mathbf{S}$ , generating a value for each word in the sentence. Instead of a single filter matrix,  $n$  filter matrices are applied to

<sup>9</sup>Categorical features are converted to one-hot encodings.

the sentence matrix  $\mathbf{S}$ , resulting in a convolutional feature matrix  $\mathbf{C} \in \mathbb{R}^{|s| \times n}$ .

To learn non-linear decision boundaries, each element of  $\mathbf{C}$  passes through the hyperbolic tangent  $\tanh$  activation function.

### 3.1.2 Max-Pooling Layer

The output matrix  $\mathbf{C}$  is then passed to the max-pooling layer. This layer will return the maximum value of each column.

### 3.1.3 Hidden Dense Layer

A hidden dense layer with  $h$  hidden units is applied to the output of the pooling layer, using Rectified Linear Unit (ReLU) as the activation function.

### 3.1.4 Softmax Layer

A softmax layer receives the output of the previous dense layer and computes probability distribution over the possible categories. We include an additional category “NIL” for the case where the sentence contains no aspect category. Since a sentence may contain more than one category, we output the categories whose output probability value is greater than a threshold  $t$ .

### 3.1.5 Network Training and Regularization

The stochastic gradient descent (SGD) algorithm is used to train the CNN network, using the back-propagation algorithm to compute the gradients. We run SGD for  $e$  epochs, where a batch size of  $b$  sentences is used. The categorical cross-entropy is used as the loss function. To prevent overfitting, the loss function is augmented with a L2 regularization term ( $l_2$ ) for the parameters of the network. The Adadelta update function (with a specific decay rate  $\rho$  and constant  $\epsilon$ ) is used to control the learning rate.

The specific values used for the hyperparameters of the network are tuned using 5-fold cross-validation. The context window size  $m$  is set to 5. The number of filter matrices  $n$  is set to 300. The probability threshold  $t$  is set to 0.2. The number of hidden units  $h$  is set to 100. The number of epochs  $e$  is set to 50 and 100 for the restaurant and laptop domain respectively. The L2 regularization term  $l_2$  is set to 0.01. The Adadelta decay rate  $\rho$  and constant  $\epsilon$  is set to 0.95 and  $1e^{-6}$  respectively.

| Restaurant               |        |
|--------------------------|--------|
| Feature                  | F1     |
| Word <sup>†</sup>        | 0.6432 |
| + Head Word              | 0.6558 |
| + Name List <sup>†</sup> | 0.6670 |
| + Word Cluster           | 0.7128 |
| + CNN Probabilities      | 0.7510 |
| CNN System               | 0.7333 |

| Laptop                   |        |
|--------------------------|--------|
| Feature                  | F1     |
| Word <sup>†</sup>        | 0.5178 |
| + Head Word <sup>†</sup> | 0.5358 |
| + Word Cluster           | 0.5463 |
| + CNN Probabilities      | 0.5983 |
| CNN System               | 0.5693 |

**Table 1:** Experimental results of 5-fold cross-validation for Slot 1. Besides using the feature stated in the current row, features stated in all previous rows are also used. <sup>†</sup> indicates features used in constrained systems.

## 3.2 Slot 1 Features

Besides the features described in Section 2, the probability output of the CNN system is used as additional features to our multi-class classification system. The CNN system is trained on the following input features: Word Embeddings, Name List (only for the restaurant domain) and Word Cluster.

We performed 5-fold cross-validation experiments to obtain performances of the system after adding each feature group. Table 1 shows the experimental results.

We also include the 5-fold cross-validation performances if we only use the CNN system output for evaluation (last row). For both domains, the CNN system achieves better performances than the multi-class classification system without the neural network features.

However, the best performances are achieved when we used the CNN probability output as additional features to the multi-class classification system. This suggests our approach of combining two different machine learning systems is a feasible approach for the task.

### 3.3 Opinion Target Extraction (Slot 2)

We treat opinion target extraction as a sequential labeling task. The sequential labeling classifiers are trained using Conditional Random Fields (CRF). Such approach is similar to previous work that achieves state-of-the-art performances (Toh and Su, 2015). The implementation of CRF is provided by the CRFsuite tool (Okazaki, 2007).

Similar to our previous work, for different evaluations involving Slot 2, we train different models. For Slot 1 & 2 evaluation (multi setting), the explicit opinion targets may be classified under more than one category. Thus, a separate CRF model is trained for each category  $C$  found in the training data, where each model is trained using the corresponding BIO labels: “B- $C$ ”, “I- $C$ ” and “O” (corresponding to start of an opinion target, continuation of an opinion target and outside respectively).

For Slot 2 evaluation (single setting), only the target span is required. Thus, all categories are collapsed into a single category (e.g. “TARGET”). A single CRF model is trained using the labels “B-TARGET”, “I-TARGET” and “O”.

We also enhance our existing CRF system by using the output of a Recurrent Neural Network (RNN) system as additional features.

Specifically, we implement the Bidirectional Elman-type RNN model described in Liu et al. (2015)<sup>10</sup>. Such a model allows long-range dependencies from the future as well as from the past to be captured, which are beneficial for sequential labeling tasks. The last layer of the model is a fully connected softmax layer to allow the model to output probabilities.

#### 3.3.1 Network Training and Regularization

The RNN network is trained using SGD for 20 epochs, using Nesterov momentum with a learning rate of 0.05 and momentum of 0.9 and a batch size of 100 sentences. The categorical cross-entropy is used as the loss function, with L2 penalty of 0.01 for regularization. The number of hidden cell units for both directions is set to 250.

<sup>10</sup>Only a single RNN model is trained with all categories collapsed into a single category.

| Restaurant ( <b>multi</b> ) |        |
|-----------------------------|--------|
| Feature                     | F1     |
| Word <sup>†</sup>           | .4413  |
| + Name List <sup>†</sup>    | .5672  |
| + Word Cluster              | .5877  |
| + RNN Probabilities         | 0.6285 |

| Restaurant ( <b>single</b> ) |        |
|------------------------------|--------|
| Feature                      | F1     |
| Word <sup>†</sup>            | 0.6151 |
| + Name List <sup>†</sup>     | 0.6768 |
| + DP Name List               | 0.6992 |
| + Word Cluster               | 0.7162 |
| + RNN Probabilities          | 0.7390 |
| RNN System                   | 0.7190 |

**Table 2:** Experimental results of 5-fold cross-validation for Slot 2. Besides using the feature stated in the current row, features stated in all previous rows are also used. **multi**: Performances of Slot 2 for Slot 1 & 2 evaluation (ignoring NULL targets). **single**: Performances of Slot 2 for Slot 2 evaluation. <sup>†</sup> indicates features used in constrained systems.

### 3.4 Slot 2 Features

Besides the features described in Section 2, the probability output of the RNN system is used as additional features to our CRF system. The RNN system is trained on the following input features: Word Embeddings, Name List and Word Cluster.

We performed 5-fold cross-validation experiments to obtain performances of the system after adding each feature group. Table 2 shows the experimental results. We tune the system for two different settings: Slot 2 predictions used for Slot 1 & 2 evaluation (multi setting), and Slot 2 predictions used for Slot 2 evaluation (single setting).

#### 3.4.1 Slot 1 & 2

To generate the predictions for Slot 1 & 2 evaluation, we combine Slot 1 and Slot 2 predictions together. First, we use all Slot 2 predictions used for Slot 1 & 2 evaluation (multi setting). This covers the cases for explicit targets. To include NULL targets, we check the Slot 1 predictions for categories that are not found in the Slot 2 predictions above. These categories are assumed to belong to NULL targets.

|            |      | Slot 1     |        |        |        |      |        |        |        |        |  |
|------------|------|------------|--------|--------|--------|------|--------|--------|--------|--------|--|

| Baseline   | C    | –          | 0.5142 | 0.3856 | 0.4407 | C    | –          | 0.3656 | 0.3912 | 0.3780 |  |

**Table 3:** Official results for our system, top three performing systems and baselines.

## 4 Results

We participated in both unconstrained and constrained settings for the English datasets. Table 3 presents the official results of our submission. For comparison, the top three performing systems and baseline results are included (Pontiki et al., 2016).

As shown from the table, our system is ranked 1st for all four evaluations we participated (Slot 1 for both restaurant and laptop domains, Slot 2 and Slot 1 & 2 for the English datasets). Similar to previous observation, the constrained systems achieved lower results than the corresponding unconstrained systems, demonstrating the use of external resources are helpful for the task.

## 5 Feature Ablation

The feature ablation experimental results are shown in Table 4 (Slot 1) and Table 5 (Slot 2). The neural network features contributed the most performance gains. However, using the Name List and Word Cluster features do not seem to be particularly effective on the testing data: There are negligible or negative performance gains for Slot 1. As these two features are also used in the CNN system, it may

be redundant to include them again in the multi-class classification system. In addition, the neural network features may have become the dominant features during training, affecting the usefulness of other features.

Further investigation may be needed to identify better ways of combining the different machine learning systems together. For example, instead of adding neural network probability output to our multi-class classification system, we could instead add our classifier probability output as additional features to our CNN system.

## 6 Conclusion

In this paper, we describe our system used in classifying aspect categories (Slot 1) and extracting opinion targets (Slot 2). We explore the use of deep learning systems to provide additional neural network features to our existing system. Our system is ranked 1st in the four evaluations on the English datasets. In future, we hope to perform better feature engineering and explore how our deep learning systems can be further enhanced for the task.

## Abstract

This paper describes a sentiment analysis system developed by the bunji team in SemEval-2016 Task 5. In this task, we estimate the sentimental polarity of a given entity-attribute (E#A) pair in a sentence. Our approach is to estimate the relationship between target entities and sentimental expressions. We use two different methods to estimate the relationship. The first one is based on a neural attention model that learns relations between tokens and E#A pairs through backpropagation. The second one is based on a rule-based system that examines several verb-centric relations related to E#A pairs. We confirmed the effectiveness of the proposed methods in a target estimation task and a polarity estimation task in the restaurant domain, while our overall ranks were modest.

## 1 Introduction

Sentiment analysis is an important technology for understanding users' intentions from review texts. Such technologies are also useful for argumentation mining because it is necessary for readers to capture targets of interest and their polarities (Sato et al., 2015). Shared tasks of aspect-based sentiment analysis (ABSA) in SemEval provide a test bed for fine-grained analysis of sentiment polarities (Pontiki et al., 2014; Pontiki et al., 2015; Pontiki et al., 2016).

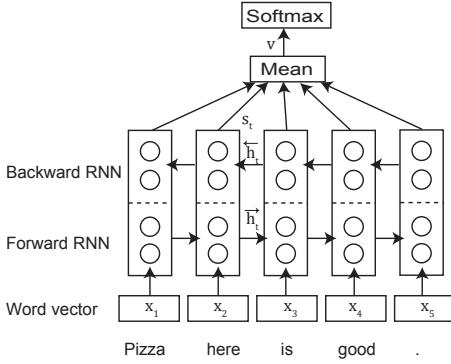

We participate in all four slots (Slot 1, 2, 1 & 2, and 3) of the restaurant domain and laptop domain in English. We focus on two types of models to capture the entity-attribute relationship, especially in Slot 2

and Slot 3. The first one is a neural network based model. The second one is a rule-based approach.

Now, we explain the problem settings of the slots and our approaches. The following is an example of sentences that provide positive opinions to the FOOD#QUALITY aspect: Pizza here is good.

Slot 1 is an extraction of all aspects mentioned in a sentence. In this example, the goal is to choose FOOD#QUALITY among many other aspects. We formulate the problem as a multi-label classification problem and use a neural network-based model. Slot 2 is an extraction of opinion target expressions. The expected output is "Pizza" in the above example. We use a pattern matching based approach and focus on gathering resources such as dictionaries. For Slot 1 & 2, we simply combine the prediction results of Slot 1 and Slot 2. Slot 3 is an estimation of sentiment polarities. In this example, we estimate the polarity of this sentence from the aspect of FOOD#QUALITY. For Slot 3, we take two approaches. The first approach is a neural attention model (Luong et al., 2015) that considers the entity attention (FOOD) and attribute attention (QUALITY) of each token. The second approach is a pattern matching-based model that examines the relationship between "Pizza" and "good" that is also used in Slot 2.

The remainder of this paper is structured as follows: In Section 2, we describe our system of phase A. In Section 3, we explain our system of phase B. Finally, Section 4 summarizes our work.

**Figure 1:** Structure of a neural network for Slot 1.

## 2 System Description of Phase A

### 2.1 Slot 1: Aspect Category

We formulate Slot 1 as a multi-label classification problem. In this problem, an entity-attribute pair is considered as a label. We use a neural model to solve this problem. The model is illustrated in Figure 1. Given a sequence of word vectors  $X = (x_1, x_2, \dots, x_T)$ , this model calculates a vector  $\mathbf{y}$  whose element represents probability of each label as:

$$\mathbf{y} = f(X). \quad (1)$$

At first, we apply Stanford Core NLP (Manning et al., 2014) to each document to obtain word sequences. Then, we use word embedding generated by Skip-gram with Negative Sampling (Mikolov et al., 2013) to convert words into word vectors. Three hundred dimensional vectors trained with Google News Corpus<sup>1</sup> are used in Slot 1.

Then, a word vector sequence  $X$  is inputted to a recurrent neural network (RNN). The RNN calculates an output vector  $s_t$  for each  $x_t$  as:

$$s_t, h_t = g(x_t, h_{t-1}), \quad (2)$$

where  $h_t$  denotes a hidden state of the RNN at position  $t$ . We use Long Short-Term Memory (LSTM) (Sak et al., 2014) and Gated Recurrent Unit (GRU) (Cho et al., 2014) as implementations of RNN units.

We use a bi-directional RNN (BiRNN) (Schuster and Paliwal, 1997) in order to consider both forward context and backward context. A BiRNN consists of

<sup>1</sup>Word embedding is available at <https://code.google.com/archive/p/word2vec/>

a forward RNN that processes tokens from head to tail and a backward RNN that processes tokens from tail to head. We concatenate forward output  $\vec{s}_t$  and backward output  $\overleftarrow{s}_t$  into  $s_t$ .

The sentence vector  $\mathbf{v}$  is then computed as a mean of RNN outputs  $s_t$ :

$$\mathbf{v} = \frac{1}{T} \sum_{t=1}^T s_t. \quad (3)$$

Finally, the probabilities in  $\mathbf{y}$  are calculated by using a single layered perceptron:

$$\mathbf{y} = \text{softmax}(\tanh(W\mathbf{v} + \mathbf{b})), \quad (4)$$

where  $W, \mathbf{b}$  denote a weight matrix and a bias vector, respectively.

We determine that a sentence contains the  $i$ -th aspect if its output  $y_i$  is greater than a threshold  $\theta$ . The threshold  $\theta$  is determined by using development data that is randomly sampled from training data.

We modify aspect names to a suitable format for our neural model. Low-frequency aspects in training datasets are replaced by a new aspect “OTHER”. The most common 10 aspects are preserved in the restaurant domain; the most common 16 aspects are preserved in the laptop domain. “NONE” labels are assigned to sentences that do not have any labels. The probability  $y_i$  in an example of a training dataset is defined as  $y_i = 1/k$  when a target sentence has the  $i$ -th aspect and a total of  $k$  aspects, otherwise  $y_i = 0$ .

We train the model by using backpropagation. The loss is calculated by using cross entropy. We use a minibatch stochastic gradient descent (SGD) algorithm together with an AdaGrad optimizer (Duchi et al., 2011). We add Dropout (Srivastava et al., 2014) layers to the input and output of the RNN. We clip the gradient norm when it exceeds 5.0 to improve the stability of training. The model parameters and  $\theta$  are trained by the training dataset of the ABSA 2015, and the hyperparameters are tuned by test dataset of the ABSA 2015. We use random sampling to tune the hyperparameters. The best settings are shown in Table 1. We implement our neural systems by using Tensorflow (Abadi et al., 2015).

### 2.2 Slot 2: Opinion Target Expression

In Slot 2, we extract text spans corresponding to target entities. The procedure of our proposed method

| Parameter        | REST  | LAPT  |
|------------------|-------|-------|
| Dropout $p_k$    | 0.8   | 0.3   |
| Learning rate    | 0.945 | 0.374 |
| hidden unit size | 128   | 64    |
| minibatch size   | 20    | 20    |
| max epochs       | 100   | 840   |
| cell             | LSTM  | GRU   |
| max token num    | 40    | 50    |
| threshold        | 0.048 | 0.11  |

**Table 1:** Hyperparameter setting for Slot 1.  $p_k$  denotes a ratio to keep values in a Dropout layer.

is as follows:

1. Creating dictionaries of food names and drink names by extracting targets in a training dataset,
2. Collecting food names and drink names in Knowledge Base and adding them to dictionaries,
3. Applying dictionary matching to sentences in a test dataset,
4. Extracting restaurant names by using syntactic rules, and
5. Checking relationship between targets extracted by step 3 and step 4 and attribute expressions.

Three key features of our method are the dictionary creation in step 2, the syntactic rules in step 4, and the estimation of the entity-attribute relationship in step 5.

### Dictionary Creation

Coverage of dictionaries is crucial to improve recall metrics. In the training dataset, we observe various instances of FOOD entities such as bread, focaccia and gazpacho. Therefore, we try to import world knowledge written in Knowledge Base. We use DBpedia <sup>2</sup> as Knowledge Base to expand the dictionaries. We write a SPARQL query to retrieve labels (rdfs:label) of entities as dictionary entries. First we prepare a list of target types. For examples, we use <http://dbpedia.org/ontology/Food> and <http://dbpedia.org/ontology/Fish> as types of FOOD entities. We also prepare a list of types to be ignored such as “dbo:Beverage”. Names of DRINK are also retrieved in the same manner as FOOD.

<sup>2</sup><http://wiki.dbpedia.org/>

| Domain | Team       | Precision | Recall | F1    |
|--------|------------|-----------|--------|-------|
| REST   | bunji      | 48.86     | 78.20  | 60.14 |
|        | baseline   | 54.19     | 67.03  | 59.93 |
|        | Ranked 1st | 72.45     | 73.62  | 73.03 |
| LAPT   | bunji      | 44.09     | 35.92  | 39.59 |
|        | baseline   | 45.92     | 31.66  | 37.48 |
|        | Ranked 1st | 56.85     | 47.81  | 51.94 |

**Table 2:** Official results of Subtask 1 Slot 1

| Domain | Team       | Precision | Recall | F1    |
|--------|------------|-----------|--------|-------|
| REST   | bunji      | 62.61     | 67.32  | 64.88 |
|        | baseline   | 51.42     | 38.56  | 44.07 |
|        | Ranked 1st | 75.49     | 69.44  | 72.34 |

**Table 3:** Official results of Subtask 1 Slot 2

### Restaurant Name Extraction

We use syntactic rules to extract restaurant names. We define a set of verb-centric rules such as “A1 visited A2” where A1 is a subject, and A2 is an object. A2 is likely to be restaurant names. We manually create 15 rules from training data.

### Entity-Attribute Relationship Estimation

We observe entities not related to sentimental expressions in dictionary-match results, which decrease precision scores. Therefore, we filter entities related to sentiment expressions. We use the same method as that in Slot 3.

## 2.3 Results

Table 2 shows the results of Slot 1. Our system marked the highest recall score among all of the teams in the restaurant domain, while our precision score is lower than that of the baseline system. This is partly because of the determination of threshold values that may be overfitted to the development sets. One possible solution is to use cross validation to estimate more reliable threshold values.

Table 3 shows the results of Slot 2. We can observe improvement of both the precision score and the recall score from those of the baseline system. The recall score is comparable to that of the ranked 1st team, while there is much room for improvement of the precision scores.

Table 4 shows the results of Slot 1 & 2. We can observe the similar tendency to Slot 1’s results because we simply merged the results of Slot 1 and Slot 2, and Slot 1 performs worse than Slot 2.

| Domain | Team       | Precision | Recall | F1    |
|--------|------------|-----------|--------|-------|
| REST   | bunji      | 35.41     | 49.01  | 41.11 |

Table 5 shows the results of Slot 1 of Subtask 2. We merge the sentence-wise results into document-wise results.

### 3 System Description of Phase B

#### 3.1 Slot 3: Sentiment Polarity

##### Neural Approach

Our method is inspired by a Deep Learning method proposed by Wang and Liu (Wang and Liu, 2015). They used estimated probabilities of Slot 1 as weights of a target entity-attribute pair, and then they inputted weighted tokens to a convolutional neural network. Instead of probabilities of Slot 1, we directly calculate entity attention and attribute attention at each token by using a neural attention model (Luong et al., 2015). The model is illustrated in Figure 2. We calculate a vector  $\mathbf{y}_p$  that represents probabilities of polarities (positive, negative,

**Figure 2:** Structure of a neural network for Slot 3.

and neutral) as:

$$\mathbf{y}_p = f(X, \mathbf{v}_e, \mathbf{v}_a), \quad (5)$$

where  $\mathbf{v}_e$  and  $\mathbf{v}_a$  denote vectors corresponding to a target entity and a target attribute. At first we calculate RNN outputs  $\mathbf{s}_t$  with Eq. 2 similarly to Slot 1. Then, attention weights for both entity and attribute are computed at attention layers. An entity-attention layer calculates weights  $\varepsilon_t$  at position  $t$ . At each position,  $e_t$  is computed to measure the relationship between  $\mathbf{s}_t$  and  $\mathbf{v}_e$ :

$$e_t = \mathbf{v}_e^T W_e \mathbf{s}_t. \quad (6)$$

Then, we transform the scale of  $e_t$  and obtain an entity-attention weight  $\varepsilon_t$  as:

$$\varepsilon_t = \frac{\exp(e_t)}{\sum_j \exp(e_j)}. \quad (7)$$

Similarly, the attribute attention layer has weights  $\alpha_t$  at position  $t$  as follows:

$$a_t = \mathbf{v}_a^T W_a \mathbf{s}_t, \quad (8)$$

$$\alpha_t = \frac{\exp(a_t)}{\sum_j \exp(a_j)}. \quad (9)$$

Then, we calculate a sentence vector  $\mathbf{r}$  that is a weighted sum of RNN output with entity attention weights and attribute attention weights as:

$$\mathbf{r} = \sum_t (\alpha_t \mathbf{s}_t || \varepsilon_t \mathbf{s}_t), \quad (10)$$

where  $||$  denotes a concatenation operator that creates a vector in  $\mathbb{R}^{2d}$  from two vectors in  $\mathbb{R}^d$ .

Finally, we calculate  $\mathbf{y}_p$  by using a single layered perceptron:

$$\mathbf{y}_p = \text{softmax}(\tanh(W_p \mathbf{r} + \mathbf{b}_p)). \quad (11)$$

We train the Slot 3 model by using backpropagation. We use a minibatch stochastic gradient descent (SGD) algorithm together with the ADAM optimizer (Kingma and Ba, 2015). Hyperparameters are tuned similarly to Slot 1. The hyperparameter settings in Slot 3 are shown in Table 6. We add Dropout (Srivastava et al., 2014) layers to the input and output of the RNN. We also apply L2-regularization to two attention layers and a softmax

| Parameter      | REST (U)             | REST (C)             | LAPT (C)             |
|----------------|----------------------|----------------------|----------------------|
| Dropout $p_k$  | 0.9                  | 0.9                  | 0.9                  |
| Learning rate  | $1.7 \times 10^{-3}$ | $1.4 \times 10^{-3}$ | $5.8 \times 10^{-4}$ |
| RNN state size | 64                   | 128                  | 64                   |
| minibatch size | 16                   | 32                   | 16                   |
| max epochs     | 12                   | 19                   | 6                    |
| L2 coef        | $1.9 \times 10^{-4}$ | $1.9 \times 10^{-4}$ | $3.3 \times 10^{-4}$ |

**Table 6:** Hyperparameter setting for Slot 3.  $p_k$  denotes a ratio to keep values in a Dropout layer.

layer. The attention unit size is 300. In an unconstrained setting, we use the same word embedding that has 300 dimensional vectors as Slot 1. In a constrained setting, we use 128-dimensional vectors that are initialized by uniform distribution. We clip the gradient norm when it exceeds 5.0 to improve stability of training. We set the maximum token length as 40. Initial values of entity vectors are created by averaging word vectors in sentences that have target entities. Attribute vectors are also initialized in the same manner as the entity vectors.

### Relation-Features Approach

This approach trains a linear classifier using relations of a given entity and a given attribute as features. In the first step, we annotate the following 11 annotations of relations to all documents:

- believe** Showing someone’s belief such as “X likes Y” and “X avoids Y”,
- significant** Showing X’s significance such as “X is impressive” and “X is terrible”,
- require** Showing requirement such as “X needs Y”,
- equivalent** Showing X is equivalent to Y, such as “X viewed Y” and “X regarded Y”,
- include** Showing inclusion or possession such as “X has Y” and “X equips Y”.
- contrast** Comparing X with Y such as “Y is ... than X” and “Y is ... compared to X”,
- affect** Showing X affects Y such as “X increases Y” and “X causes Y”,
- state** Showing statement such as “X doubts that Y”,
- negation** Showing negations such as “not X” and “no X”,
- shift** Reversing X’s polarity such as “X ban” and “X shortage”, and
- absolutize** Fixing polarity of X such as “X problem” and “X risk”.

These annotations were originally developed for an argument-generation system (Sato et al., 2015).

In the second step, we identify an entity expression and an attribute expression that correspond

|        | bunji(neural) | C   | 70.29    |
| LAPT   | baseline      | C   | 70.04    |
|        | Ranked 1st    | U   | 82.77    |

**Table 7:** Official results of Subtask 1 Slot 3. (neural) and (rel) denote the neural approach and the relation-feature approach, respectively.

to a given entity-attribute pair. We use a simple dictionary-matching approach. In the restaurant domain, we use a given target annotation as an entity expression. In the laptop domain, we prepare a list of entities extracted from a training dataset. For both domains, we create an attribute dictionary. Entries of the dictionary are manually extracted from training datasets. Then, we assign a sentimental polarity (positive, negative, or neutral) to each entry.

In the third step, we create features for a linear classifier. Those features are generated by combining annotations to capture various relations of a target entity-attribute pair. For example, we examine whether an affect annotation is negated or not and whether a target entity is a subject of an affect annotation or an object.

Finally, we classify a sentimental polarity by using a linear classifier. We use a linear SVM in scikit-learn (Pedregosa et al., 2011) as an implementation of the classifier, on the parameter  $C = 0.1$ ,  $\text{loss} = \text{squared\_epsilon\_insensitive}$ , and  $\text{penalty} = \text{l2}$ .

### 3.2 Results

Table 7 shows the results for Slot 3. We select a suitable method from the neural method and the rule-based method for each domain by comparing scores in the ABSA15 dataset. In the restaurant domain, we can observe that the proposed method improves the accuracy by 10 percentage points compared with the baseline system.

We merged sentence-wise estimation and created document-wise estimation. We gathered polarities of an entity-attribute pair. If a result was both positive and negative, then we judged it as conflicting. Table 8 shows the results for Subtask 2. We can see

| Domain | Team          | C/U | Accuracy |
|--------|---------------|-----|----------|
| REST   | bunji(neural) | U   | 70.54    |
|        | bunji(neural) | C   | 66.58    |
|        | baseline      | C   | 74.26    |
| LAPT   | Ranked 1st    | U   | 81.93    |
|        | bunji(rel)    | U   | 60.00    |
|        | bunji(neural) | C   | 62.20    |
|        | baseline      | C   | 73.03    |
|        | Ranked 1st    | U   | 75.05    |

**Table 8:** Official results of Subtask 2 Slot 3. (neural) and (rel) denote the neural approach and the relation-feature approach, respectively.

a similar tendency to the results in Subtask 1.

## 4 Conclusions

In this paper, we described the participation of the bunji team in SemEval-2016. We used both a neural approach and a rule-based approach to model an entity-attribute relationship. We confirmed the effectiveness of the proposed methods in a target estimation task and a polarity estimation task in the restaurant domain, while our overall ranks were modest.

As a future work, we plan to investigate network structures that are simple enough to be trained with a relatively small dataset. For the rule-based system, we plan to add more rules to improve precision scores.

## Abstract

This paper describes the system submitted by IHS-RD-Belarus team for the sentiment detection polarity subtask on Aspect Based Sentiment Analysis task at the SemEval 2016 workshop on semantic evaluation. We developed a system based on artificial neural network to detect the sentiment polarity of opinions. Evaluation on the test data set showed that our system achieved the F-score of 0.83 for restaurants domain (rank 4 out of 28 submissions) and F-score of 0.78 for laptops domain (rank 4 out of 21 submissions).

## 1 Introduction

Social media texts found in user review services have a great data-mining potential, as they offer real-time data that can be useful to monitor public opinion on brands, products, events, etc.

Most of recent approaches to sentiment analysis task are based on bag-of-words features, syntactic dependency features, out-of-domain and domain-specific sentiment lexicons, to train an supervised model that predicts the polarity of each given term or aspect category. This approach is very popular but it relies on heavy pre-processing of the data which involves careful choosing of the right features, empirical thresholds and intuitive analysis of the training set (Brun et al., 2014, Saias, 2015).

In this paper, we present an approach to the opinion polarity detection task based on an artificial neural network and sentiment orientation score of words.

## 2 Task description

The SemEval-2016 shared task on Aspect based Sentiment Analysis focuses on identifying the Opinion target expressions (OTE), the Aspect categories and the sentiment expressed towards each OTE or Aspect category.

The main focus of this paper is polarity subtasks, such as OTE polarity in restaurant subject domain and Aspect category polarity in laptop subject domain.

In the OTE polarity subtask, the input consists of a review sentence and the set of terms or aspect categories. The expected output is a polarity label (positive, negative or neutral) for each of the associated terms or aspect categories.

For example, the system should determine the polarity of *fajitas* and *salads* in the following sentence: *I hated their fajitas, but their salads were great.*

As for the Aspect category polarity, the task is more complicated. In the following sentence, the system has to determine the polarity of display quality (DISPLAY#QUALITY) and display usability (DISPLAY#USABILITY): *The display has a great resolution but has difficulty always seeing the small print.*

The task organizers provided a dataset of customer reviews with manually annotated opinion targets: 2500 sentences for laptop domain and 2000 sentences for restaurant domain.

Evaluation was to be carried out according to Precision, Recall and F1 metrics.

### 3 System description

The central idea behind our system is the visualization of sentiment orientation in a word sequence using heatmap, that highlights regions with higher or lower “temperature”. The “temperature” of a word is its sentiment polarity, positive or negative, and the intensity is calculated based on sentiment orientation score of word.

#### 3.1 Sentiment orientation lexicon

Sentiment orientation score indicates the strength of association of words ( $w$ ) with positive ( $pr$ ) and negative ( $nr$ ) reviews. Following Turney and Littman (2003), we calculated SO as the difference using Pointwise Mutual Information (PMI) measures:

$$SO(w) = PMI(w, pr) - PMI(w, nr)$$

SO score is positive when the word or phrase tends to occur mostly in positive reviews and negative when the word occurs more often in negative reviews. The magnitude indicates the degree of association.

We followed the lexicon-generation approach proposed by Kiritchenko et al. (Kiritchenko et al., 2014) and when generating the sentiment lexicons we distinguished the terms appearing in negated and affirmative contexts. Sentiment scores were then calculated separately for these two types of contexts.

We created uni-, bi- and tri-gram lexicons based on Yelp restaurant reviews and Amazon reviews.

#### 3.2 Sentiment orientation score

The final SO score of n-gram in a sentence can be affected by some neighbour terms, such as valence shifters and intensifiers (Kennedy and Inkpen, 2006). We created short wordlists and tuned final SO score of n-gram if words from these lists were found in term context.

##### 3.2.1 Valence shifters

Valence shifters are terms that can change the semantic orientation of another term, for example, combining positively valenced words with a nega-

tion flips the positive orientation to a negative orientation. The most important shifters are negations such as *not*, *never*, *none*, *nobody*, etc. (Polanyi and Zaenen, 2004).

As it was mentioned above we included negations, such as *not* and *never*, as n-gram postfix into lexicons. If the n-gram in negative context is not found in lexicon or its raw frequency in review corpus is less than 5, the final SO score is calculated based on calculation rules showed in table 1.

These negation rules are designed in order to improve the sentiment text analysis and are based on simple assumption: the negation flips positive the valence of a word to a negative with the same strength, but the negation doesn’t flip the valence of a negative word, it rather reduces its strength.

| SO of word  | calculation rule | Example                                |
|-------------|------------------|--|
| positive SO | SO=pos_SO * -1   | SO(love) = +2.6<br>SO(not love) = -2.6 |
| negative SO | SO=neg_SO * 0.5  | SO(hate) = -2.2<br>SO(not hate) = -1.1 |

**Table 1:** SO calculation rules in negative context.

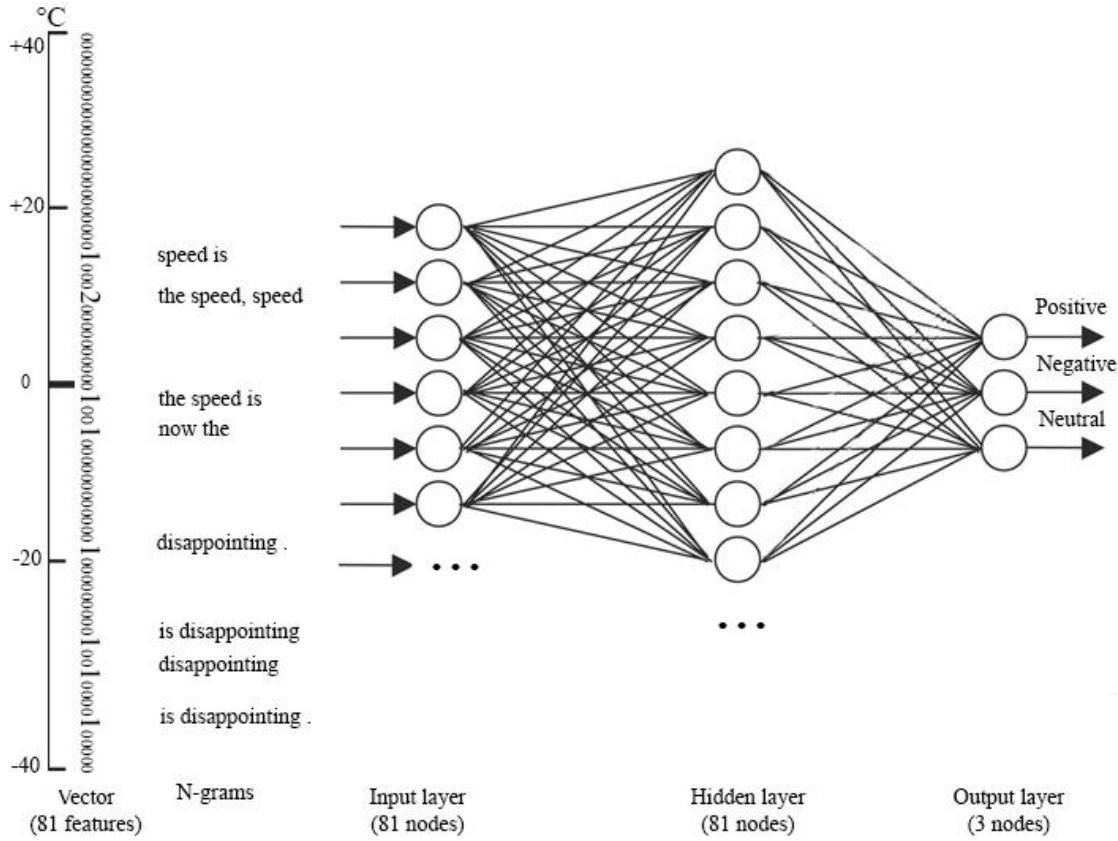

##### 3.2.2 Intensifiers

Intensifiers are terms that change the degree of the expressed sentiment. For example, in the sentence “*The waterfly cases are very good.*”, the term *very good* is more positive together than just *good* alone. So to calculate the final SO score we multiply sentiment score of n-gram by 3.

On another side, in the sentence “*The waterfly cases are barely good.*”, the term *barely* makes this statement less positive. We created 4 lists of intensifiers of different intensity of affecting the final SO score of n-gram.

##### 3.2.3 Unreality and conditionality

A sentence in reviews can express not only a real user experience, but also an unreal opinion, for example a wish, “*I should have bought something better.*” or “*The laptop may be better*”. We collected all surface patterns which can express unreality or conditionality. The SO of all positive n-grams in unreal context is flipped to negative with the same strength. The SO of negative n-grams is not changed.

**Fig. 1:** System architecture

### 3.3 Neural network architecture

A fully connected multilayer neural network with back-propagation is applied. The network, illustrated in Fig. 1, contains 3 layers:

- input with 81 nodes - one for each feature presenting “temperature” range;
- hidden layer with 80 nodes - each node in the input layer is connected to each node of the hidden layer;
- output layer with 3 nodes - one for each of 3 classes.

As the activation function the sigmoid function is used. We apply dropout to our hidden layers, as described in Srivastava et al. (Srivastava et al., 2014), to prevent network overfitting.

The network architecture is implemented on Keras<sup>1</sup>, which is an effective deep learning framework implementation in python.

At the first step, we detect the context of opinion target expressions or category. If the sentence has only one opinion target, the term context will include all words from the beginning to the end of the sentence. If the sentence has many targets, the context will include all words surrounding the term enclosed between two separators. As a separator we consider all punctuation marks, the next opinion target, the end and the beginning of the sentence. In the laptops subtask we had to detect polarity of the category that is not bounded to any word in the sentence. That is why we considered the whole sentence as context for every aspect category.

For training, each term context was represented as a vector of 81 features that resembles the scale of “temperature” from -40 (very negative) to 40 (very positive). Each word according to its SO score was placed on this scale. The value of a feature means the number of words within this range of sentiment orientation.

---

<sup>1</sup> <http://keras.io/>

Table 2 illustrates a set of n-grams with their final SO scores and “temperature” extracted from the sentence “*Now the speed is disappointing*”.

|           | n-gram             | SO score | °C  |
|-----------|--------------------|----------|-----|
| Uni-grams | disappointing      | -3.0     | -30 |
|           | speed              | +1.0     | +10 |
| Bi-grams  | is disappointing   | -2.7     | -27 |
|           | disappointing .    | -1.7     | -17 |
|           | now the            | -0.4     | -4  |
|           | the speed          | +1.0     | +10 |
| Tri-grams | speed is           | +1.4     | +14 |
|           | is disappointing . | -3.5     | -35 |
|           | the speed is       | -0.1     | -1  |

Table 2: SO scores of n-grams

The number of training epochs is set to 2. More epochs would lead to overfitting because the training set that is relatively small.

#### 4 Results and further work

The 3-fold cross-validation procedure was used to test the system performance. It uses 66% of the data to train and the remaining 33% to assess the accuracy. This is repeated 3 times with a different 33% left. Table 3 represents the results.

|                       | restaurants       | laptops          |
|-----------------------|-------------------|------------------|
| <b>total accuracy</b> | <b>0.82838934</b> | <b>0.8030438</b> |
| F1 positive           | 0.882567          | 0.8479           |
| F1 negative           | 0.762167          | 0.796867         |
| F1 neutral            | 0.0               | 0.0              |

Table 3: 3-fold cross-validation results

The results on the official test set are given in Table 4. They are similar to our best results attained during the developments stage.

|                       | restaurants      | laptops          |
|-----------------------|------------------|------------------|
| <b>total accuracy</b> | <b>0.8393481</b> | <b>0.7790262</b> |
| F1 positive           | 0.9078           | 0.8308           |
| F1 negative           | 0.753            | 0.7588           |
| F1 neutral            | 0.0              | 0.0              |

Table 4: Official results

On both sets our system did not recognize neutral (mildly positive or mildly negative sentiment) sentiments, although we used 3 classes classification. The reason is the low number of neutral sentiments in the annotated corpus.

As a future work, we intend to develop more complex artificial neural network architecture and try to use review-long memory about the polarity of previous targets. Also we are going to investi-

gate the influence of words with extremely high or low sentiment orientation score on the SO scores of neighbouring words.

#### 5 Conclusion

We have presented a simple neural network architecture that predicts polarity of word sequence based the heatmap of sentence that highlights regions with higher or lower sentiment intensity. We submitted runs corresponding to the slot3 subtasks, obtaining competitive results. Our submission was ranked 4<sup>th</sup> out of 28 submissions for restaurants domain and 4<sup>th</sup> out of 21 submissions for laptops domain.

Brno University of Technology,  
Faculty of Information Technology,  
IT4Innovations Centre of Excellence  
Božetěchova 2, 612 66 Brno, Czech Republic  
qmachacek@stud.fit.vutbr.cz

## Abstract

This paper describes an approach used to solve *Aspect Category Detection* (Subtask 1, Slot 1) of *SemEval 2016 Task 5*. The core of the presented system is based on *Supervised machine learning* using bigram *bag-of-words* model. The performance is enhanced by several pre-processing methods, most importantly by a term substitution technique. The system has reached a very good performance in comparison with other submitted systems.

## 1 Introduction

As the Internet more and more becomes the means of expressing opinions about various subjects, the need to effectively process those opinions (subjective information) is becoming more and more important. Many companies around the world are now interested in gathering public opinion and performing strategic moves accordingly. Thus, *Sentiment Analysis* (also known as *Opinion mining*) has become an important area of interest.

Existing systems performing sentiment analysis usually only predict polarity of a given sentiment. While this can be sufficient in a lot of cases, sometimes we wish to analyze opinions about different aspects of the same entity. This task is known as *Aspect-based Sentiment Analysis*.

*SemEval 2016 Task 5* (Pontiki et al., 2016) consists of three subtasks. The first subtask is about sentence-level sentiment analysis and is divided into three slots: *Aspect Category Detection*, *Opinion Target Expression* and *Sentiment Polarity Detection*.

There are multiple distinct domains in which participants were given the opportunity to test their systems. Each domain was available for one of the following languages: Arabic, Chinese, Dutch, English, French, Russian, Spanish and Turkish.

For all domains, there is a limited, known in advance, list of entities and aspects the system should recognize. Each entity can be associated with only certain aspect(s). The set of all possible entity-aspect pairs is also limited and known in advance.

Each submitted system could run in two modes: *Constrained* (using no external data sources like lexicons or additional training sets) and *Unconstrained* (no data source restriction).

The system I propose is focused on *Aspect Category Detection* only, i.e. it only predicts which aspects of a given entity a given sentiment has opinions about. I decided to participate in the English language, for which two domains were available: restaurant and laptop reviews. There were 12 entity-aspect pairs for the restaurants domain and over 80 for the laptops domain.

## 2 Approach

My approach was inspired by the NLANGP system (Toh and Su, 2015) which achieved excellent results in *SemEval 2015* (Pontiki et al., 2015) with a straightforward solution.

I model the task as a *multi-label* classification with *binary relevance* transformation, where labels correspond to the entity-aspect pairs. All train and test sentences are pre-processed (see Section 2.2). Words from each sentence are used as individual binary features of that sentence. For each entity-aspect

pair, all training sentences are used as positive or negative examples of that entity-aspect pair.

*Vowpal Wabbit*<sup>1</sup>, a supervised machine learning tool, is used to train the resulting binary classifiers. More precisely, a variant of *online gradient descent* algorithm is used to perform *logistic regression* with *squared cost function*.

## 2.1 Model properties

It has been observed that the model offers higher accuracy if bigrams are allowed in VW. However, additional raising the  $n$  of VW's  $n$ -gram feature is counterproductive. Allowing skips inside bigrams also does not help. For the RESTAURANT#MISCELLANEOUS aspect category, however, setting  $n = 5$  seemed to be a better choice. The system has generally unsatisfying score of predicting aspect categories associated with the MISCELLANEOUS attribute. Setting  $n > 2$  did not improve the accuracy for any other aspect category.

I have also tuned VW's *learning rate* and a threshold  $T$  for comparing probabilities returned from VW's classifiers. When it predicts that a sentiment has opinion(s) about an aspect category  $C$  with the probability of  $P$ , the system drops the prediction iff  $P < T$ . Table 1 shows the tuned properties.

| Domain                   | Restaurants | Laptops |
|--------------------------|-------------|---------|
| Learning rate            | 0.41        | 0.38    |
| Prediction threshold $T$ | 0.40        | 0.34    |

Table 1: Tuned learning rate and the prediction threshold

## 2.2 Text pre-processing

The initial text pre-processing step consists of removing the punctuation from each sentence and converting all characters to lower case. *Stanford CoreNLP*<sup>2</sup> is used to tokenize each sentence, *lemmatize* all words and also extract their *part of speech* (*POS*).

### 2.2.1 Filtering words

The POS tags are useful to estimate how much important given words are in terms of aspect category detection. The system does not introduce the tags to the machine learning algorithm, but it uses each tag to consider removing the corresponding

| Food      | Service   | Opinion       | Laptop   |
|-----------|-----------|---------------|----------|
| pizza     | staff     | good          | computer |
| sauce     | clerk     | average       | machine  |
| entree    | she       | terrific      | notebook |
| hot dog   | friendly  | disappointing | netbook  |
| croquette | attentive | poor          | desktop  |
| ...       | ...       | ...           | ...      |

Table 2: Example term lists compilation

word from its sentence. Also, some words are removed regardless of their POS.

An automated experiment over the official training set has been implemented to produce a POS filter and a list of stop words, for each domain separately. Both features are included in the constrained mode.

The experiment showed that for the restaurants domain, it was not demonstrably beneficial to remove any word based on its POS. On the other hand, it generated a list of tags for the laptops domain.

The lists of stop words that the experiment produced were surprisingly small. It seemed there were just few high frequency words which were irrelevant in the learning process.

### 2.2.2 Term groups

As a part of the pre-processing phase, a simple substitution system has been implemented to support machine learning. When multiple  $n$ -grams have roughly the same meaning, or they are related in a certain way, it is often beneficial if classifiers do not distinguish between them. A set of  $n$ -gram (term) lists in the fashion depicted in Table 2 has been manually compiled. Presence of the listed terms is then checked in each sentence and if found, each occurrence is replaced by its representative. Terms are always compared by their lemmas. The lists have been compiled by applying the following:

1. For each entity and attribute independently, only those sentences from the train dataset that contain the entity or attribute were selected. Then all unigrams from the sentences were sorted by number of occurrences. The most frequent words were manually checked, one by one, and the ones closely related to a particular entity or attribute were added to the respective lists.

<sup>1</sup>[https://github.com/JohnLangford/vowpal\\_wabbit/wiki](https://github.com/JohnLangford/vowpal_wabbit/wiki)

<sup>2</sup>Homepage: <http://stanfordnlp.github.io/CoreNLP/>

2. In case of the restaurants domain, opinion targets from the train datasets were also extracted. This resulted in much shorter lists of high precision terms. All terms could be therefore individually checked in a reasonable time. Again, terms closely related to an entity or attribute were added to the respective lists. Some  $n$ -grams were split into multiple pieces, e.g. *lava cake dessert* → {*lava cake*, *dessert*}.
3. While performing the preceding two methods, I also noticed that some terms played a certain role in aspect category detection even if they were not associated with just a single entity or attribute but rather a set of them. This, for example, included opinion words (indicating attributes GENERAL and QUALITY) and words describing problems (e.g. *fail*, *problematic*, *blue screen* – indicating attributes OPERATION\_PERFORMANCE, QUALITY and possibly some other).

The following methods for extending the lists were also used but they are not applied in the constrained mode:

4. For some specific words (e.g. adjectives expressing food taste), an online dictionary<sup>3</sup> has been used to search for their synonyms and the term lists have been manually appended with suitable words.
5. Several lists of words publicly available on the Internet have also been included:
  - Food: <http://eatingatoz.com/food-list/> and <https://www.atkins.com/how-it-works/atkins-20/phase-1/low-carb-foods>; both lists have been manually checked and some misleading items removed (mostly words related to drinks)
  - Drinks: [http://cocktails.lovetoknow.com/List\\_of\\_Popular\\_Cocktails](http://cocktails.lovetoknow.com/List_of_Popular_Cocktails) and others compiled manually
  - Laptop manufacturers: [https://en.wikipedia.org/wiki/List\\_of\\_laptop\\_brands\\_and\\_manufacturers#Major\\_brands](https://en.wikipedia.org/wiki/List_of_laptop_brands_and_manufacturers#Major_brands)

### 2.2.3 Other pre-processing steps

The system also tries to improve its accuracy by replacing all numbers by the word *number*. Numbers preceded by a currency symbol (\$, ₩, £) are replaced with the word *price* (which then indicates the PRICES attribute).

Words containing both alpha and numeric characters are replaced with the word *model* as it was observed that in most cases, such words represent particular model names (e.g. *i7*, *G73JH-x3*, *d620*). This seemed to be helpful notably in the laptops domain.

The system removes all words shorter than two characters. It is important to note that this step comes after removing all non-alphanumeric characters. This means words like *w/* are eventually removed.

The system also neutralizes consecutive letters which effectively replaces words like *waay* or *waaaaay* by the word *way*.

### 2.3 Prediction post-processing

The presence of previously detected opinion words indicates the QUALITY and GENERAL attributes. The corresponding aspect categories are correctly

| Domain                             | Rest | Lapt |
|------------------------------------|------|------|
| Basic text pre-processing          | 63.9 | 49.6 |
| Bigrams                            | 65.3 | 50.1 |
| Minimal word length                | 65.7 | 50.7 |
| Lemmatization                      | 65.8 | 50.7 |
| Consecutive letters neutralization | 65.8 |      |
| Prices recognition                 | 66.1 | 50.9 |
| Numbers+models recognition         | 66.2 | 51.0 |
| POS filter                         |      | 52.4 |
| Stop words                         | 66.4 | 52.4 |
| Prediction post-processing         | 68.0 |      |
| Term groups (constrained)          | 71.6 | 53.5 |
| Term groups (unconstrained)        | 72.1 | 53.8 |

**Table 3:** The F-measure in percentage using 4-fold cross validation over the training sets. Each row represents the system’s accuracy when the corresponding technique and all those from previous rows are enabled. The prediction threshold, as well as VW’s learning rate, is always optimized. Missing values represent unused techniques.

predicted by VW only in cases in which the opinion words are directly preceded or followed by words indicating entities (i.e. they make up bigrams). When these words are separated by one or more other words, no aspect category is predicted. For this reason, the system always looks for an entity-related word which is closest to the opinion word and still not farther than four skips. If such word is found, the corresponding aspect category is additionally predicted. The same process is repeated with the PRICES attribute with the difference that when no suitable entity is found, RESTAURANT#PRICES is predicted. The system does no post-processing in the laptops domain.

### 3 Results

All techniques and features described in Section 2 have been tuned separately for each domain using *4-fold cross* validation. Table 3 displays the reached accuracy.

The tuned system has been trained using the official training sets containing 2000 and 2500 sentences in the restaurants and laptops domains respectively. The test sets consisted of 676 sentences in the restaurants domain and 808 sentences in the laptops domain.

The system achieved very good results, especially

| Domain Mode | Restaurants   |               | Laptops       |               |
|-------------|---------------|---------------|---------------|---------------|
|             | C             | U             | C             | U             |
| 1st place   | <b>71.494</b> | 73.031        | 47.891        | 51.937        |
| 2nd place   | 68.701        | 72.886        | <b>47.527</b> | 49.105        |
| 3rd place   | 67.817        | <b>72.396</b> | 46.728        | 49.076        |
| 4th place   | 67.350        | 71.537        | 45.629        | <b>48.396</b> |
| 5th place   | 65.563        | <b>71.494</b> | 43.754        | 47.891        |

**Table 4:** Rankings in ACD (slot 1) of the Subtask 1. The F-score of the submitted systems is represented in percentage. Results of my system are highlighted in bold-faced font. C stands for the constrained and U for the unconstrained mode.

in the restaurants domain where it ranked *third* in the unconstrained mode, falling behind the winner only by 0.635%, and *first* in the constrained mode. Table 4 shows the F-score of the top five systems in each domain and mode. The best accuracy in the unconstrained mode has been reached in both domains by the NLANGP team which has ranked first also in SemEval 2015.

### 4 Conclusion

This paper described my approach to aspect category detection. The presented system has ranked as one of the most accurate in this task. As I have never contributed to the field of aspect-based sentiment analysis (and SA generally) before, I find my results more than satisfactory.

The system has an advantage of its relatively high adaptability to work with previously unseen domains. All techniques except the term groups and the prediction post-processing can be tuned automatically with no additional manual help needed. Multilinguality is limited by the used lemmatizer(s) but since lemmatization offers just a mild increase in accuracy, it is possible to omit it when working with unsupported languages.

The system does not take review context of input sentences into consideration. In my future work I would like to remove this flaw. The term groups described in Section 2.2.2 will be significantly improved by extending them and creating new groups for other important terms.

## Abstract

This paper reports the IIT-TUDA participation in the SemEval 2016 shared Task 5 of Aspect Based Sentiment Analysis (ABSA) for subtask 1. We describe our system incorporating domain dependency graph features, distributional thesaurus and unsupervised lexical induction using an unlabeled external corpus for aspect based sentiment analysis. Overall, we submitted 29 runs, covering 7 languages and 4 different domains. Our system is placed first in sentiment polarity classification for the English laptop domain, Spanish and Turkish restaurant reviews, and opinion target expression for Dutch and French in restaurant domain, and scores in medium ranks for aspect category identification and opinion target extraction.

## 1 Introduction

The advent of web technologies has made an unprecedented opportunity for online users to share and explain their views and opinions. The correlation between the views expressed by the users and the market strategies by the organizations strikes the importance of analyzing such reviews. But, valuable as they are, user-generated review texts are unstructured and very noisy. Major research studies adopted Natural Language Processing (NLP) and text mining techniques to better understand and process various types of information in user-generated reviews. Such efforts have come to be known as

opinion mining, sentiment analysis or review mining (Pang and Lee, 2008).

Aspect level analysis performs a finer-grained sentiment analysis by addressing three sub-problems: extracting aspects from the review text, identifying the entity that is referred to by the aspect, and finally classifying the opinion polarity towards the aspect (Liu, 2012). For example, a review of the “entity” laptop is likely to discuss distinct “aspects” like size, processing unit, and memory, and a single product can trigger a positive “opinion” about one feature, and a negative “opinion” about another.

In an attempt to support the efforts on Aspect Based Sentiment Analysis (ABSA), the SemEval 2016 shared Task 5 ABSA (Pontiki et al., 2016) offers the opportunity to experiment and evaluate on benchmark datasets (reviews) across various domains and languages through three subtasks. Subtask 1 covers the three sub-problems mentioned above, namely: aspect category identification (Slot 1), opinion target expression (OTE) (Slot 2) and sentiment polarity classification (Slot 3). We participated in Slot 1 and Slot 3 for English, Spanish, Dutch, French, Turkish, Russian and Arabic language for all available domains except telecoms. We also conducted experiments for Slot 2 for English, Spanish, Dutch and French. Overall, we submitted 29 runs, covering 7 languages and 4 different domains.

## 2 Method for Aspect Based Sentiment Analysis

In this section, we describe our data preprocessing and feature extraction. We also introduce an unsupervised approach for expanding the coverage of existing lexical resources based on the notion of distributional thesaurus. We use Support Vector Machine (SVM) (Cortes and Vapnik, 1995) as the baseline classifier for aspect category detection and sentiment polarity classification, and Conditional Random Fields (CRF) (Lafferty et al., 2001) for opinion target expression identification.

### 2.1 Preprocessing

We tokenize the data using Stanford tokenizer, normalize all digits to ‘num’ and remove stop words for tf-idf computation. For opinion target expression, we run Stanford CoreNLP<sup>1</sup> suite in order to extract information such as lemma, Part-of-Speech (PoS) and named entity (NE) in English language. For languages other than English, we use the universal parser<sup>2</sup> for tokenization and parsing. Since we deal with the OTE as a sequence labelling problem, it is necessary to identify the boundary of OT properly. We follow the standard BIO notation, where ‘B-ASP’, ‘I-ASP’ and ‘O’ represent the beginning, intermediate and outside tokens of a multi-word OTE respectively. e.g. In, ‘Chow (B-ASP) fun (I-ASP) was (O) very (O) dry (O) . (O)’, ‘Chow Fun’ is the OTE.

### 2.2 Features for Aspect Category Detection

- Domain Dependency Graph: We use the aspects list produced by Domain Dependency Graph (DDG) for each domain by (Kohail, 2015). The idea is to detect topics underlying a mixed-domain dataset, aggregate individual dependency relations between domain-specific content words, weigh them with tf-idf and produce a DDG by selecting the highest-ranked words and their dependency relations. Since the domains are already given, no topic modeling is required. However, only one domain was provided for French and Spanish, we used ex-

| Token    | DT Expansion                            |
|----------|---|
| drinks   | beers, wines, coffee, liquids, beverage |
| price    | prices, pricing, cash, cost, pennies    |
| fresh    | fresher, new, refreshing, clean, frozen |
| laptop   | pc, computer, notebook, tablet, imac    |
| toshiba  | samsung, sony, acer, asus, dell         |
| touchpad | mouse, trackball, joystick, trackpad    |

**Table 1:** Example of DT expansions for frequent aspects.

ternal reviews dataset to compute tf-idf. We use movies reviews<sup>3</sup> for Spanish; and books, music and DVD reviews<sup>4</sup> for French. The resulting graphs were filtered and only ‘amod’ (adjective modifying a noun) and ‘nsubj’ (nominal subjects of predicates) relations were selected. For each extracted aspect from the opinion-aspect pairs, we determine the existence or absence of this aspect using a binary feature.

- Distributional Thesaurus: A Distributional Thesaurus (DT) is an automatically computed lexical resource that ranks words according to the semantic similarity. We employ an open source implementation of DT computation as described in (Biemann and Riedl, 2013). For every top five significant words based on tf-idf score in each aspect category (for example: ‘overpriced’, ‘\$’, ‘pricey’, ‘cheap’, ‘expensive’ are the most significant terms in ‘food#price’ category), we find ten most similar words according to DT. The presence or absence of these words in the review is used as a feature for aspect category identification. Examples from the distributional thesaurus are presented in Table 1.
- Tf-Idf Score: Each aspect category has some discriminative aspect terms. We extract a maximum of top five distinguishing words in each category based on tf-idf score. Presence or absence of each token in the review denotes the feature.
- Bag of Words: This feature denotes the number of occurrences of each word in the review.

## 2.3 Features for Opinion Target Expression

- Word and Local Context: We use the current token, its lowercase form and the context tokens in a window of [-5..5] as features.
- Part-of-Speech (PoS) Information: We use PoS information of the current, preceding two and following two tokens as the features.
- Head Word and its PoS: We use the head word of the noun phrase and PoS information of the head word.
- Prefix and Suffix: We use prefix and suffix of length up to four characters.
- Frequent Aspect Term: We build a list of frequently occurring OTEs from the training set. An OTE is considered to be frequent if it appears at least four times in the training corpus. We define a binary feature for the presence or absence of extracted OTEs.
- Dependency Relations: In English language, features are defined in line with (Toh and Wang, 2014). For other languages, feature is defined by considering whether the current token is present in dependency relations ‘nsubj’, ‘dep’, ‘amod’, ‘nmod’ and ‘dobj’ or not.
- Character N-grams: We use all substrings up to length 5 of the current token as features.
- Orthographic feature: This feature checks whether the current token starts with the capitalized letter or not.
- DT features: We use the top 5 DT expansions of current token as the features.
- Expansion Score: OTEs have opinion around them. Opinions are regularly lexicalized with words found in sentiment lexicons. We calculate sentiment score based on SentiWordNet<sup>5</sup> (Esuli and Sebastiani, 2006) in English language. For Non-English language, we use our induced lexicons. We calculate sentiment score by considering the window size of 10 (preceding 5 and following 5 tokens of the target one).

---

<sup>5</sup><http://sentiwordnet.isti.cnr.it/>

We additionally extract the following features only for English language.

- Chunk information: To identify the boundaries of multi-word OTEs, we use chunk information of the current token as the features.
- Lemma: Lemmatization trims the inflectional forms and derivationally related forms of a token to a common base form.
- WordNet: We use top 4 noun synsets of current token from WordNet as the features.
- Named entity information: We extract named entity information of the current token with Stanford CoreNLP tool, and use the NER-sequence labels in BIO-scheme as features.

## 2.4 Features for Sentiment Polarity Classification

- Lexical Acquisition: We use lexical expansion for inducing sentiment words based on distributional hypothesis. We observe that for rare words, unseen instances and limited coverage of available lexicons, the distributional expansion can provide a useful backoff technique, also cf. (Govind et al., 2014).

For all languages, we construct a polarity lexicon using an external corpus and seed sentiment lexicon. For seed lexicons, we use English (Salameh et al., 2015) and Arabic (Salameh et al., 2015) versions of Bing Liu’s lexicon (Hu and Liu, 2004) for English and Arabic respectively, VU sentiment lexicon<sup>6</sup> for French, Dutch and Spanish, a lexicon by (Panchenko, 2014) for Russian, and Senti-TurkNet (Dehkharghani et al., 2015) and NRC Emotion for Turkish<sup>7</sup>. For inducing a lexicon, we obtain the top 100 DT expansion of each word in the seed lexicon. Next we accept candidate terms that a) occur in the expansions of at least 10 seed terms, b) have a corpus frequency

<sup>7</sup><http://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm>

| Language | Seed Lexicon |          |         | Induced Lexicon | Common Entries |
|----------|--------------|----------|---------|-----------------|----------------|
|          | Positive     | Negative | Neutral |                 |                |
| English  | 2005         | 4789     | -       | 12953           | 4120           |
| Dutch    | 3314         | 5923     | -       | 8496            | 2992           |
| French   | 9338         | 10339    | 5993    | 18308           | 7636           |
| Spanish  | 2175         | 1737     | 7869    | 12480           | 4306           |
| Russian  | 3217         | 8849     | -       | 7697            | 2945           |
| Turkish  | 1900         | 2515     | 1382    | 6547            | 1838           |
| Arabic   | 1916         | 4467     | -       | 9077            | 1447           |

**Table 2:** Expansion statistics for induced lexicons. Common entries denote the number of words which are present both in the seed lexicon and the induced lexicon.

of more than 50 in the background corpus (English<sup>8</sup>, French<sup>9</sup>, Spanish<sup>10</sup>, Dutch<sup>11</sup>, Russian<sup>12</sup>, Arabic<sup>13</sup>). Finally, we compute the normalized positive, negative and neutral score for each word similar to (Kumar et al., 2015), and inspired by (Hatzivassiloglou and McKeown, 1997). The core assumption is that words tend to be semantically more similar to words of same sentiment. Hence, words appearing more in the expansions of positive (negative/neutral) words get assigned a higher positive (negative/neutral) sentiment score. Here, in difference to (Kumar et al., 2015), we compute normalized positive, negative and neutral scores rather than assigning one of the polarity class to the words. It should be noted that the volume of induced lexicon depends on two factors: (i) number of words in the seed lexicon that have expansions and (ii) pruning threshold for obtaining the induced lexicon. The unavailability of expansions for all words in the seed lexicon and higher threshold on conditions for accepting candidate terms reduces the volume of induced lexicon. Expansion statistics for the induced lexicons are provided in Table 2.

We compute the sum of positive, negative and

<sup>12</sup>[lib.ruc.ecebooks](http://lib.ruc.ecebooks)

<sup>13</sup><http://corpora2.informatik.uni-leipzig.de>

neutral scores of tokens using induced lexicon for that language as features. In addition, scores as given in the seed lexicon are also used as features. For English, we also computed these features from different lexicons: AFINN (Nielsen, 2011), NRC Hashtag, Sentiment 140 (Zhu et al., 2014), NRC Emotion (Mohammad and Turney, 2013) and Bing Liu (Hu and Liu, 2004).

- Word N-gram: All unigrams and bigrams tokens are extracted from the training set are used as a binary feature, where 1 and 0 indicates the presence and absence of n-grams in the review.
- Entity-Attribute Pair: We use E#A pair as a binary feature for sentiment classification.

### 3 Datasets, Experimental Results and Discussions

For feature selection and hyperparameter tuning, we perform five-fold cross-validation on the training set. For Slot 1 and Slot 3, we use supervised classification using Support Vector Machine (SVM)<sup>14</sup>. Based on cross-validation results, we set the probability threshold of 0.185, 0.13 and 0.145 for restaurants, laptops and phones, respectively, for predicting aspect categories in the review. All E#A pairs having predicted probability greater than the threshold are enlisted as aspect categories. For Slot 2, we use CRFSuite<sup>15</sup> with default parameters. CRF-

| French   | Restaurants | 57.8 (U, 2), 57.0 (C, 3) / 6    | 66.6 (U, 1) / 3     | 72.2 (U, 5) / 6       |
| Russian  | Restaurants | 62.6 (C, 3), 58.1 (C, 4) / 7    | -                   | 73.6 (U, 3) / 6       |
| Turkish  | Restaurants | 56.6 (U, 3), 55.7 (C, 4) / 5    | -                   | 84.2 (U, 1) / 3       |
| Dutch    | Phones      | 45.4 (U, 2), 45.0 (C, 3) / 4    | -                   | 82.5 (U, 2) / 3       |
| English  | Laptops     | 43.9 (U, 12), 42.6 (C, 14) / 22 | -                   | 82.7 (U, 1) / 22      |
| Arabic   | Hotels      | -                               | -                   | 81.7 (U, 2) / 3       |

**Table 3:** Evaluation result for Subtask 1. Mode of submission (C-constrained, U-unconstrained) and rank is given in the parenthesis.

F1 and Acc. denote F1-Score and Accuracy. #Entries is the total number of submissions for respective slot and domains.

| Dataset             | All Features | All w/o E#A Pair | All w/o Induced Lexicon |
|---------------------|--------------|------------------|-------------------------|
| English Restaurants | 86.729       | 86.224           | 86.390                  |
| English Laptops     | 82.772       | 82.310           | 82.457                  |
| Dutch Restaurants   | 76.998       | 76.250           | 74.228                  |
| Dutch Phones        | 82.576       | 82.058           | 80.896                  |
| Russian Restaurants | 73.615       | 73.158           | 70.657                  |
| French Restaurants  | 72.222       | 71.898           | 70.154                  |
| Spanish Restaurants | 83.582       | 82.920           | 79.589                  |
| Turkish Restaurants | 84.277       | 83.650           | 80.788                  |
| Arabic Hotels       | 81.720       | 80.650           | 78.680                  |

**Table 4:** Feature Ablation Experiment for Sentiment Polarity Classification

Suite is a fast implementation of Conditional Random Field (CRFs) for segmenting and labelling sequential data.

Teams were allowed to submit their systems in two modes: constrained and unconstrained modes. In constrained mode, the participants are allowed to use only the resources and dataset provided by the organizers whereas in unconstrained submission, participants can use any external resource. For Slot 2 and Slot 3, we only sent unconstrained submission, while for Slot 1 we sent constrained as well as unconstrained submissions except for Russian restaurants.

Our system achieves the best results in sentiment polarity classification for reviews about English laptops, Spanish restaurants and Turkish restaurants. We score second for English restaurants. We also produce the maximum F1-score value for opinion target expression for French and Dutch restaurants. Our evaluation results across all domains and lan-

guages are given in Table 3.

The results show that our system performs comparably well for sentiment polarity classification and opinion target expression. A feature ablation experiment given in Table 4 shows the effectiveness of induced lexicon for Slot 3 task. We get a significant improvement on adding information from the induced lexicons in each language. This holds especially for languages other than English, where existing sentiment lexicons are less comprehensive. We also note that entity-attribute pairs also help in resolving conflicting sentiments (for example: *cheap food* (*positive*) to *cheap service* (*negative*)).

We score in medium ranks for Slot 1 task. Distributional thesaurus based expansion for discriminative terms and aspects obtained through domain dependency graph results in marginal increments. This could be attributed to conflict in very fine grained aspect categories (for example: Restaurant#Prices, Food#Prices, Drink#Prices)

| Language | F1-measure |
|----------|------------|
| English  | 68.45      |
| Dutch    | 64.37      |
| Spanish  | 69.73      |
| French   | 69.64      |

**Table 5:** Result on Slot 2 task after modification

which may not have been captured explicitly by the external features. For the Slot 2 task, we have found some inconsistencies in our extraction pipeline, unfortunately were not able to correct them in time for the submission.

After the evaluation period, we revised our feature representation to ensure that it matches the correct input format for CRF. We also added two new features including unsupervised PoS tags (Biemann, 2009) as the feature for all the languages and SentiWordNet score for English language. For the current token, we use PoS tag, distributional thesaurus, lexical expansion score, unsupervised PoS tag, SentiWordNet score of context tokens [-2, -1, 0, 1, 2], prefix (upto 3-character), suffix (upto 3-character) and chunk information of context tokens [-1, 0, 1]. The updated results of after modification are shown in Table 5. If we had incorporated these changes earlier, we would have scored third for English and first for the other three languages.

## 4 Conclusions and Future Work

In this paper, we report our work on the task of Aspect Based Sentiment Analysis, which covers three slots: aspect identification, opinion target extraction and sentiment polarity classification. By leveraging a distributional thesaurus, we expand the existing domain specific aspect list and sentiment lexicons for different languages to reach a higher coverage on sentiment words. Our system was ranked first in five out of 29 submitted runs. While performance is satisfactory for Slot 3 and Slot 2 (after correction), our setup compares unfavorably to others for Slot 1. We will continually improve our system in future work.

## Abstract

This paper describes in detail the approach carried out by the GTI research group for SemEval 2016 Task 5: Aspect-Based Sentiment Analysis, for the different subtasks proposed, as well as languages and dataset contexts. In particular, we developed a system for category detection based on SVM. Then for the opinion target detection task we developed a system based on CRFs. Both are built for restaurants domain in English and Spanish languages. Finally for aspect-based sentiment analysis we carried out an unsupervised approach based on lexicons and syntactic dependencies, in English language for laptops and restaurants domains.

## 1 Introduction

In the last years, with the growth of Internet, people use it as a means of expressing their opinions and experiences about several subjects. That is the reason why there is a great amount of user generated information available online, through many different platforms, such as blogs, social networks, etc. This information became very valuable for companies, politicians, etc., who are interested in what users say about them or their products. Due to this, Sentiment Analysis (SA) techniques have attracted the interest of researchers, trying to process all this amount of information by means of usually supervised methods based on classifiers.

Most of these researches focus on extracting the sentiment of a whole review or text (Liu, 2012). This is enough for many applications and purposes. However, sometimes there is a need for analysing

the text in a deeper way, at entity or aspect level. For example, a review in the restaurants domain can include different opinions about different aspects, such as the service or the food quality, so it is interesting to distinguish the different opinions for each of these aspects. This is the reason why some studies emerged about the so-called aspect-based sentiment analysis (Marcheggiani et al., 2014; Lu et al., 2011).

Hence this is the subject of the task 5 of the SemEval 2016 (Pontiki et al., 2016), divided into different subtasks. Groups are asked to detect aspect categories in a review or sentence, which are predefined for each domain and formed by an entity and an attribute. Then, there is a subtask which consists of detecting the opinion target expression, which are related to the categories found. Finally, aspect-based sentiment analysis is required for one of the subtasks, associating a polarity, which can be positive, negative or neutral, to each of the categories found in the sentence or review. Datasets in different languages and domains are available for proving the approaches.

The remainder of this paper is structured as follows. In Section 2 we make a description of the system developed for all the subtasks. Section 3 contains the results of all the different subtasks, as well as detailed scores for each slot. Finally, in section 4 we summarize the main aspects of our system and extract some final conclusions.

## 2 System Overview

In this section we make a brief description of the system submitted for the different subtasks. We presented our submission for English restaurants

dataset for subtask 1, slots 1, 2 and 3, and subtask 2, slots 1 and 3. For English laptops dataset we sent a submission for subtasks 1 and 2 only in slot 3. Then, the system was also developed for Spanish language and restaurants dataset in subtasks 1, slots 1 and 2 and subtask 2, slot 1. In the next subsections we describe the different stages carried out for obtaining all the different results.

## 2.1 Preprocessing

As a first step for all the subtasks, each preprocessed social media review must first be broken into tokens, in order to derive the syntactic context. Part-of-speech (POS) tagging and lemmatization are performed to ensure that all the inflected forms of a word are covered. In the case of English, Stanford Tagger is applied due to its better results, however it does not provide lemmatization. That is why using the resulting form and tag, lemma is extracted by means of Freeling Tagger (Atserias et al., 2006; Padró and Stanilovsky, 2012). On the other hand, for Spanish language only Freeling Tagger is used. Freeling is a library that provides multiple languages among which are English and Spanish. Food and drinks recognition is also performed, based on dictionaries<sup>1</sup>, in order to identify words referring to those topics for the subsequent processing of the sentences.

POS tagging allows the identification of lexical items that can contribute to the correct recognition of targets in a message. These items are namely adjectives, adverbs, verbs and nouns. The lemmatized and POS-annotated messages are fed to a parser that transforms the output of the tagger into a full parse tree. Finally, the tree is converted to dependencies, and the functions are annotated. The entire process is performed by means of Freeling Parser (Padró and Stanilovsky, 2012).

## 2.2 Subtask 1: Sentence-level Aspect-Based Sentiment Analysis (ABSA)

This subtask contains different slots, having participated in three of them, which are slot 1, slot 2 and slot 3. The system for Spanish and English language is exactly the same for both slots 1 and 2.

---

<sup>1</sup>Taken from the lists available at <https://es.speaklanguages.com/inglés/vocabulario/comidas>

### 2.2.1 Slot 1 Aspect category detection

The aim of this task is to assign to each sentence a category, which is a tuple (entity, attribute), from a given set of 12 different predefined categories. To do this, we used a linear SVM classifier combined with word lists. These word lists are created from the training file provided by the organization, which was composed of 2000 sentences, grouped in 350 reviews. Different datasets were provided for several languages and topics. Our system was developed for restaurants dataset, both in English and Spanish.

The library libsvm (Chang and Lin, 2011) was used to implement the SVM classifier, using the following features for each sentence:

- Words: those words appearing in the sentence, which are nouns, verbs or adjectives are extracted.
- Lemmas: lemmas from nouns, verbs and adjectives are selected.
- POS tags: part of speech from nouns, verbs and adjectives in the sentence.
- Bigrams: all the bigrams found in the sentence.

We developed 12 different binary classifiers, one for each possible category. If the output of one classifier for a particular sentence is “1”, then we add the related category to the sentence. If more than one category is found for the same sentence, we add all of them to the list of categories. After this, the outputs are improved by means of our word lists, as we can see in Algorithm 1, executed for each sentence. The word lists were created automatically from the training file, extracting all the nouns and adjectives appearing in sentences from the same category, and manually filtered later in order to remove noisy items. Six different lists are composed, containing terms related to: ambience, service, prices, quality, style options and location.

The inputs defined for the following algorithm are the list of categories obtained from SVM for each sentence (CList(s)) and the six word lists created previously. The output is the new list per sentence, containing the old categories from SVM and the new ones added.

**Algorithm 1:** Combining SVM outputs with word lists for a sentence  $s$ .

         {DRINKS#STYLEOPTIONS}
33     else
34       newList( $s$ ) = newList( $s$ )  $\cup$ 
         {FOOD#STYLEOPTIONS}
35     end
36   end
37 end
```

---

## 2.2.2 Slot 2 Opinion target expression

For this slot, teams were asked to extract the exact expressions or words in the sentence, in which an opinion is expressed. The implementation for this slot is made by means of CRFs, using CRF++ tool (Kudo, 2005) and the training file provided for building the model. A training file is needed to build as input for the CRF, whose structure is as follows. In the first column, all the words for every sentence are written, then in the second column, the corresponding lemma. The third column represents the tag and the last one represents if the word is an aspect or not or if it is included in a multiword aspect. Then for creating the model we take into account all these features, as well as all the possible bigrams in each sentence. In the output, if no target is found, no opinion is returned for that sentence.

## 2.2.3 Slot 3 Sentiment polarity

This slot is implemented only for English language, both restaurants and laptops datasets. Our system is fully unsupervised, this can explain the low results obtained for this slot. An adjustment was made to the system already implemented for sentiment analysis in the whole sentence, which was presented in Semeval 2015, task 10: sentiment analysis in Twitter (Fernández-Gavilanes et al., 2015), which was also unsupervised. For this dataset, a new polarity lexicon was generated automatically from the training dataset, applying a polarity rank algorithm, as explained in the mentioned article. Then, it was merged with SOCAL (Taboada et al., 2011) and AFINN (Nielsen, 2011) lexicons, which are general context ones, by applying an average for those words which appeared in more than one of them.

Our system for the restaurant dataset implements the following syntactic rules:

- If there is no opinion or only one target expression in the sentence, the system automatically takes the polarity of the whole sentence and assign it to all the categories which appear in this sentence.
- If there is only one different target expression but appearing more than once, we check if there is an adversative clause in the sentence built with “but” particle. If not, we also take the

polarity of the whole sentence for all the opinions. If the previous condition is fulfilled, we will take the polarity of the first clause of the sentence, which is the piece of sentence placed before the “but” and then apply a polarity linear system, which consists of summing up all the polarities found in the dictionary created. For the next opinions which have the same target, we will follow the same procedure but with the piece of sentence after the “but”. For this linear approach, we take negations in account only for adjectives, flipping the polarity of the adjectives which come immediately after a negation particle, as “no” or “not”.

- When there are several different opinion targets, we split the sentence to detect the scope of each target and apply the same linear polarity algorithm explained in the previous point. To detect the scope of the target, we take the words which appear before and after the target, splitting by punctuation marks (“;”, “,”, “：“, “?”, “!”, “-”).

For the laptops dataset, since there are no opinion target expressions, we take the polarity of the whole sentence to assign the polarity of each category.

### 2.3 Subtask 2: Text-level ABSA

Subtask 2 is similar to subtask 1, but instead of implementing aspect detection at sentence-level, it is performed at text-level. Participants are asked to implement slots 1 and 3 for this subtask. We participate in slot 1 for Spanish and English language, following the same procedure for both. Slot 3 is just implemented for English language for restaurants and laptops datasets.

#### 2.3.1 Slot 1 Aspect category detection

Once we performed aspect category detection at sentence-level, we use this output as input for text-level detection. All the categories found are grouped at sentence-level and added all of them at review-level. Besides this, if RESTAURANT#GENERAL is not explicitly assigned to any sentence of the review, we add it anyway.

#### 2.3.2 Slot 3 Sentiment polarity

Similarly to slot 1, we use the output from subtask 1 slot 3 as input for this slot. All the polarities found are again grouped for all the sentences contained in the review and added them to text-level. If there are different polarities for the same category, some rules are applied: if polarities are negative and neutral, negative is finally assigned; if there are positive and neutral opinions, positive polarity is assigned; if there are positive and negative opinions for the same category, the tag “conflict” is assigned to that category at review-level.

Moreover, as RESTAURANT#GENERAL is compulsory for every review, if no sentence has this category assigned, we take into account all the polarities of the other categories found and then assign the polarity for this category. Again, if there are different polarities containing positive and negative, “conflict” tag is assigned. The same process is followed for laptops dataset, with the LAPTOPS#GENERAL category.

## 3 Experimental Results

In this section, we describe the experiments carried out for the different subtasks and slots and the datasets provided by the organization. These datasets are composed of several reviews, splitted in sentences, for restaurants and laptops topics. The performance of slots 1 and 2, for both subtasks, are measured by means of the F-score, while slot 3 is evaluated by means of the accuracy.

Table 1 represents the precision, recall and F-score obtained for restaurants datasets and all the slots submitted. For English language, an unconstrained system was presented, while for Spanish language both constrained and unconstrained systems were submitted. The constrained approaches do not need any external resources, but only the training files provided, while in the unconstrained ones, food and drinks lexicon was used in the pre-processing step for identifying different foods and drinks.

It can be seen that there is not much difference between constrained and unconstrained systems for Spanish language, so we can assume that the recognition of different names of foods or drinks does not increase the knowledge of the classifiers, perform-

|        |             | Prec. | Rec.  | F     |
|--------|-------------|-------|-------|-------|

|       | N      | 62.75 | 38.1  | 47.41 |       |
|       | NEU    | 18.18 | 8.7   | 11.76 |       |
|       | CONFL. | 7.61  | 63.64 | 13.59 |       |

**Table 2:** Detailed scores for slot 3, restaurants dataset in English language.

|       |        | Prec. | Rec.  | F     | Acc.  |
|-------|--------|-------|-------|-------|-------|
| Subt1 | P      | 68.78 | 87.94 | 77.19 | 67.29 |
|       | N      | 63.39 | 42.34 | 50.77 |       |
|       | NEU    | 0     | 0     | 0     |       |
| Subt2 | P      | 74.64 | 76.63 | 75.62 | 58.35 |
|       | N      | 60.81 | 27.78 | 38.14 |       |
|       | NEU    | 12.12 | 12.9  | 12.5  |       |
|       | CONFL. | 10.99 | 71.43 | 19.05 |       |

**Table 3:** Detailed scores for slot 3, laptops dataset in English language.

As it can be seen in Table 2 and Table 3, the results obtained for the sentiment slot are not quite competitive with the other teams. This can be due to the fact that our system is fully unsupervised, while the others are usually supervised systems, based on training. Moreover, we performed a simple adaptation from our original system, made for sentiment analysis in Twitter, presented to SemEval 2015, so there is still a lot of improvement on this field.

## 4 Conclusions

This paper describes the participation of the GTI group, AtlantTIC Research Center, University of Vigo, in the SemEval 2016, Task 5: Aspect-Based Sentiment Analysis. We developed a supervised system based on SVM classifiers for category detection, and CRFs for opinion target detection. Then, for the aspect-based sentiment analysis we submitted a fully unsupervised system, based on syntactic dependencies and context-based polarity lexicons.

| Test sets |          |          | Position    |
|-----------|----------|----------|-------------|
| EN        | REST     | Subtask1 | Slot1 10/20 |
|           |          | Slot2    | 4/15        |
|           |          | Slot3    | 19/20       |
|           | Subtask2 | Slot1    | 1/3         |
|           |          | Slot3    | 4/4         |
|           | LAPT     | Subtask1 | Slot3 14/15 |
|           |          | Subtask2 | Slot3 4/4   |
| SP        | REST     | Subtask1 | Slot1 1/6   |
|           |          | Slot2    | 1/3         |
|           |          | Subtask2 | Slot1 1/2   |

**Table 4:** Position of our approach in the different datasets and subtasks submitted, according to the results published by the organisation.

As we can see in Table 4, competitive results were obtained for aspect and category detection, being in first position for Spanish language, both in subtask 1 and subtask 2. Moreover, in subtask 2, which is aspect detection at review level, we also achieved the first position for English language in restaurants datasets. However, our system did not perform as well as expected in slot 3, maybe due to the fact of the lack of supervision for our model. It results not competitive against other supervised approaches, although its main advantage is that there is no need of training sets, which is time and resource consuming in order to manually tag them.

## Abstract

This paper describes our submissions to the Aspect Based Sentiment Analysis task of SemEval-2016. For Aspect Category Detection (Subtask1/Slot1), we used multiple ensembles, based on Support Vector Machine classifiers. For Opinion Target Expression extraction (Subtask1/Slot2), we used a sequence labeling approach with Conditional Random Fields. For Polarity Detection (Subtask1/Slot3), we used an ensemble of two supervised classifiers, one based on hand crafted features and one based on word embeddings. Our systems were ranked in the top 6 positions in all the tasks we participated. The source code of our systems is publicly available.

## 1 Introduction

The amount of user-generated content on the web has grown rapidly in recent years, leading to increased interest in sentiment analysis and, more generally, opinion mining. The task of Aspect Based Sentiment Analysis of SemEval-2014 (SE-ABSA14) and SemEval-2015 (SE-ABSA15) was concerned with identifying the aspects of given target entities and extracting the sentiment expressed towards each aspect (Pontiki et al., 2014; Pontiki et al., 2015). The task of Aspect Based Sentiment Analysis of SemEval-2016 (SE-ABSA16) is a continuation of those tasks (Pontiki et al., 2016). We participated in Aspect Category Detection (ACD, Subtask1/Slot1), Opinion Target Expression (OTE, Subtask1/Slot2), and Polarity Detection (PD, Subtask1/Slot3).

In ACD, we participated in the English language, for both Laptops and Restaurants, submitting both

constrained and unconstrained systems. Our constrained system used only the provided training data for the corresponding domain. Features were extracted from lexicons created from the training data. One Support Vector Machine (SVM) classifier (Vapnik and Vapnik, 1998) was trained for each Entity and Attribute category (called E and A respectively). Our unconstrained system used word embeddings as additional resources (Mikolov et al., 2013). For each category (E or A), we used an ensemble of two systems: our constrained system and one new system, which was based on word embeddings.

In OTE, we participated with both a constrained and an unconstrained system.<sup>1</sup> The task is to identify aspects of given target entities. We addressed the problem as a sequential labeling task (Toh and Wang, 2014), assigning one label to each word in a sentence, indicating whether the word was an aspect term or not. In this task, we used Conditional Random Fields (Lafferty et al., 2001). Similarly to ACD, our unconstrained system differed in that it also used word embeddings as features.

In PD, we participated only with an unconstrained system, in both domains, in the English language. We used an ensemble of two classifiers. The first classifier used hand crafted features and sentiment lexicons with scores. The second classifier was based on IDF-weighted centroids of the word embeddings of each sentence (Kosmopoulos et al., 2015).

The remainder of this paper is structured as follows. In Section 2, we describe our systems in detail, including data preprocessing and feature de-

<sup>1</sup>Only the restaurants domain was available in OTE.

scriptions. In Sections 3 and 4, we present our official results and experiments, respectively. Finally, Section 5 summarizes our work and proposes future directions.

## 2 Systems

All our submissions used supervised learning. In Restaurants, the training data were 350 reviews (2,000 sentences), annotated with 2,499 aspects and their polarities. Each aspect consists of one Entity (E) and one Attribute of E (A), thus, forming an E#A pair. The sentiment polarity of any aspect may be positive, negative or neutral. Included, were also annotations for linguistic expressions, called Opinion Target Expressions (OTE), indicating the origin of each E. For example, in “The food was well prepared and the service impeccable.” there were two annotations:

- 1st OTE: “food” offsets: 4 to 8
  - category: FOOD#QUALITY
  - polarity: positive
- 2nd OTE: “service” offsets: 35 to 42
  - category: SERVICE#GENERAL
  - polarity: positive

In Laptops, the training data were 450 reviews (2,500 sentences), annotated with 2,923 {E#A, Polarity} labels. In this domain, no OTE annotations were included.

As a preprocessing step, we excluded sentences with no opinion tuples and sentences labeled as “Out of Scope”.<sup>2</sup> All the features and hyper-parameter values used are described in a publicly available report, along with the source code of our systems.<sup>3</sup>

### 2.1 Aspect Category Detection

In Aspect Category Detection (ACD), each aspect E#A (e.g., FOOD#PRICE) in a sentence should be discovered. The possible E and A labels were predefined; thus, we considered this to be a classification task.

---

<sup>2</sup>Sentences including opinions that can not be described by the SE-ABSA16 annotation schema, are “Out of Scope”.

<sup>3</sup><https://github.com/nlpaeub/aueb-absa>

### Constrained ACD system

One Support Vector Machine (SVM) classifier was trained for each predefined E and A, based on lexicons created from the training data.<sup>4</sup> <sup>5</sup> The lexicons assigned scores to unigrams (stemmed and unstemmed) and bigrams (stemmed, unstemmed or using only POS tag bigrams). For each unigram or bigram, we computed its Precision, Recall and F1 over the training data, following the work of Karampatsis et al. (2014). We used the average, median, maximum, and minimum values for each score (Precision, Recall, F1) and for each lexicon (stemmed unigrams, unstemmed unigrams, stemmed, unstemmed, POS tag bigrams), thus, yielding 12 features per lexicon and 60 features overall.

One Support Vector Machine (SVM) classifier was trained for each E and A label, yielding 11 classifiers for Restaurants and 31 for Laptops. Given a new text, the confidence scores of all the classifiers were examined and the Es and As of the classifiers whose confidence exceeded a threshold were used to form the E#A aspects.<sup>6</sup> All the possible E#A combinations are formed, provided that they appeared at least once in the training data. Thus, assuming that the classifiers of  $|E|$  entities and  $|A|$  attributes exceeded the threshold, we form at most  $|E| \cdot |A|$  aspects.

Following the work of Hsu et al. (2010), we used a 5-fold cross validation on the training data for tuning and we performed a loose grid search, followed by a fine grid search. During the loose grid search, various kernels were examined (i.e., Linear, Sigmoid, Polynomial and RBF) and hyper-parameter values were searched with a big step and in a big range of values. During the fine grid search, the best kernel of the loose grid search was used and hyper-parameter values were searched with a smaller step in a much smaller range of values.

### Unconstrained ACD system

Our unconstrained system was based on multiple ensembles, one for each E and A combination encountered in our training data. Each ensemble

---

<sup>4</sup>Lexicons were created only for tokens that appeared more than 2 times in the training dataset, for each E and A category.

<sup>5</sup><http://scikit-learn.org/stable/>

<sup>6</sup>The threshold was manually fixed to 0.4.

returned the linear combination of the confidence scores of two systems.<sup>7</sup> The first system in each ensemble was the corresponding constrained system. The second system in each ensemble was a system based on word embeddings (Mikolov et al., 2013).

We used the Amazon product review data to produce word embeddings and Inverse Document Frequency (*IDF*) scores (McAuley et al., 2015).<sup>8</sup> Word embeddings were produced, with 200 dimensions and the skip-gram model, using Gensim.<sup>9</sup> Then, following the work of Kosmopoulos et al. (2015), for each sentence  $s_i$  in our data, we computed its centroid  $c(s_i)$  as follows:

$$c(s_i) = \frac{\sum_{j=1}^{|V|} e_j \cdot TF(w_j, s_i) \cdot IDF(w_j)}{\sum_{i=1}^{|V|} TF(w_j, s_i) \cdot IDF(w_i)}$$

where  $|V|$  is the size of the vocabulary,  $e_j$  is the embedding of word  $w_j$ ,  $TF(w_j, s_i)$  is the Boolean term frequency of  $w_j$  in sentence  $s_i$ , and  $IDF(w_j)$  is the *IDF* score of  $w_j$ . Preliminary experiments in both domains, with *IDF* scores and term frequency (Boolean or not) scores, showed that the use of Boolean term frequency scores along with *IDF* scores was better than any other combination.

We normalized each centroid using L2 normalization and we computed the cosine similarity between the centroid of the sentence and the word embedding of the label of each possible E or A. The final feature vector of each unconstrained E or A classifier (2nd classifier in each ensemble) is produced by concatenating all the cosine scores and the normalized centroid. We trained one SVM classifier per E and A, yielding 11 unconstrained classifiers for Restaurants and 31 for Laptops, as already noted. All the unconstrained classifiers were tuned similarly to our constrained classifiers.

In a final step, our unconstrained system returns one score per E and A, which is the linear combination of the confidence scores of the constrained and unconstrained classifiers in the corresponding

<sup>7</sup>The weights of the two confidence scores were set to 0.5, i.e. we used the average of the two scores. Other weights were also examined, but they did not lead to better performance.

<sup>8</sup>We used the files for individual product categories from the Amazon product data corpus, which had duplicate item reviews removed (<http://jmcauley.ucsd.edu/data/amazon/>).

<sup>9</sup><https://radimrehurek.com/gensim/>

ensemble. Similarly to our constrained system, E#A aspects are then returned.

## 2.2 Opinion Target Expression

Opinion Target Expression is addressed as a sequential labeling problem. Each word in a sentence is assigned the label “B” to indicate the start of an aspect term, “I” to indicate the continuation of an aspect term, and “O” if the token is not an aspect term.

Both our constrained and unconstrained systems use Conditional Random Fields (CRF) (Lafferty et al., 2001).<sup>10</sup> However, our unconstrained system extends our constrained one, by incorporating more features. The features used in each system are discussed below.

### Constrained OTE system

The features of our constrained system are the following:

- Morphological (Boolean), about the current token:
  - Capital first letter
  - All letters in capitals
  - Only digits
  - Existence of punctuation mark
  - Other
- Lexicon-based (one-hot)
  - POS tags (both of current token and context)
  - Word affixes (prefixes and suffixes) of the current token
  - Aspect terms

For features based on lexicons, we used the training data to form lists of POS tags, word affixes of various lengths (prefixes and suffixes of length 1, 2 and 3 characters) and aspect terms. Then, we formed a single one-hot vector (i.e., a vector of 0’s and a single 1) per list, indicating which member of the list the token being examined corresponds to. We used 5 vectors for the POS based features (one for the current token and 4 for the context; two on the left and two on the right), 6 vectors for features based on word affixes (prefixes and affixes of one, two and

<sup>10</sup><https://pystruct.github.io/index.html>

three letters) and 1 vector for aspect terms seen in the training data. Finally, we concatenated the vectors and the Boolean features to yield one overall feature vector.

### Unconstrained OTE system

Our unconstrained system extends our constrained system by incorporating the following features:

- Word embedding of the current token
- Word embeddings of the context

For each word, we compute its embedding and incorporate it to our constrained system’s feature vector. Word embeddings were calculated as in Section 2.1; each word corresponds to a 200-dimensional embedding. We also incorporate features for the word’s context. We compute the embeddings of the words in a 5-context window (i.e., two words on the left and two on the right) and concatenate them to a 1000-dimensional vector.

If a word from the context had no embedding, we replaced it by the previous (for left context) or next (for right context) word that had an embedding. Also, in order to cope with missing words at the beginning and the end of a sentence, we introduced four special tokens, for the first two and the last two words of the sentence. The respective tokens were positioned before and after each sentence of the Amazon product reviews corpus, before producing word embeddings.

### 2.3 Polarity Detection

The objective of Polarity Detection (PD) was to detect the correct sentiment label for each aspect E#A in a sentence; possible sentiment labels were positive, negative and neutral (i.e., mildly positive or negative). Sentences could contain multiple aspects; e.g., the sentence “Excellent food, although the interior could use some help.” contains two aspects; “FOOD#QUALITY” and “AMBIENCE#GENERAL”, which should be labeled positive and negative respectively.

We used an Ensemble of two Multi-class Logistic Regression (LR) classifiers, trained with different sets of features. Each classifier yields one confidence sentiment (for each E#A) per sentiment label.

Then, for each sentiment label, our ensemble computes a linear combination of the corresponding two scores of the classifiers and the label with the highest combined score is returned.<sup>11</sup>

We describe below the feature sets of the two LR classifiers, LRI and LRII.

### LR I PD classifier

In LRI, we used 50 hand crafted features, which could be categorized by nature:

- Morphological (Karampatsis et al., 2014)
  - frequency based (number of exclamation and question marks, etc.)
  - Boolean based (exclamation or question mark in the end of the sentence, etc.)
- POS based (number of nouns, adjectives, verbs and adverbs) (Karampatsis et al., 2014)
- E#A based (number of aspects and bags of entities and attributes)
- Sentiment lexicons
  - AFINN<sup>12</sup>
  - Hu & Liu<sup>13</sup>
  - NRC<sup>14</sup>

For features based on sentiment lexicons, besides the already given word scores, we compute new scores, which are relative to our data. Following the work of Karampatsis et al. (2014), we computed Precision and *F1* scores per sentiment label, for each word in the lexicon and for each POS bigram (i.e., two sequential part of speech tags).

To take into consideration negation phenomena, we used the negation lexicon compiled by Zhang et al. (2014). If a negation word precedes a word in a lexicon, we reverse the word’s score sign; i.e., positive becomes negative and vice versa. Also, we make special use of words only in upper case. If a word in upper case exists in a lexicon we multiply

<sup>11</sup>We used the average of the two scores in practice.

<sup>12</sup>[http://www2.imm.dtu.dk/pubdb/views/publication\\_details.php?id=6010](http://www2.imm.dtu.dk/pubdb/views/publication_details.php?id=6010), AFINN-111

<sup>13</sup><http://github.com/woodrad/Twitter-Sentiment-Mining/tree/master>

<sup>14</sup><http://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm>

| Domain          | Precision | Recall | F-measure | Rank   |
|-----------------|-----------|--------|-----------|--------|
| Restaurants (U) | 67.75%    | 75.77% | 71.54%    | 4th/30 |
| Restaurants (C) | 64.22%    | 70.79% | 67.35%    | 4th/12 |
| Laptops (U)     | 45.60%    | 53.19% | 49.10%    | 2nd/22 |
| Laptops (C)     | 40.69%    | 51.94% | 45.63%    | 4th/9  |

**Table 1:** AUEB-ABSA’s evaluation in Aspect Category Detection. The first column shows the domain and the run (C for constrained and U for unconstrained). The last column shows the rank of our system.

| Domain          | Precision | Recall | F-measure | Rank   |
|-----------------|-----------|--------|-----------|--------|
| Restaurants (U) | 71.82%    | 69.12% | 70.44%    | 2nd/19 |
| Restaurants (C) | 64.35%    | 58.99% | 61.55%    | 6th/8  |

**Table 2:** AUEB-ABSA’s evaluation in Opinion Target Expression.

its score, in order to make it more significant.<sup>15</sup> The resulting feature vector is normalized to [0,1] with the Euclidean norm.

### LR II PD classifier

The second PD classifier uses the centroid of the word embeddings of each sentence as features. The centroids are compiled as in Section 2.1, but without the *IDF* scores in the denominator.<sup>16</sup> Words without embeddings or *IDF* scores are ignored when computing the centroids. The same applies to words with *IDF* scores below a given threshold.<sup>17</sup> Word embeddings are normalized with the Euclidean norm.

## 3 Results

Table 1 shows the results of our Aspect Category Detection (ACD) system. In Restaurants, our unconstrained ACD system was ranked 4th among 30 submissions. Our constrained ACD system was also ranked 4th, but amongst 12 submissions. In Laptops, our unconstrained ACD system was ranked 2nd among 22 submissions and our constrained one was ranked 4th among 9 submissions.

Table 2 shows the results of our Opinion Target Expression (OTE) system. Our unconstrained OTE system was ranked 2nd out of 19 submissions, while our constrained OTE system was ranked 6th out of 8 submissions.

<sup>15</sup>Here, we arbitrarily tripled the score

<sup>16</sup>Our experiments have shown that removing the *IDF* from the denominator improves the performance of LRII

<sup>17</sup>The threshold was set to 0.5, which led to best results on the validation data.

| Domain          | Accuracy | Rank   |
|-----------------|----------|--------|
| Restaurants (U) | 83.24%   | 6th/28 |
| Laptops (U)     | 76.90%   | 6th/21 |

**Table 3:** AUEB-ABSA’s evaluation on Polarity Detection.

Table 3 shows the evaluation of our PD system (unconstrained only). We were ranked 6th out of 28 submissions in Restaurants and 6th out of 21 submissions in Laptops.

## 4 Experiments & Discussion

As described in Section 2.1, our unconstrained ACD system used an ensemble of two systems, one based on word embeddings and one based on features calculated only on the training data. Preliminary experiments showed that the ensemble is better than each system alone and better than a single system combining all the features of the two systems.

In the same task, experiments in the domain of Restaurants showed that there is no important difference between having one classifier for each possible E#A label, and having separate classifiers for each E and each A label. However, in Laptops, the latter approach led to slightly better results and, hence, it was preferred.

In the task of OTE, our constrained system is below the median participant (6th out of 8 submissions). However, when extended with features based on word embeddings (our unconstrained system), its performance is outstanding (2nd out of 19 submissions).

It is also worth noting that, in preliminary experiments for OTE, the use of a context vector (i.e., concatenated embeddings of words in a 5-context window of the word in question) gave far better results than using the centroid of these word embeddings.

| System             | Restaurants         | Laptops             |
|--------------------|---------------------|---------------------|
| LRI (hand crafted) | 80.71% (12th)       | 73.92% (9th)        |
| LRII (embeddings)  | 74.94% (22th)       | 73.12% (11th)       |
| Ensemble           | <b>83.24% (6th)</b> | <b>76.90% (6th)</b> |

**Table 4:** Accuracy of our submitted PD ensemble and its two subsystems, LRI (feature based) and LRII (based on word embeddings). In parentheses are estimated ranks of the two subsystems and the official rank of our ensemble.

For PD, we performed some post-experiments on the gold test data. As can be seen in Table 4,

our ensemble, which is our final PD system, outperforms its two subsystems, both in Restaurants (2.5% - 8.3%) and Laptops (3%-3.8%). Also, post-experiments showed that the negation lexicon improved the Accuracy of our ensemble by 0.5% in Restaurants and 1% in Laptops.

## 5 Conclusions and future work

We presented our approach to sentence level Aspect Based Sentiment Analysis (SE-ABSA16), which includes the subtasks of Aspect Category Detection (ACD), Opinion Target Expression (OTE) and Polarity Detection (PD). We observed and showed in post-experiments the benefits of using word embeddings and ensembles. The source code of our systems is publicly available. Future work includes the incorporation of neural networks in our ensembles.

## Acknowledgments

This work was carried out during the BSc projects of the first two authors, which were co-supervised by the other three authors.

## Abstract

This paper describes the polarity classification system designed for participation in SemEval-2016 Task 5 - ABSA. The aim is to determine the sentiment polarity expressed towards certain aspect within a consumer review. Our system is based on supervised learning using Support Vector Machine (SVM). We use standard features for basic classification model. On top this, we include rules to check precedent polarity sequence. This approach is experimental.

## 1 Introduction

In the consumer-focused markets today, understanding opinions expressed on the online platforms or review portals is of key essence for the businesses. Statistical or Machine learning methods and Natural Language Processing are now being widely applied to extract important information or patterns from the opinion data. A review statement may have a mix of sentiments towards different aspects. For e.g., consider *the food and ambiance at xyz hotel were extraordinary, as expected. However, the waiters seemed rude.* Here, the main entity of review is a 'hotel'. Henceforth, we will refer to such main entity as *global item*. However, there is no definite overall sentiment expressed towards the *global item*. Different sentiments are expressed towards *food* and *ambiance* aspects (*extraordinary*: positive) and towards the aspect of service (*waiters*, *rude*: negative). Thus, it is important to approach sentiment detection as an aspect-based problem.

The SemEval-2016 Task 5 - Aspect Based Sentiment Analysis (ABSA) focuses on this problem

(Pontiki et al., 2016). This task is a continuation from SemEval-2015 ABSA task (Pontiki et al., 2015). The task was organized across different domains and languages. We participated in Restaurant domain in English language. The focus of our system is polarity detection and not aspect extraction. Thus, we use dataset in which aspects are already known.

To develop our system, we have used standard features for basic model and also rules to check effect of precedent-polarity sequence pattern on polarity to be predicted. We focus on experimenting with sequence pattern. The system is described in Section 3. Pre-processing is described in Sub-section 3.1. selected features are discussed in Sub-section 3.2 and sequence pattern discussed in Sub-section 3.3. In section 4, we discuss the analysis and evaluation results for our system.

## 2 Related Work

Aspect-based sentiment analysis has been a subject of some interesting works so far. (McAuley et al., 2012) employ topic modeling paradigm to address this problem. Deep Learning has also been explored in this area, such as by (Wang and Liu, 2015). They used Convolutional Neural Network for aspect-based analysis of SemEval-2015 ABSA data and reported performance comparable to top systems of the 2015 task. Previously, the system by (Kiritchenko et al., 2014) achieved the best performance in Polarity Detection task in SemEval-2014. They used various innovative linguistic features, publicly available sentiment lexicon corpora and automatically generated polarity lexicons. In

Semeval-2015, SENTIUE system by (Saias, 2015) provided remarkable results. They used wide range of features such as Bag-of-Words, negation words, bigram after negation, polarity inversion, polarized terms in last 5 tokens, publicly available lexicons etc. They used Mallet<sup>1</sup> with Maximum Entropy classifier.

### 3 Classification System

Our system uses Support Vector Machine (SVM) with Radial Basis Function (RBF) kernel as classifier. The scikit-learn SVM implementation has been used (Pedregosa et al., 2011). This classifier is trained using dataset provided by task organizers. This dataset consists of several reviews, each with a unique review ID (rID). Each review consists of several sentences. A sentence may have single or multiple aspects. Sentences under same rID express sentiment towards the same *global item*. In our case, the *global item* is some *restaurant*. The data are parsed into following format:

```
{Review(rID) {Sentence1 aspect1:(target, category, polarity, from, to)}, {Sentence2 aspect1:(target, category, polarity, from, to)}, ..., {SentenceN aspect1:(target, category, polarity, from to) ... aspectM:(target, category, polarity, from, to)} }.
```

Here, Review(rID) is just one instance out of several such reviews. (target, category, polarity, from, to) are values belonging to an aspect of a sentence. Polarity values are *positive*, *negative* or *neutral*. SentenceN is an example of a sentence which contains multiple aspects. The test data are also parsed in the same format except that polarity values are not provided. Henceforth, (target, category, polarity, from, to) will be referred to as (tar, cat, p, f, t) for simplicity.

To develop our system, we have used NLTK package (Loper and Bird, 2002) in Python with resources such as WordNet package<sup>2</sup>, SentiWordNet, Bing Liu's opinion lexicon and MPQA subjectivity lexicon<sup>3</sup>.

### 3.1 Pre-processing

Consider following sentence,

*Chow fun was dry; pork shu mai was more than usually greasy and had to share a table with loud and rude family*<sup>4</sup>

For this sentence, we have following (tar, cat, p, f, t) values:

```
target="Chow fun", category="FOOD#QUALITY", polarity="negative", from="0", to="8"; target="pork shu mai", category="FOOD#QUALITY", polarity="negative", from="18", to="30"; target=NULL, category="RESTAURANT#MISCELLANEOUS", polarity="negative", from="0", to="0"
```

Here, from-to values provide the location of *tar* within the sentence.

Based on the observation made on the provided dataset, we hypothesize that only the terms related to *tar* affect the aspect-polarity *p*. In the example above, only "more than usually greasy" is relevant for "pork shu mai". Thus, first we decompose any {SentenceX aspect1:(tar, cat, p, f, t) ... aspectM:(tar, cat, p, f, t)} into {SubSent1 aspect1:(tar, cat, p, f, t), ..., SubSentM aspectM:(tar, cat, p, f, t)}, where M is greater than or equal to 1 and SentenceX is any sentence with aspect values assigned to it.

For decomposition, we first use Stanford Dependency Parser (de Marneffe et al., 2006) to obtain a dependency graph of SentenceX. Using the obtained graph, we choose terms in SentenceX which are more closely related to *tar* terms. For e.g., in the staff acted like we were imposing on them and they were very rude, the underlined terms are related in the dependency graph. Here, *tar* is 'staff'. SubSent for any *tar* can be formed using only such related terms.

SubSent formation is not straightforward when *tar* is NULL. We use self-generated *tar* values in such cases. Our intuition is that the terms express-

(Wiebe et al., 2005). Bing Liu's lexicons and SentiWordnet are available as part of NLTK package. Bing Liu's lexicons and MPQA are binary, i.e., they simply classify words or terms as positive or negative. SentiWordNet provides a range of positive and negative scores for terms.

<sup>4</sup>This sentence, and all sentences henceforth, are taken from training dataset.

ing sentiment should be related to a noun or pronoun subject (for instance, "loud" and "rude" related to *family*). Thus, after eliminating all SubSent for non-NUL<sub>tar</sub>, sentiment terms in the remaining sentence are identified by looking-up terms in the lexicon corpora. Then, a noun or pronoun related (in dependency graph) to identified terms is considered as *tar*. Since the *global item* is restaurant, if 'food', 'drinks', 'service', 'waiter', 'price', 'staff' or 'ambiance' are present, they are preferably considered as *tar*. Also, 'they', 'she' and 'he' are frequently used to refer to service staff in the provided dataset. Hence, these terms are also preferred as *tar*.

After decomposing, we filter-out stop words selected from NLTK's stop word list. Numbers and symbols (except '!') are also filtered-out using regular expression.

### 3.2 Features

Following basic features have been used in our model:

1. **Sentiment lexicons** - Separate features for Bing Liu's (binary), MPQA (binary) and SentiWordNet (range of scores).

*Presence of negation terms* : The scores of sentiment lexicons are modified according to negation (e.g., 'not', 'didn't', 'don't' etc.). Bing Liu and MPQA features are simply reversed ( $\text{pos} \rightarrow \text{neg}$ ,  $\text{neg} \rightarrow \text{pos}$ ). For SentiWordnet features, negation is made in proportion to the scores. For e.g., a word like 'extraordinary' having higher positive score is less affected by negation compared to a word like 'good' having lower positive score. We use a simple scheme for score modification:  $\text{pos} = \text{pos} + \frac{(\text{neg}-\text{pos})}{2}$  and  $\text{neg} = \text{neg} + \frac{(\text{pos}-\text{neg})}{2}$ . Here, pos and neg are positive and negative lexicon scores of a term, respectively. A significant work on negation problem has been done by (Zhu et al., 2014). They provide several methods to perform shifting of sentiment scores.

2. **Uni-grams and Bi-grams** extracted from each SubSent.
3. **Self-generated list of neutral terms** - Based on observation made on provided training

dataset, we found that following terms frequently occur in "neutral" polarity SubSent(s): 'average', 'normal', 'simple', 'okay', 'ok', 'not great', 'nothing great', 'moderate', 'typical', 'alright', 'fair', 'mediocre', 'just', 'fine', 'not too good', 'good enough'

These terms and phrases do not necessarily fall in positive or negative category of lexicon features. Hence, these are used as separate unigrams. Terms in a phrase like 'not too good' are concatenated as 'not0too0good'.

4. **Punctuation** like '!'. In the training dataset, this punctuation mostly co-occurs with positive polarity. Hence, the occurrence of the punctuation is checked.

5. **Keywords associated with specific aspect category** - There are a total of 12 aspect-categories (*cat*) such as FOOD#QUALITY, FOOD#PRICES, RESTAURANT#GENERAL, SERVICE#GENERAL etc. in the provided dataset. For a specific *cat*, there could be keywords which, when co-occurring with the *cat*, express some sentiment. For e.g., high and low are generic terms but for FOOD#PRICES they can indicate a polar sentiment. We divide the dataset into 12 documents, one for each *cat*. Then, we identify keywords based on Term Frequency - Inverse Document Frequency (TF-IDF) scores. The frequently occurring terms are added to a keyword list. Frequency thresholds of min:0.3 & max:0.8 are used. Total 12 keyword lists are obtained, one for each *cat*. Then, for each {SubSent aspect:(tar, cat, p, f, t)}, we check for presence of keywords corresponding to *cat* in SubSent. If found, the keywords are used as new uni-gram features.

These are the features used for basic classification model. In the next sub-section, we describe inclusion of sequence pattern.

### 3.3 Using precedent polarity sequence (experimental)

Following observations are made on the provided training dataset:

1. In majority of the cases, the sentences under the

same rID exhibit similar sentiment. In other words, polarity values  $\{p_1, p_2, \dots, p_N\}$ , under same rID, are equal. Henceforth, we will refer to this as *Flow*.

2. There are sentences where the polarity values change, i.e.,  $p_i$  is not equal to  $p_{i-1}$ , under same rID. Henceforth, we will refer to this as *Trans* (transition). *Trans* instances may be identified by explicit contrast terms present around *tar*. The common contrast terms found in the dataset are: 'but', 'however', 'though', 'tho', 'although', 'yet', 'except'

For instance, *The decor is right tho...but they REALLY need to clean that vent in the ceiling...its quite un-appetizing, and kills your effort to make this place look sleek and modern*

target="place" polarity="negative"; target="decor" polarity="positive"; target="vent" polarity="negative"

However, this does not imply that a contrast term is always present when *Trans* happens.

Exploiting the '*Flow* or *Trans*' patterns can help address ambiguity. This is the main reason for including sequence pattern. Consider following sentence:

*The manager came to the table and said we can do what we want, so we paid for what we did enjoy, the drinks and appetizers.*

For a classifier, the sentiment expressed towards 'manager' may be ambiguous. Our basic model classifies this as *neutral*, while the true polarity is *negative*. However, if we take previous sentence in consideration - *The level of rudeness was preposterous* - the state of mind of the reviewer becomes more clear.

Based on this observation, we hypothesize that, under same review (rID), precedent polarity outcome affects current polarity outcome, either by *Flow* or *Trans*, given certain conditions. (Vanzo et al., 2014) propose a context-based model for sentiment analysis of tweets, on similar lines. They use sequence of tweets to build Conversational context, hashtags to build Topical context and also use Markovian approach.

We describe our methods to account for *Flow* or *Trans* here.

**Method1:** We use new set of features instead of basic feature-set discussed in sub-section 3.2. First, we generate the features representing conditions for

*Flow* or *Trans*. We use two conditions for our model - contrast keywords and sentiment keywords - present in a SubSent. The training dataset is divided into 3 sub-sets according to polarity labels. Then, we search for sentiment terms belonging to one of the lexicon corpora, sentiment terms with negation terms (bi-grams and tri-grams) and terms belonging to our neutral word list. A new dictionary  $D$  is created with these terms. Moreover, TF-IDF based selection is performed on the 3 sub-sets (or documents). Frequency thresholds are min:0.3 & max:0.8. This ensures inclusion of any frequent keywords which are not already a member of  $D$ . Then, for a  $SubSent_i$ , feature set  $X_i = \{posD, negD, neutD, cont\}_i$  is generated. Here,  $posD$ : terms in a SubSent belonging to positive section of  $D$ ;  $negD$ : terms in a SubSent belonging to negative section of  $D$ ;  $neutD$ : terms in a SubSent belonging to neutral section of  $D$ ;  $cont$ : contrast terms in SubSent.

Separate sentiment classes have been used here to let the classifier learn how strongly a SubSent is inclined towards any particular sentiment type. The classifier should learn that if such inclination is strong, then ambiguity is low. So, effect of previous SubSent should also be low.

New input feature-set corresponding to  $SubSent_i$  is  $\mathbf{X(i)} = \{X_i, X_{i-1}, X_{i-2}\}$ , plus, selective features from sub-section 3.2. For initial two SubSent(s) under a rID,  $X_{i-2}$  or both  $X_{i-1}$  and  $X_{i-2}$  are empty. We do not use n-gram and neutral word features because terms are now selected from  $D$ . Punctuation is ignored since its effect is minimal (Table 1). *cat* specific keywords are included because they are extracted using different document-types. Lexicon scores are also included to capture sentiment strength. The same SVM-RBF classifier is then trained with  $\mathbf{X}$  to predict polarities. For test data, same dictionary  $D$  is used to generate new features.

**Method2:** This method is along the lines of auto-regression<sup>5</sup>. However, polarity sequence is not a strict time-series. Hence, we devise our mathematical model with necessary considerations. A first set of predicted polarities  $P_1 = \{p_{11}, p_{12}, \dots, p_{1k}\}$  are obtained using SVM-RBF with all of the basic

---

<sup>5</sup><<http://paulbourke.net/miscellaneous/ar/>>

features from sub-section 3.2. Polarities are mapped as  $\{positive, negative, neutral\} \rightarrow \{1, -1, 0\}$ . The aim is to obtain final predictions,  $P_2 = \{p_{21}, p_{22}, \dots, p_{2k}\}$ . Feature-set  $X_i = \{posD_i, negD_i, neutD_i, cont_i\}$  for  $SubSent_i$  of test data is obtained using  $D$ . However, we do not predict using these features. The *Flow* or *Trans* effect is directly calculated using  $P_1$  values. For each  $SubSent_i$ , we define following values:

$s_i^p$  : positive vote. This is initialized by 0, then incremented by +1 for first term found in  $posD_i$  and by +0.5 for every next term in  $posD_i$ ,

$s_i^n$  : negative vote. This is initialized by 0, then incremented by -1 for first term found in  $negD_i$  and by -0.5 for every next term in  $negD_i$ ,

$s_i^o$  : neutral vote. This is initialized by 0.4 ( $s_{imin}^o$ ), then incremented by  $(1-s_i^o)/4$  for every term found in  $neutD_i$ , keeping the value below 1.

$c_i$  : contrast vote. This is initialized by +1; assigned  $c_i = 2$ , if  $cont_i$  is not empty,

$w_i$  : aggregate voting weight. This is calculated as,  $w_i = |p_{1i}|(|(p_{1i}+1)/2|(|2s_i^p + s_i^n| + |(p_{1i}-1)/2|(|s_i^p + 2s_i^n| + s_{imin}^o)) + ||p_{1i}|-1||s_i^o|$ ,

Since, a SubSent must express some sentiment, we assume a basic neutral characteristic in each SubSent. Hence,  $s_{imin}^o$  is added.

We define a function  $g(w, p) = |w|(|p| + ||p|-1|)$ . Then, using these parameters we calculate a weighted effect,  $\hat{p}(i)$ , for polarity as,

$$E_i = g(w_{i-1}, p_{1,i-1}) + \sum_{r=l}^{r=i-1} (c_r / c_{r-1}) g(w_{r-1}, p_{1,r-1}), \\ E_{i(avg)} = E_i / (1 + \sum_{r=l}^{r=i-1} (c_r / c_{r-1})), \\ \hat{p}(i) = g(w_i, p_{1i}) + E_{i(avg)} / 2c_i.$$

The increment and assignment values have been chosen after experimenting with different values. Also, for our model,  $l = i-2$  works best. Effect value  $E_i$  captures the effect of precedent polarities. The effect of a polarity value  $p_{1,i-2}$  should be amplified with respect to  $p_{1,i-1}$  if  $p_{1,i-1}$  came by contrast and reduced if  $p_{1,i-2}$  itself came by contrast. Hence,  $p_{1,i-2}$  is multiplied with  $c_{i-1}/c_{i-2}$ . Finally, the average effect  $E_{i(avg)}$  should be reduced if current  $SubSent_i$  has explicit contrast terms. Hence, the division by  $2c_i$ . Then, if  $\hat{p}(i) < 0$ ,  $p_{2i} = -1$ ; if  $\hat{p}(i) > 1$ ,  $p_{2i} = 1$ ; otherwise,  $p_{2i} = 0$ .

These equations are tuned based on observations made on training data. More generic and robust equations need to be formed. This needs further investigation.

| Features                          | Accuracy        |
|-----------------------------------|-----------------|
| n-grams only                      | 0.61 (+/- 0.04) |
| lexicons-with-negation (lx) only  | 0.64 (+/- 0.06) |
| n-grams + lx                      | 0.69 (+/- 0.05) |
| n-grams + lx + neutral terms (nt) | 0.71 (+/- 0.04) |
| n-grams + lx + nt + punctuation   | 0.71 (+/- 0.05) |
| n-grams + lx + nt + keywords (kw) | 0.75 (+/- 0.04) |
| Method1 + n-grams + lx + nt + kw  | 0.79 (+/- 0.04) |
| Method1 + lx + kw                 | 0.80 (+/- 0.04) |
| Method2                           | 0.82 (+/- 0.04) |

Table 1: Model performance on training dataset.

## 4 Analysis and Evaluation Results

### 4.1 Analysis using training data

The analysis of our system on training data is provided in Table 1. SVM-RBF with parameters : [C=100, kernel='rbf', gamma = 0.001] is used (same for evaluation/test). Parameters are obtained using grid search. The accuracy scores are obtained using 10-fold cross-validation from scikit-learn (Pedregosa et al., 2011). N-grams obtained using dependency relation with aspect-target are base features. Lexicons are essential to capture sentiment types and scores. However, we found that there were some terms occurring in neutral sentences which were not listed in lexicon corpora. Hence, we generated our own list of neutral words. Punctuation (!) has negligible effect on the performance. Including aspect-category keywords improves accuracy. As discussed earlier, keywords are required to include terms that express some opinion specific to a category. These are the only basic features used. On top of this, we include polarity sequence pattern. It can be seen that Method2 provides better result than Method1 by a slight margin only. Method2 may not be necessarily better, but we prefer using it. It theoretically permits using more than one precedent polarities in the sequence, if required, without involving complex features; only the summation series needs to be expanded as we go along a polarity sequence. Method2 is used in final Evaluation model.

Due to time constraint, we focus more on inclusion of polarity sequence pattern instead of engineering better features or classifier ensemble.

| System              | Accuracy | Ratio   | Rank |
|---------------------|----------|---------|------|
| AKTSKI              | 0.717    | 616/859 | 24   |
| Highest1 : XRCE     | 0.881    | 757/859 | 1    |
| Highest2 : IIT-TUDA | 0.867    | 745/859 | 2    |
| Baseline            | 0.764    | 657/859 | 21   |

**Table 2:** Evaluation results. Ratio is no. of correct predictions/total no. of aspects. Accuracy values are on scale of 0 to 1.

## 4.2 Evaluation result

The result of evaluation is provided in Table 2. There were 676 sentences in the evaluation (test) data and 859 instances of aspect values (tar, cat, f, t). The polarity values had to be predicted. The system predictions were evaluated against gold labels by the organizers. There were total 30 submissions in polarity detection task for Restaurant domain and English language. This included multiple submissions from single teams as well. Relative performance of our system was poor. This may be attributed to less effort invested on improving classifier model (using ensembles, or otherwise) or on using more robust features. We also suspect that {posD, negD, neutD, cont} features may be biased towards training data as the keyword dictionary  $D$  was generated on the full training dataset before evaluation. Moreover, Method2 is tuned using training data and expected to perform weaker on unseen datasets.

## 4.3 Further evaluation on gold-labeled data

We did further evaluation of our system after release of gold-labeled test data. This was aimed at checking the effect of using sequence pattern. The results are provided in Table 3. The accuracy obtained against gold labels without using sequence pattern was 0.668. By using Method1, the accuracy increased to 0.702. With Method2, the accuracy obtained was 0.717. These are small increments. Also, the method has obvious caveats as mentioned above. So, the usage of sequence pattern needs to be improved by more research.

## 5 Conclusion

We submitted unconstrained system for sentiment polarity detection. The system was unconstrained in the sense that it used several external resources

| Score     | System1 | System2 | System3 |
|-----------|---------|---------|---------|
| Accuracy  | 0.668   | 0.702   | 0.717   |
| Precision | 0.480   | 0.510   | 0.500   |
| Recall    | 0.482   | 0.500   | 0.506   |

**Table 3:** Comparative performance. System1: without sequence pattern, System2: using Method1, System3: Using Method2. Accuracy values are on scale of 0 to 1.

for feature generation. Apart from standard features, we experimented with polarity sequence pattern. This approach provides slight improvement in prediction accuracy as checked on evaluation data. However, for any serious purpose, this approach requires deeper investigation. Our next step would be to devise more robust feature-extraction to handle polarity sequence patterns. Moreover, this approach needs to be tested on broader datasets. We will also explore using sequence pattern with multi-class Platt Scaling (Zadrozny and Elkan, 2002) or ensemble models to check performance.

## Abstract

This paper describes aspect-based polarity detection system for Russian, used in aspect-based sentiment analysis task (ABSA) of SemEval-2016 (Task 5, subtask 1, slot 3). The system consists of two independent classifiers: for opinion target expressions and for implicit opinion target mentions. We introduce a set of standard unigram features together with more sophisticated ones: based on sentence syntactic structure and based on lemmas vector representation.

Being applied to Russian restaurant reviews, our system achieved best quality among four participants.

## 1 Introduction

Aspect-based sentiment analysis task (ABSA) drew much attention with the growth of Internet retail sites and facilities for customers to make a free text product review. ABSA systems allow businesses to track reputation of their products even more granularly than before: per aspect. At the same time, customers can be provided with per-aspect sentiment summaries of reviews about concurrent products to simplify their choice.

SemEval-2016 Task 5 (ABSA) organizers (Pontiki et al., 2016) proposed two subtasks: Sentence-level ABSA and Text-level ABSA. First subtask was split to three slots: Aspect Category Detection, Opinion Target Expression, Sentiment Polarity. Training data for the task were available for various languages (English, Russian, etc.) and domains (restaurants, laptops, etc.).

Slot 3 can be described as follows: given a set of reviews labeled with OTEs (opinion target expressions: start-end-entity-attribute quadruples) determine a polarity label for each OTE: positive, negative, neutral (mildly positive or mildly negative sentiment). Additionally polarity labels should be computed for entity-attribute pairs assigned to reviews sentences.

This paper describes our team participation in slot 3 evaluation for Russian language Restaurant domain. The rest of the article is structured as follows: section 2 mentions some recent approaches to aspect-based polarity detection task, section 3 contains our system description, section 4 provides our system evaluation results.

## 2 Related work

According to (Andrianov et al., 2015), aspect-based polarity detection methods can be divided to three categories: classifier-based (Zhang and Lan, 2015; Hamdan et al., 2015; Blinov and Kotelnikov, 2015), neural network-based (Tarasov, 2015) and unsupervised (García Pablos et al., 2015). Most promising approaches according to recent evaluations results (Pontiki et al., 2015; Loukachevitch et al., 2015) are classifier-based methods, especially semi-supervised ones which bring “external knowledge” (word2vec (Mikolov et al., 2013), Brown clusters (Brown et al., 1992), polarity lexicons (Baccianella et al., 2010; Wilson et al., 2005)) into the table. Semi-supervised techniques become extremely useful due to lack of labeled data for the aspect-based sentiment analysis task in general and polarity detection subtask in particular.

### 3 System Description

Our aspect-based polarity detection system consists of two independent parts: OTE polarity classifier and implicit entity mention polarity classifier. Both parts are based on linear SVM with L2 regularization for three classes: positive, negative, neutral (available training set contains the only conflict polarity label, thus it is ignored).

At first, we preprocess review using Texterra (Tur-dakov et al., 2014) system. We perform tokenization, part of speech tagging, lemmatization and syntactic parsing for each review sentence.

All used features can be grouped to several classes:

- opinion target features;
- sentence-level lexical features;
- syntactic-level features.

Some most valuable features are based on word vector representation obtained by word2vec. For word2vec training we used 40140 unlabeled reviews from restoclub<sup>1</sup> resource. All word2vec models were trained with same dimensionality (100) and same window size (10). We tried word2vec with different input data preprocessing approaches: without preprocessing, with lowercased words and with lemmatized words. The last one demonstrates the best result on 8-fold cross-validation (see section 4 for details).

The rest of this section describes each group of features in details.

#### 3.1 Opinion Target Features

Initially we tried to train separate SVM classifiers for each entity-aspect pair. Unfortunately training data contains just a few examples of certain entity-attribute pairs (e.g., *DRINKS#PRICES* are presented in training data only 17 times). Moreover, we suspect that different entities can share most part of sentiment vocabulary for some attributes (e.g., quality).

So, we decided to use a single SVM classifier for all entity-aspect labels and to extract two additional features: opinion target entity label and opinion target attribute label. These features are used in both system parts.

<sup>1</sup>[www.restoclub.ru](http://www.restoclub.ru)

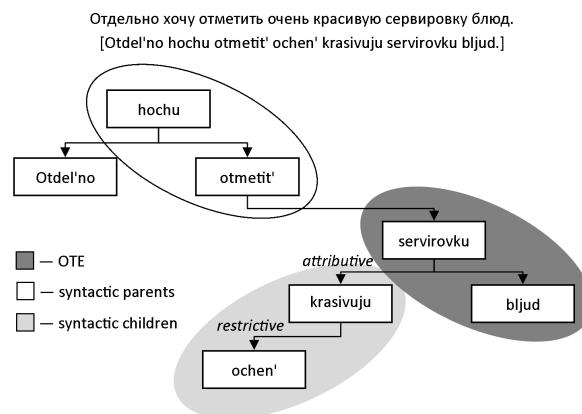

#### 3.2 Sentence-level Features

As implicit entity mention has no boundaries, we use the whole sentence to extract its features. We use a number of common features, usually exploited in NLP tasks: sentence word unigrams, sentence lemma unigrams, part of speech tag of each word in sentence. Moreover we use frequency of punctuation token unigrams in sentence as a feature.

Described features group is used for implicit entity mention polarity classifier as well as for OTE polarity classifier, because of slight quality improvement.

For OTE polarity classification information about entity mention is also used: we utilize vector representations of lemmatized sentence words. We extract lemmas in window of size 5 (5 words to the left and 5 words to the right from OTE), map them to vector representations and concatenate these representations.

#### 3.3 Syntactic-level features

**Figure 1:** Syntactic dependency parsing for review sentence “I would like to mention very nice table appointments.”

OTE polarity classifier exploits a number of syntactic-level features. Our basic assumption is that OTE polarity is closely related to some dependent words (especially adjectives), which may express sentiment. Our system uses Texterra syntactic dependency parser to produce syntactic tree of input sentence.

Each OTE should match subtree in syntactic tree, which is treated as a single node. In case OTE is not a subtree, syntactic-level features for classifi-

| Data source | Preprocessing | Accuracy      | Positive F1   | Negative F1   | Neutral F1    |
|-------------|---------------|---------------|---------------|---------------|---------------|
| Wikipedia   | –             | 0.8095        | 0.8907        | 0.5615        | 0.2766        |
|             | lowercase     | 0.8089        | 0.8909        | 0.5515        | 0.2820        |
|             | lemmatization | 0.8113        | 0.8928        | 0.5566        | 0.2930        |
| Restoclub   | –             | 0.8137        | 0.8937        | 0.5700        | 0.2906        |
|             | lowercase     | 0.8158        | 0.8955        | 0.5662        | 0.3086        |
|             | lemmatization | <b>0.8189</b> | <b>0.8966</b> | <b>0.5817</b> | <b>0.3271</b> |

**Table 1:** 8-fold cross-validation with different word2vec training settings

cation are abandoned. For instance, Figure 1 depicts syntactic tree extracted from review sentence “I would like to mention very nice table appointments.”. Opinion target expression “Table appointments” is a subtree, so it is treated as a single node.

We start from using OTE parent words as features: we extract a chain of parent words for given OTE (up to 3 words), and use their lemmas vector representations as features. In example syntactic tree (Figure 1) there are two parent words: “otmetit” at depth 1 and “hochu” at depth 2.

Additionally we use syntactic children chains to extract some relevant features. For each word dependent on OTE (in parent-child chains of length up to 2) we use syntactic relations path conjoint with word form, lemma and lemma vector representation as features. In example (Figure 1) syntactic children words are “krasivuju” with relations path “attributive” and “ochen” with relations path “attributive-restrictive”.

## 4 Evaluation

### 4.1 word2vec Training Settings

During system development we tried several word2vec models trained with different settings. We varied data sources (Russian Wikipedia and restaurant reviews obtained from restoclub.ru) and data preprocessing (without preprocessing, lower-cased words and lemmatized words). We experimented with 8-fold cross-validation on training data. The best result was obtained with restoclub.ru data source and lemmatization preprocessing (see Table 1).

### 4.2 Features Impact

In this section we try to evaluate each feature group impact. We test quality of our system with all de-

scribed features on test data (using gold labels provided by organizers after evaluation) and using 8-fold cross-validation on train data (as we did before evaluation). Then we consecutively test our system without some group of features. Test results are presented in Table 2.

| Features             | cv on train data | on test data            |
|----------------------|------------------|-------------------------|
| All                  | <b>0.8189</b>    | 0.7808                  |
| All - opinion target | 0.8128 (-0.0061) | <b>0.7923 (+0.0123)</b> |
| All - sentence-level | 0.7793 (-0.0396) | 0.7038 (-0.0770)        |
| All - syntactic      | 0.8142 (-0.0047) | 0.7777 (-0.0031)        |
| All - word2vec       | 0.8029 (-0.0160) | 0.7661 (-0.0147)        |

**Table 2:** Features impact evaluation. Accuracy score of the system with various features sets

In spite of the fact that word lemmas vector representation features are present in sentence-level and syntactic features groups, we additionally test these features impact separately.

As it could be seen, most significant feature groups are sentence level features and lemma vector representation features. However, large impact of sentence-level features group is explained with the fact that implicit entity mention polarity classifier uses a few additional features, and when we don’t use sentence-level features it uses only opinion target features. If we test OTE polarity classifier separately, we obtain 0.8115 accuracy score without sentence-level features versus 0.8287 with all features on cross-validation (0.0172 impact) and 0.7746 versus 0.7860 on test data (0.0114 impact).

### 4.3 Evaluation Results

The official results are presented in Table 3. Our system (MayAnd) official result differs from result presented in Table 2 due to regrettable inadvertence with training dataset. Our system was trained on ini-

tially published data instead of revised dataset that had been published later. Table 2 reflects actual quality of our system (trained on the latest published dataset).

| System name     | Result (Accuracy) |
|-----------------|-------------------|
| MayAnd          | <b>0.7792</b>     |
| INSIG.          | 0.7508            |
| IIT-T.          | 0.7362            |
| Danii.          | 0.7331            |
| <i>baseline</i> | 0.7100            |

**Table 3:** Evaluation official results

## 5 Conclusion

Aspect-based sentiment analysis task and polarity detection subtask are still at their early days. Current methods are not able to significantly overcome trivial baselines. The following directions of future work can be recommended: collecting more reviews for various languages and domains to improve quality of unsupervised techniques like word2vec; development of sentiment lexicons for non-English languages and various domains.

## Abstract

This paper describes our deep learning-based approach to multilingual aspect-based sentiment analysis as part of SemEval 2016 Task 5. We use a convolutional neural network (CNN) for both aspect extraction and aspect-based sentiment analysis. We cast aspect extraction as a multi-label classification problem, outputting probabilities over aspects parameterized by a threshold. To determine the sentiment towards an aspect, we concatenate an aspect vector with every word embedding and apply a convolution over it. Our constrained system (unconstrained for English) achieves competitive results across all languages and domains, placing first or second in 5 and 7 out of 11 language-domain pairs for aspect category detection (slot 1) and sentiment polarity (slot 3) respectively, thereby demonstrating the viability of a deep learning-based approach for multilingual aspect-based sentiment analysis.

## 1 Introduction

With access to the Internet becoming more prevalent, an increasing number of people express their opinions online in a plethora of lan-

guages. Sentiment analysis (Liu, 2012) enables us to derive shallow insights from these opinions related to their overall polarity. Often, however, e.g. in reviews, people do not express their opinion towards the entity as a whole, but refer to specific aspects such as the service in a restaurant.

Aspect-based sentiment analysis allows us to go deeper and determine sentiment towards such aspects of an entity. Past research in aspect-based sentiment analysis has largely focused on the English language, while SemEval 2016 Task 5 (Pontiki et al., 2016) for the first time provides a forum for multilingual aspect-based sentiment analysis.

Recently, deep learning-based approaches have demonstrated remarkable results for text classification and sentiment analysis (Kim, 2014). A cascade of non-linearities allows them to model complex functions such as sentiment compositionality, while their ability to process raw signals renders them language and domain independent. In spite of these factors, they have largely gone untested for aspect-based sentiment analysis, particularly in the multilingual setting.

In this paper, we introduce our deep-learning

based approach to aspect-based sentiment analysis as part of our participation in SemEval-2016 Task 5 Aspect-based Sentiment Analysis Slot 1 (Aspect Category Detection) and Slot 3 (Sentiment Polarity).

## 2 Related work

Aspect-based sentiment analysis is traditionally split into an aspect extraction and a sentiment analysis subtask.

Previous approaches to aspect extraction framed the task as a multiclass classification problem and relied mostly on CRS that leveraged a plethora of common features, e.g. NER, POS tagging, parsing, semantic analysis, bag-of-words, as well as domain-dependent ones, such as word clusters learnt from Amazon and Yelp data, while previous sentiment analysis approaches have used different classifiers with a wide range of features based on n-grams, POS, negation words, and a large array of sentiment lexica (Pontiki et al., 2014; Pontiki et al., 2015).

Past deep learning-based approaches have focused mostly on the sentiment analysis subtask: Tang et al. (2015) use a target-dependent LSTM to determine sentiment towards a target word, while Nguyen and Shirai (2015) use a recursive neural network that leverages both constituency as well as dependency trees.

In contrast to previous approaches, our model neither relies on expensive feature engineering, availability of a parser, nor positional information, but solely on a language’s input signals.

## 3 Model

The model architecture we use is an extension of the CNN structure used by Collobert et al. (2011), which has been successfully used by many others (Kim, 2014).

The model takes as input a text, which is

padded to length  $n$ . We represent the text as a concatenation of its word embeddings  $x_{1:n}$  where  $x_i \in \mathbb{R}^k$  is the  $k$ -dimensional vector of the  $i$ -th word in the text.

The convolutional layer slides filters of different window sizes over the input embeddings. Each filter with weights  $w \in \mathbb{R}^{h^k}$  generates a new feature  $c_i$  for a window of  $h$  words according to the following operation:

$$c_i = f(w \cdot x_{i:i+h-1} + b) \quad (1)$$

Note that  $b \in \mathbb{R}$  is a bias term and  $f$  is a non-linear function, ReLU (Nair and Hinton, 2010) in our case. The application of the filter over each possible window of  $h$  words or characters in the sentence produces the following feature map:

$$c = [c_1, c_2, \dots, c_{n-h+1}] \quad (2)$$

Max-over-time pooling in turn condenses this feature vector to its most important feature by taking its maximum value and naturally deals with variable input lengths.

A final softmax layer takes the concatenation of the maximum values of the feature maps produced by all filters and outputs a probability distribution over all output classes.

## 4 Methodology

### 4.1 Preprocessing

We lower-case and tokenize the corpus, where applicable, keeping the 10,000 most frequent words as the vocabulary for each language and domain. For Chinese, in preparation for the previous step, we additionally segment the corpus using the `mmseg` Python library.

### 4.2 Hyperparameters

We randomly split off 20% of each training data set as a validation set. We use this to optimize

**Listing 1:** Example sentence with aspect and sentiment annotations for the English laptops domain.

```
1 <sentence id="347:0">
2   <text>I bought it for really cheap also and its AMAZING.</text>
3   <Opinions>
4     <Opinion category="LAPTOP#PRICE" polarity="positive"/>
5     <Opinion category="LAPTOP#GENERAL" polarity="positive"/>
6   </Opinions>
7 </sentence>
```

hyperparameters via random search over a wide range of values.

For both tasks and all languages and domains, we use the following hyperparameters, which are similar to those reported by Kim (2014): mini-batch size of 10, maximum sentence length of 100 tokens, word embedding size of 300, dropout rate of 0.5, and 100 filter maps. We use filter lengths of 3, 4, and 5, and of 4, 5, and 6 for aspect extraction and aspect-based sentiment analysis respectively since these produced good results for the respective task.

English word embeddings are initialized with 300-dimensional GloVe vectors (Pennington et al., 2014) trained on 840B tokens of the Common Crawl corpus for the unconstrained submission. Word embeddings for the constrained submission, for all other languages, as well as for words not present in the pre-trained set of words are initialized randomly.

We train for 15 epochs using mini-batch stochastic gradient descent, the Adadelta update rule (Zeiler, 2012), and early stopping.

### 4.3 Aspect Category Detection

To extract aspects, e.g. LAPTOP#PRICE and LAPTOP#GENERAL from sentences as in Listing 1, we cast aspect extraction as a multi-label classification problem and train a convolutional

neural network (CNN) to output probability distributions over aspects, minimizing the cross-entropy loss. To model multi-label output as a probability distribution, we define an aspect  $a$ 's probability  $p$  given a sentence  $s$  as  $p(a|s) = 1/n$  if  $a$  appears in  $s$  and  $s$  contains  $n$  aspects, otherwise  $p(a|s) = 0$ . We define a threshold  $f$  and discard all aspects with  $p(a|s) < f$ . After training, we select  $f$  maximizing the F1 score on the validation set.

We observe that aspect distributions vary significantly depending on the domain and language. For instance, the English laptops domain contains 82 aspects, while the restaurants domain only contains 13 aspects.

In every domain, we thus replace all aspects that occur less than 5 times with an OTHER aspect.<sup>1</sup> E.g. this produces 51 aspects covering 98% of occurrences and all 13 aspects for the English laptops and restaurants domain respectively. For instance, in the English laptops domain, aspects such as HARDWARE#MISCELLANEOUS and BATTERY#USABILITY, which occur less than 5 times are replaced with OTHER during training. We add a NONE aspect to each sentence containing no aspect to enable the CNN

---

<sup>1</sup>We found that replacing all aspects with fewer than 5 occurrences yields the best trade-off between accuracy and recall.

to make no aspect prediction. During inference, every time the model predicts OTHER, the most frequent aspect replaced by OTHER for each domain is output instead. For the English laptops domain, this can be one of several aspects, e.g. SOFTWARE#QUALITY occurring four times. Finally, we discard all predicted NONE aspects.

We experimented with producing representations for the preceding and subsequent sentence to take context information into account, but this did not improve results.

#### 4.4 Sentiment Polarity

For aspect-based sentiment analysis, we feed the aspect vector together with the word embeddings of the input sentence into a CNN. To obtain the aspect vector, we follow an approach similar to the one used by Socher et al. (2013) to represent named entities: We split each aspect into its constituent tokens, e.g. RESTAURANT#GENERAL → *restaurant*, *general*. We embed the tokens of all aspects in an embedding space. We then look up the embedding of each of the tokens and average them to retrieve the aspect vector. This way, the model should learn that aspects sharing the same entity, e.g. *restaurant* are correlated without the need to train several tiered models to classify between entities (*restaurant*) and attributes (*general*).

For aspect-based sentiment analysis in the English language, we embed aspect tokens in the same embedding space as word tokens to exploit the semantics of pre-trained embeddings. For all other languages, we keep the embedding spaces separate, as aspect tokens are in English and word tokens are in the respective languages. Translating aspect tokens into the source language did not provide any benefits, but the use of pre-trained embeddings in the source language could ameliorate this.

We have experimented with different variants of adding aspect embeddings to our model: We evaluated summation, concatenation, and multiplication of word vectors and aspect vectors before the convolution, and multiplication and concatenation of the max-pooled sentence vector and the aspect vector after the convolution. We find that concatenating each word vector with the aspect vector before the convolution yields the best results.

To summarize, for the sentence in Listing 1 and the aspect LAPTOP#PRICE, our model first pads the input sentence, then looks up the embeddings of each of the input words. It creates the aspect vector by splitting LAPTOP#PRICE into the aspect tokens *laptop* and *price*. For these, it looks up the embeddings in the aspect embedding space (which is the same as for word embeddings for English) and averages both embeddings. The resulting aspect vector is then concatenated with each word vector, which are then concatenated to produce a 100x600 sentence matrix. Convolutions, max-pooling and softmax are applied to this matrix as described in section 3.

We observe for some languages an incremental performance improvement when using additional average-pooling as reported by Tang et al. (2014). We further note that simply using a low-dimensional embedding space to embed aspects leads to superior results on a few occasions when no pre-trained word embeddings are used.

## 5 Evaluation

We have participated for all domains and languages in Slot 1: Aspect Category Detection and Slot 3: Sentiment Polarity. We report results for aspect extraction in Table 1 and results for aspect-based sentiment analysis in Table 2.

### 5.1 Aspect Category Detection

Despite using only the input sentence as data, our system is able to achieve competitive performance for multilingual aspect extraction, placing first or second in 5 out of 11 language-domain pairs. However, for English, Spanish, French, and Turkish, the differential with regard to the best performing system still remains large. We observe that initializing the system with general-purpose pre-trained embeddings provides a significant performance boost, which is most pronounced in the English restaurants domain.

Consequently, we hypothesize that the most straightforward way to overcome this performance differential is to initialize the system with embeddings trained on a large mono-

lingual corpus in the target language. Incorporating domain information used by best-performing systems (Pontiki et al., 2015) by pre-training on a large in-domain corpus such as the dataset released as part of the Yelp Dataset Challenge<sup>2</sup> should further improve results.

The multi-label condition is currently enforced only after prediction through the application of a threshold, which may potentially discard promising aspects or retain erroneous ones, while the current normalization of aspect probabilities might lead to the loss of signals. To make the model more robust, the multi-label condition can be integrated more naturally into the architecture, e.g. by adapting the error function and using a trainable thresholding function as in (Zhang et al., 2006).

### 5.2 Sentiment Polarity

We report convincing results for multilingual aspect-based sentiment analysis, placing first or second for 7 out of 11 language-domain pairs. Again, the difference in performance compared to the best-performing system is largest for English, Spanish, French, and Turkish. To mitigate this, pre-trained word embeddings as described in 5.1 can be used.

However, without relying on dependency and constituency trees (Nguyen and Shirai, 2015) or positional information (Tang et al., 2015), the model falls short of being able to reliably triangulate aspects, particularly in sentences with opposing sentiments toward different aspects. Simply concatenating each word vector with the aspect vector does not seem to provide the model with enough expressiveness to model truly aspect-dependent sentiment. Training the model to associate different surface forms with their aspect instantiations should help to ame-

liorate this.

## 6 Conclusion

In this paper, we have presented a deep learning-based approach to aspect-based sentiment analysis, which employs a convolutional neural network for aspect extraction and sentiment analysis as part of our submission to SemEval-2016 Task 5. We have demonstrated convincing results in the multilingual setting, which is particularly appropriate for neural networks due to their language and domain independence. We have evaluated our model, outlining weaknesses and potential future improvements.

## Abstract

This paper gives the description of the TGB system submitted to the Aspect Based Sentiment Analysis Task of SemEval-2016 (Task 5). The system is built on linear binary classifiers for aspect category classification (Slot 1), on lexicon-based detection for opinion target expressions extraction (Slot 2), and on linear multi-class classifiers for sentiment polarity detection (Slot 3). We conducted several different approaches for feature selection to improve classification performance on both Slot 1 and Slot 3. Our proposed methods are easily adaptable to all languages and domains since they are built as constrained systems which do not use any additional resources other than the provided datasets and which uses standard preprocessing methods.

## 1 Introduction

Since Web 2.0 and social media platforms have become popular in recent times, the amount of accessible text data has shown rapid increase. The manual analysis of this huge amount of data is almost impossible to accomplish in a reasonable time, thus automatic sentiment analysis and opinion mining have turned into a significant requirement for companies. The most of earlier studies conducted in this area were generally focused on document level

(Yıldırım, et al., 2015; Pang, et al., 2002; Esuli & Sebastiani, 2006) until the recognition of that different opinions can exist in the same sentence or paragraphs. Another disadvantage of general sentiment analysis approaches is the disability to match the sentiment polarities to the target entities. Therefore, this type of analysis becomes insufficient for deep understanding of opinions about products and features. The most commonly referenced study (Liu, 2012) on Aspect-Based Sentiment Analysis (ABSA) discusses the problem as extracting the tuples including multiple opinions.. The need for a detailed sentiment analysis with respect to specific target entities has given birth to ABSA. In International Workshop on Semantic Evaluation (SemEval), a shared task called Aspect-based Sentiment Analysis has been actualized since 2014 (Pontiki, et al., 2014; Pontiki, et al., 2015; Pontiki, et al., 2016). In this year's task, the data is annotated at both sentential and textual levels with reference to predefined domain-dependent aspect categories. For more information and details about the aspect categories consult (Pontiki et al., 2016). The task description (SemEval, 2016) provides regulations as to how these categories should be determined.

This paper presents our system prepared for ABSA 2016. It covers 3 different languages, namely, English, Spanish and Dutch. The system has multi-lingual capabilities giving nearly con-

sistent performances for each language. Our proposed methods are easily adaptable to all languages due to their multi-lingual nature by switching language codes for stemming phase. Considering the individual tasks, we have applied specific methods for each characteristic problem. In order to accomplish the task, we used different approaches for different slots. In order to find aspect category (Slot 1), we used a multi classifier approach which uses textual and probabilistic features. A lexicon based approach is chosen to extract the opinion target expressions (OTE) (Slot 2). We used a linear classifier which utilizes aspect category, aspect attribute and OTE features as well as textual features to detect the sentiment class for an opinion tuple (Slot 3).

## 2 System Description

In this section we present our aspect based sentiment analysis system. The system is experimented on the Restaurant datasets. Our submission is composed of the experiments on three languages; English, Dutch and Spanish. English dataset consists of 300 reviews and 2000 sentences, Spanish dataset has 627 reviews and 2070 sentences, and Dutch dataset contains 300 reviews and 1722 sentences.

The following preprocessing steps are used in all datasets:

- Removing html codes/URLs
- Tokenization
- Stemming

Sentences are tokenized and analyzed with Apache Lucene (Foundation, 2016) Analyzers which contains different types of operations. These operations are tokenization, filtering and transforming. In this system, we have used Standard Lucene Tokenizer for tokenization. Afterwards, we applied lowercase transformation on top of the previous step. In the following stage stemming is applied to all tokens using Snowball stemmer (Porter, 2001). An applied version of Snowball stemmer is already presented in the Lucene project. Finally, Lucene Shingle Filter is used to extract unigram and bigram features. In all of the introduced methods, we used these unigrams and bigrams (of the word stems in the datasets) as textual features,.

For the classification task, we use logistic regression from LIBLINEAR (Fan, 2008-9) classification library. LIBLINEAR is an open source library for large-scale linear classification (Fan, 2008-9). It

provides easy-to-use command-line tools and library calls for users and developers.

We have implemented a generic framework to make text classification on LIBLINEAR library. Our framework basically provides an infrastructure to developers for building custom preprocessing steps and classification systems. Developers only need to be aware of framework's interfaces and Lucene Analyzers.

### 2.1 Aspect Category Classification (Slot 1)

In order to detect aspect categories, we used a two-layered approach. First layer consists of one-vs-all binary classifiers for the detection of each different aspect entity (E) and aspect attribute (A). This first layer is used to obtain the possibilities of an instance to belong to the corresponding classes (entity or attribute). The obtained probabilities will be further used in the second layer for the ultimate classification.

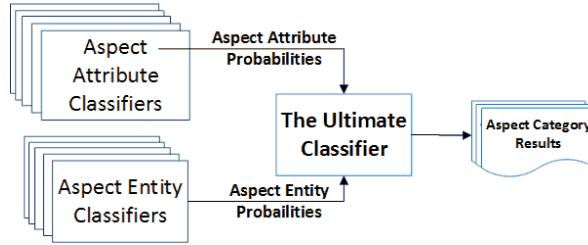

In the first layer, according to the instances available in different training sets (for each different language), at most 11 distinct binary classifiers are independently trained. For instance representation, we use unigram and bigram features occurring in the training sets.

| Features           | Instance         |
|--------------------|------------------|
| Textual Features 1 | 1                |
| ⋮                  | ⋮                |
| Textual Features n | 0                |
| FOOD               | 0,45             |
| DRINKS             | 0,33             |
| SERVICE            | 0,41             |
| AMBIENCE           | 0,65             |
| LOCATION           | 0,17             |
| RESTAURANT         | 0,75             |
| GENERAL            | 0,5              |
| PRICES             | 0,33             |
| QUALITY            | 0,65             |
| STYLE&OPTIONS      | 0,67             |
| MISCELLANEOUS      | 0,85             |
| CLASS              | AMBIENCE#GENERAL |

**Table 1:** Feature representation of ultimate classifier

In the second layer, we construct an ultimate classifier which uses additional features extracted

from the first layer's output. These are entity and attribute labels used as real-valued features (as opposed to the binary unigram and bigram textual features). This feature representation is depicted in Table 1. The probabilities from the previous layer are assigned as values for these features. The ultimate classifier is trained in order to produce aspect categories (E#A) that are composed of both entity and attribute label. Architectural model of the proposed method can be seen in Figure 1.

**Figure 1:** Slot 1 System Architecture

## 2.2 Opinion Target Extraction (Slot 2)

In opinion target extraction task, we basically follow the baseline opinion target extraction (OTE) procedure proposed in SemEval ABSA 2016 shared task with some changes and assumptions over it.

First, we extracted all opinion targets of each E#A pair from the training set, then used them to check if an opinion target is matched when a new sentence is examined during testing. If an opinion target is detected and the E#A pair of sentence is identical with the E#A pair of stored opinion target, this opinion target is assigned to the sentence. While we are extracting opinion targets from the training data, we applied different preprocessing steps composed of only lowercasing and ascification. However, in some cases many different opinion targets are found to be related to the same E#A pair. In these situations, we applied different approaches to choose the most suitable opinion target from all possible candidates.

Our first assumption is that if an opinion target already contains another one in itself (as a sub-unit), the longer one should be the specialized version of the same opinion target and assumed to be the most proper indication of the relevant opinion target. For instance, “*traditional dishes*” is better than only “*dishes*” while it contains the subsequent.

Even if we aimed to singularize extracted opinion targets with the first assumption, it is still possible to end up with several opinion candidates after this reduction method. Therefore, we applied some secondary approaches to singularize them. First, we experimented with utilizing the frequencies of opinion targets for each E#A pair. For instance, if “pasta” and “spaghetti” are detected as possible opinion targets of a sentence, and “pasta” is more frequent than “spaghetti” for “FOOD#PRICE” pair, “pasta” is preferred in this scenario. Second, we examined the selection of the longest opinion target from all candidates for the same E#A pair because of the similar assumption to the first one: the longer, the better. well decorated and lighted place” is a better choice than “charming place”.

After we evaluated the success of our assumptions, we found the best results by selecting the first inclusive opinion targets, and later the longer ones if still necessary.

## 2.3 Slot 1&2

To generate the predictions for Slot 1&2, we combine Slot 1 predictions with that of Slot 2. In this phase, instead of using gold E#A pair annotations to match them to opinion target expressions as we did in the Slot 2 prediction phase, we directly utilize the predictions of Slot 1. If any of the predictions of Slot 1 cannot be linked to any opinion targets, we assigned a NULL expression to these opinion targets.

## 2.4 Polarity Detection (Slot 3)

For sentiment polarity detection, gold standard aspect category and aspect terms are provided in the training sets. Therefore, the problem is to find and fill the sentiment polarity of each opinion tuple. We use a single classifier approach for solving the problem. Our classifier is able to determine the polarity class of the tuple from three types of polarity. Polarity classes are “positive”, “negative” and “neutral”.

We use textual as well as the features obtained from the previous aspect category detection phase. In other words aspect entity, aspect attribute and aspect terms are also placed in the feature representation of the train set. Each of the aspect entity, aspect attributes and aspect terms are represented with binary features. Therefore, 6 additional features for aspect entity, 5 additional features for aspect attribute and additional OTE features of the number of

unique opinion targets in dataset are used in our feature representation. While producing feature value set for an instance, values are assigned according to the feature existence in the instance. The mentioned features can be shown in Table 2. After the feature representation, a single classifier is trained using the Logistic Regression algorithm.

| Features                | Instance |
|-------------------------|----------|
| Textual Features 1      | 1        |
| :                       | :        |
| Textual Features n      | 0        |

Table 2: Slot 3 feature representation

### 3 Results

We submitted our constrained system predictions to all slots of Subtask 1 for the restaurant domain. Since we use a common method for each language, we expected to have similar results for each language. According to the results of the task's evaluation, this expectation seems to be satisfied. Except for the English dataset, we highly ranked for all slots and languages that we've applied. In Dutch dataset, our Slot 1, Slot 1&2 and Slot 3 results are the best one and we obtained the second rank for Slot 2.

However, we would like to emphasize that the best result for Slot 2 is obtained by an unconstrained system. So, we may say that our system provides successful results for constrained systems. We attained similar successful results also in the Spanish dataset especially among constrained systems. In the English dataset we obtained fourth best score among thirty constrained system for Slot 3 and third best score for Slot 1&2.

## 4 Conclusion

In this paper, we show our experiments and approaches on aspect category classification and sentiment polarity detection using supervised machine learning methods and opinion target extraction using lexicon based approaches. For these problems, we used only the supplied resources by the shared task committee. We built well-performed multi-lingual systems which do not require additional resources and special manipulations for different languages and domains except only stemmers for the preprocessing stage. By the successful data preparation and feature extraction methods, our system gives reasonable results on aspect category classification and sentiment polarity prediction of sentences and detection of related opinion expressions if in question.

## Abstract

This paper describes our system used in the Aspect Based Sentiment Analysis (ABSA) task of SemEval 2016. Our system uses Maximum Entropy classifier for the aspect category detection and for the sentiment polarity task. Conditional Random Fields (CRF) are used for opinion target extraction. We achieve state-of-the-art results in 9 experiments among the constrained systems and in 2 experiments among the unconstrained systems.

## 1 Introduction

The goal of Aspect Based Sentiment Analysis (ABSA) is to identify the aspects of a given target entity and estimate the sentiment polarity for each mentioned aspect. In recent years the aspect-based sentiment analysis has undergone rapid development mainly because of competitive tasks such as SemEval 2014 (Pontiki et al., 2014) and SemEval 2015 (Pontiki et al., 2015). The highest ranking participants are for SemEval 2014 (Kiritchenko et al., 2014; Brun et al., 2014; Castellucci et al., 2014; Toh and Wang, 2014; Wagner et al., 2014; Brychcín et al., 2014) and for SemEval 2015 (Saias, 2015; Toh and Su, 2015a; San Vicente et al., 2015; Zhang and Lan, 2015).

In the current ABSA task - SemEval 2016 task 5 (Pontiki et al., 2016) has attracted 29 participating teams competing in 40 different experiments among 8 languages. The task has three subtasks: Sentence-level (SB1), Text-level (SB2) and Out-of-domain ABSA (SB3). The subtasks are further divided into three slots:

- 1) Aspect Category Detection – the category consists of an entity and attribute (E#A) pair.
- 2) Opinion Target Expression (OTE)
- 3) Sentiment Polarity (positive, negative, neutral, and for SB2 conflict)

In phase A we solved slots 1 and 2. In phase B we were given the results for slots 1 and 2 and solved slot 3. We participate in 19 experiments including Chinese, English, French, and Spanish.

## 2 System Description

Our approach to the ABSA task is based on supervised Machine Learning. Detailed description for each experiment can be found in Section 2.2 and Section 2.3.

### 2.1 Features

Our system combines a large number of features to achieve competitive results. In this section we will describe the features in detail.

#### 2.1.1 Semantics Features

We use semantics models to derive word clusters from unlabeled datasets. Similarly to (Toh and Su, 2015b) we use the Amazon product reviews from (Blitzer et al., 2007) and the user reviews from the Yelp Phoenix Academic Dataset<sup>1</sup> to create semantic word clusters. Additionally, we use a review Opentable dataset<sup>2</sup>. In this paper we consider the following semantics models.

<sup>1</sup>[https://www.yelp.com/dataset\\_challenge](https://www.yelp.com/dataset_challenge)

<sup>2</sup>downloaded from <http://opentable.com>

|       | <b>Dimension</b> | <b>Window</b> | <b>Iterations</b> |
|-------|------------------|---------------|-------------------|
| GloVe | 300              | 10            | 100               |
| CBOW  | 300              | 10            | 100               |
| LDA   | –                | sentence      | 1000              |

**Table 1:** Model settings.

**Global Vectors (GloVe)** (Pennington et al., 2014) use the ratios of the word–word co-occurrence probabilities to encode the meanings of words.

**Continuous Bag-of-Words (CBOW)** (Mikolov et al., 2013) is model based on Neural Network Language Model (NNLM) that tries to predict the current word using a small context window around the word.

**Latent Dirichlet Allocation (LDA)** (Blei et al., 2003) discovers the hidden topics in text. We experiment with 50, 100, 200, 300, 400, and 500 topics.

The settings of the GloVe and CBOW models reflect the results of these methods in their original publications (Pennington et al., 2014; Mikolov et al., 2013). The detailed settings of all these methods are shown in Table 1.

We used the GloVe implementation provided on the official website<sup>3</sup>, CBOW model uses the Word2Vec<sup>4</sup> implementation and the LDA implementation comes from the MALLET (McCallum, 2002) software package.

CLUTO software package (Karypis, 2003) is used for words clustering with the  $k$ -means algorithm and cosine similarity metric. All vector space models in this paper cluster the word vectors into four different numbers of clusters: 100, 500, 1000, and 5000.

The following features are based on the word clusters created using the semantic models.

**Clusters (C)** – The occurrence of a cluster at a given position.

**Bag of Clusters (BoC)** – The occurrence of a cluster in the context window.

**Cluster Bigrams (CB)** – The occurrence of cluster bigram at a given position.

**Bag of Cluster Bigrams (BoCB)** – The occurrence of cluster bigram in the context window.

### 2.1.2 Constrained Features

**Affixes (A)** – Affix (length 2-4 characters) of a word at a given position with a frequency  $> 5$ .

**Aspect Category (AC)** – extracted aspect category. We use separately the entity, attribute, and the E#A pair.

**Aspect Target (AT)** – listed aspect target.

**Bag of Words (BoW)** – The occurrence of a word in the context window.

**Bag of Words filtered by POS (BoW-POS)** – The occurrence of a word in the context window filtered by POS tags.

**Bag of Bigrams (BoB)** – The occurrence of a bigram in the context window.

**Bag of Words around Verb (5V)** – Bag of 5 words before verb and a bag of 5 words after verb.

**Bag of 5 Words at the Beginning of Sentence (5sS)** – Bag of 5 words at the beginning of a sentence.

**Bag of 5 Words at the End of Sentence (5eS)** – Bag of 5 words at the end of a sentence.

**Bag of Head Words (BoHW)** – bag of extracted head words from the sentence parse tree.

**Emoticons (E)** We used a list of positive and negative emoticons (Montejo-Ráez et al., 2012). The feature captures the presence of an emoticon within the text.

**Head Word (HW)** – extracted head word from the sentence parse tree.

**Character N-gram (ChN)** – The occurrence of character n-gram at a given position.

**Learned Target Dictionary (LTD)** – presence of a word from learned<sup>5</sup> dictionary of aspect terms.

**Learned Target Dictionary by Category (LTD-C)**

- presence of a word from the learned dictionary<sup>5</sup> of aspect terms grouped by category.

<sup>3</sup><http://nlp.stanford.edu/projects/glove>

<sup>4</sup><https://code.google.com/p/word2vec>

<sup>5</sup>from training data

**N-gram (N)** – The occurrence of n-gram in the context window.

**N-gram Shape (NSh)** – The occurrence of word shape n-gram in the context window. We consider unigrams with frequency  $>5$  and bigrams, trigrams with frequency  $> 20$ .

**Paragraph Vectors (P2Vec)** is an unsupervised method of learning text representation (Le and Mikolov, 2014). Resulting feature vector has a fixed dimension while the input text can be of any length. The model is trained on the *One billion word benchmark* presented in (Chelba et al., 2013), resulting vectors<sup>6</sup> are used as features for a sentence. We use the implementation by Řehůřek and Sojka (2010).

**POS N-gram (POS-N)** – The occurrence of POS n-gram in the context window.

**Punctuation (P)** – The occurrence of a question mark, an exclamation mark or at least two dots in the context window.

**Skip-bigram (SkB)** – Instead of using sequences of adjacent words (n-grams) we used skip-grams (Guthrie et al., 2006; Reyes et al., 2013), which skip over arbitrary gaps. We consider skip-bigrams with 2 to 5 word skips and remove skip-grams with a frequency  $\leq 5$ .

**Target Bag of Words (T-BoW)** – BoW containing parent, siblings, and children of the target from the sentence parse tree.

**TF-IDF (TF-IDF)** – Term frequency - inverse document frequency of a word computed from the training data.

**Verb Bag of Tags (V-BoT)** – Bag of syntactic dependency tags of parent, siblings, and children of the verb from the sentence parse tree.

**Verb Bag of Words (V-BoW)** – Bag of words for parent, siblings, and children of the verb from the sentence parse tree.

<sup>6</sup>Vector dimension has been set to 300.

**Word Shape (WSh)** – we assign words into one of 24 classes<sup>7</sup> similar to the function specified in (Bikel et al., 1997).

**Words (W)** – The occurrence of word at a given position (e.g. previous word).

### 2.1.3 Unconstrained Features

**Dictionary (DL)** – presence of a word from dictionary extracted from the Annotation Guidelines for Laptops.

**Dictionary (DR)** – presence of a word from dictionary extracted from the Annotation Guidelines for Restaurants.

**Enchanted Dictionary (ED)** – presence of a word from a dictionary extracted from website<sup>8</sup>.

**Group of Words from ED (EDG)** – presence of any word from a group from the ED dictionary.

**Dictionary of Negative Words (ND)** – presence of any negative word from the negative words list<sup>9</sup>.

**Sentiment (S)** – this is a union of features dealing with sentiment. It consists of *BoG* features where the groups correspond to various sentiment lexicons. We used the following lexicon resources: Affinity lexicon (Nielsen, 2011), Senticon (Cruz et al., 2014), dictionaries from (Steinberger et al., 2012), MICRO-WNOP (Cerini et al., 2007), and the list of positive or negative opinion words from (Liu et al., 2005). Additional feature includes the output of Stanford CoreNLP (Manning et al., 2014) v3.6 sentiment analysis package by (Socher et al., 2013).

## 2.2 Phase A

**Sentence-level Category (SB1, slot 1)** We use maximum entropy classifier for all classes. Then a threshold  $t$  is used to decide which categories will be assigned by the classifier.

<sup>7</sup>We use edu.stanford.nlp.process.WordShapeClassifier with the WORDSHAPECRIS1 setting.

<sup>8</sup><http://www.enchantedlearning.com/wordlist/>

<sup>9</sup><http://dereference.blogspot.cz/2010/05/negative-ve-words-adjectives-list-for.html>

**Chinese** We used identical features for both domains (*BoB*, *BoHW*, *BoW*, *ChN*, *N*), where *ChN* ranges from unigram to 4-gram and *ChN* with frequency  $< 20$  are removed and *N* ranges from unigram to trigram and *ChN* with frequency  $< 10$  are removed. The threshold was set to  $t = 0.1$ .

**Spanish** For Spanish we used the following features: *5V*, *5eS*, *BoB*, *BoHW*, *BoW*, *BoW-POS*, *ChN*, *V-BoT*, where *5V* considers only adjective, adverb, and noun, *5eS* considers adjectives and adverbs with frequency  $> 5$ , *ChN* ranges from unigram to 4-gram and *ChN* with frequency  $< 20$  are removed, *BoW-POS* is used separately for adverbs, nouns, verbs, and a union of adjectives, adverbs, nouns, and verbs, *V-BoT* is used separately for adverbs, nouns, and a union of adjectives and adverbs while reducing feature space by 50 occurrences. The threshold was set to  $t = 0.2$ .

**English** English features employ lemmatization. The threshold was set to  $t = 0.14$ . Common features for all experiments in this task are *5V*, *5eS*, *BoB*, *BoHW*, *BoW*, *BoW-POS*, *P*, *TF-IDF*, *V-BoT*, where *5V* considers only adjective, adverb, and noun, *5eS* filters only adjective and adverb, *BoW-POS* contains adjectives, adverbs, nouns, and verbs, *V-BoT* filters adjectives and adverbs with frequency  $> 20$ .

The unconstrained model for the Laptops domain additionally uses *BoC*, *BoCB*, *DL*, *ED*, *P2Vec* *BoC* and *BoCB* include the *GloVe* and *CBOW* models computed on the *Amazon* dataset.

The constrained model for the restaurant domain additionally uses *5sS*, *ChN*, *LTD*, *LTD-C*, *P2Vec* *5sS* filters only adjective and adverb, *ChN* in this case means character unigrams with frequency  $> 5$ . This model also considers separate *BoW-POS* features for groups for adverbs, nouns and verbs.

The unconstrained model for the restaurant domain uses *BoC*, *BoCB*, *DR*, *LDA*, *ND*, *NSh* on top of the previously listed features for the constrained model.

*BoC* and *BoCB* include the *GloVe*, *CBOW*, and *LDA* models computed on the *Yelp* dataset and *CBOW* model computed on the *Opentable* dataset.

**Sentence-level Target (SB1, slot 2)** Similarly to (Brychcín et al., 2014), we have decided to use Conditional Random Fields (CRF) (Lafferty et al., 2001)

to solve this subtask. The context for this task is defined as a five word window centred at the currently processed word. English features for this subtask employ lemmatization.

The baseline feature set consists of *A*, *BoB*, *BoW-POS*, *HW*, *LTD*, *LTD-C*, *N*, *POS-N*, *V-BoT*, *W*, *WSh*. *BoW-POS* contains adjectives, adverbs, nouns, verbs, and a union of adverbs and nouns. We consider *POS-N* with frequency  $> 10$ . *V-BoT* includes adverbs, nouns, and a union of adjectives, adverbs, nouns, and verbs.

In the unconstrained model, we extend this with the semantic features *C*, *CB* (created using the *CBOW* model computed on the *opentable* dataset) and with lexicons *DR*, *EDG*.

### Sentence level Category & Target (SB1, slot 1&2)

We firstly assign targets as described above and then combine them with the best five candidates for aspect category<sup>10</sup>. We also add aspect categories without target. This produces too many combinations thus we need to filter the unlikely opinions. We remove the opinions without target in a sentence where the aspect category is already present with a target. When there is only one target and one aspect category in a sentence we combine them into a single opinion.

**Text-level Category (SB2, slot 1)** We used the baseline algorithm: the predicted sentence-level tuples (SB1, slot 1) are copied to text-level and duplicates are removed.

## 2.3 Phase B

### Sentence level Sentiment Polarity (SB1, slot 3)

Our sentiment polarity detection is based on the Maximum Entropy classifier, which works very well in many NLP tasks, including document-level sentiment analysis (Habernal et al., 2014).

**Chinese** We used identical features for both domains (*5V*, *5eS*, *5sS*, *AC*, *BoB*, *BoHW*, *BoW*, *BoW-POS*, *ChN*, *N*, *NSh*, *P*, *SkB*, *V-BoT*, *V-BoW*), where *5V* considers adjectives and adverbs with frequency  $> 5$ , *5eS* and *5sS* contain adjectives, adverbs, nouns, and verbs, *BoW-POS* is used separately for adjectives and adverbs, *ChN* ranges from unigram to 5-

<sup>10</sup>We use the same settings and approach as in the sentence-level category detection (SB1 slot 1).

gram and  $ChN$  with frequency  $< 5$  are removed,  $N$  ranges from unigram to 5-gram and  $ChN$  with frequency  $< 2$  are removed,  $V\text{-}BoT$  is used separately for verbs, and a union of adjectives and adverbs,  $V\text{-}BoW$  is used separately for adjectives, adverbs, verbs, a union of adjectives and adverbs and a union of adjectives, adverbs, nouns, and verbs, while reducing feature space by 2 occurrences.

**French** We employ lemmatization for French. The first constrained model includes the following features:  $AC$ ,  $BoB$ ,  $BoHW$ ,  $BoW$ ,  $BoW\text{-}POS$ ,  $ChN$ ,  $LTD$ ,  $LTD\text{-}C$ ,  $N$ ,  $NSh$ ,  $P$ ,  $SkB$ ,  $V\text{-}BoT$ , where  $BoW\text{-}POS$  is used separately for adjectives, adverbs and a union of adjectives, adverbs, nouns, and verbs,  $ChN$  ranges from unigram to 5-gram and  $ChN$  with frequency  $\leq 5$  are removed,  $N$  ranges from unigram to 5-gram and  $N$  with frequency  $< 2$  are removed,  $V\text{-}BoT$  is used separately for verbs, and a union of adjectives and adverbs.

The second constrained model additionally uses  $5V$ ,  $5eS$ ,  $5sS$ ,  $AT$ ,  $T\text{-}BoW$ ,  $V\text{-}BoW$ , where  $5V$  considers only adjective and adverb,  $5eS$ ,  $5sS$  considers adjective, adverb, noun, and verb,  $T\text{-}BoW$  is used for adjectives, adverbs, nouns, and verbs,  $V\text{-}BoW$  is used separately for adjectives, adverbs, verbs, a union of adjectives and adverbs and a union of adjectives, adverbs, nouns, and verbs, while reducing feature space by 2 occurrences.

**Spanish** We employ lemmatization for Spanish. We used the following features:  $5V$ ,  $5eS$ ,  $AC$ ,  $BoB$ ,  $BoHW$ ,  $BoW$ ,  $BoW\text{-}POS$ ,  $E$ ,  $ChN$ ,  $LTD$ ,  $LTD\text{-}C$ ,  $N$ ,  $NSh$ ,  $P$ ,  $SkB$ ,  $T\text{-}BoW$ ,  $V\text{-}BoT$ ,  $V\text{-}BoW$ , where  $5V$  considers only adjective and adverb,  $5eS$  considers adjective, adverb, noun, and verb,  $BoW\text{-}POS$  is used separately for adjectives, adverbs,  $ChN$  ranges from unigram to 5-gram and  $ChN$  with frequency  $\leq 5$  are removed,  $N$  ranges from unigram to 5-gram and  $N$  with frequency  $< 2$  are removed,  $T\text{-}BoW$  is used for adjectives, adverbs, nouns, and verbs,  $V\text{-}BoT$  is used separately for verbs, and a union of adjectives and adverbs,  $V\text{-}BoW$  is used separately for adjectives, adverbs, verbs, a union of adjectives and adverbs and a union of adjectives, adverbs, nouns, and verbs, while reducing feature space by 2 occurrences.

**English** We use lemmatization in this subtask. Common features for all experiments in this task

are  $5V$ ,  $5eS$ ,  $5sS$ ,  $AC$ ,  $AT$ ,  $BoB$ ,  $BoHW$ ,  $BoW$ ,  $BoW\text{-}POS$ ,  $E$ ,  $ChN$ ,  $LTD$ ,  $LTD\text{-}C$ ,  $N$ ,  $NSh$ ,  $P$ ,  $SkB$ ,  $V\text{-}BoT$ ,  $V\text{-}BoW$ , where  $5V$  considers adjectives and adverbs,  $5eS$ ,  $5sS$  consists of adjectives, adverbs, nouns, and verbs,  $BoW\text{-}POS$  contains adjectives and adverbs,  $N$  ranges from unigram to 5-gram and  $N$  with frequency  $< 2$  are removed,  $V\text{-}BoT$  is used separately for verbs, and a union of adjectives and adverbs,  $V\text{-}BoW$  is used separately for adjectives, adverbs, verbs, a union of adjectives and adverbs and a union of adjectives, adverbs, nouns, and verbs, while reducing feature space by 2 occurrences.

The unconstrained model for the Laptops domain additionally uses  $BoC$ ,  $BoCB$ ,  $ED$ ,  $S\ BoC$  and  $BoCB$  include the `GloVe` and `CBOW` models computed on the Amazon dataset.

The constrained model for the restaurant domain additionally uses  $T\text{-}BoW$ ,  $TF\text{-}IDF$ , where  $T\text{-}BoW$  is used for adjectives, adverbs, nouns, and verbs.

The unconstrained model for the restaurant domain uses  $BoC$ ,  $BoCB$ ,  $ED$ ,  $ND$ ,  $S$  on top of the previously listed features for the constrained model.

$BoC$  and  $BoCB$  include the `GloVe` and `CBOW` models computed on the `Yelp` dataset and `CBOW` model computed on the `Opentable` dataset.

**Text-level Sentiment Polarity (SB2, slot 3)** The baseline algorithm traverses the predicted sentence-level tuples of the same category and counts the respective polarity labels (positive, negative or neutral). Finally, the polarity label with the highest frequency is assigned to the text-level category. If there are not any sentence-level tuples of the same category the polarity label is determined based on all tuples regardless of the category.

Our improved algorithm contains an additional step, that assigns polarity for cases (categories) with more than one sentence-level polarity labels. The resulting polarity is determined by the following algorithm:

```
if(catPolarity == lastPolarity){  
    assign lastPolarity;  
}else if(catPolarity == entPolarity){  
    assign entPolarity;  
}else{  
    assign CONFLICT;  
}
```

where `catPolarity` is the polarity label with the highest frequency for the given category

| Target      |      |         | Category & Target |           |           | Target    |               | Category & Target |           |           |
|             |      |         | Rank              | $F_1[\%]$ | Rank      | $F_1[\%]$ | Rank          | $F_1[\%]$         | Rank      | $F_1[\%]$ |
| Restaurants | EN   | SB1     | 1.                | 66.9      | 4.        | 41.1      | 3.            | 67.1              | 6.        | 41.1      |

**Table 2:** Achieved ranks and results (in %) by UWB for all submitted systems.

(E#A tuple), `entPolarity` is the polarity label with the highest frequency for the entity E and `lastPolarity` is the last seen polarity label for the given category. This follows our belief that the last polarity tends to reflect the final sentiment (opinion) toward the aspect category.

## 2.4 System Settings

For all experiments we use Brainy (Konkol, 2014) machine learning library.

Data preprocessing includes lower-casing and in some cases lemmatization.

We utilize parse trees, lemmatization and POS tags from the Stanford CoreNLP (Manning et al., 2014) v3.6 framework. We chose it because it has support for Chinese, English, French, and Spanish.

## 3 Results and Discussion

As shown in the Table 2 we achieved very satisfactory results especially for the constrained experiments.

In the English sentence level Laptops domain our constrained method was slightly better than the unconstrained one (by 0.6%). We believe this is not a significant deviation.

The baseline algorithm for text-level category (SB2, slot 1)<sup>11</sup> achieves an  $F_1$  score of 96.08% on the Laptops domain and 97.07% on the Restaurants domain for English. When we add the corresponding general class for the

given domain (e.g. RESTAURANT#GENERAL and LAPTOP#GENERAL) the algorithm achieves an  $F_1$  score of 96.87% on the Laptops domain and 99.75% on the Restaurants domain for English.

The baseline algorithm for text-level sentiment polarity (SB2, slot 3)<sup>11</sup> achieves an Accuracy of 86.8% on the Laptops domain and 89.6% on the Restaurants domain for English, while the improved algorithm achieves an Accuracy of 94.5% on the Laptops domain and 97.3% on the Restaurants domain for English.

## 4 Conclusion

We competed in 19 constrained experiments and won 9 of them. In the other 10 cases we have reached at worst the 4th place. Our unconstrained systems participated in 10 experiments and achieved 5 ranks ranging from the 1st to 3rd place.

In the future we aim to explore the benefits of using neural networks for sentiment analysis.

# SentiSys at SemEval-2016 Task 5: Opinion Target Extraction and Sentiment Polarity Detection

Hussam Hamdan

Aix-Marseille University

hamdan.hussam@gmail.com

## Abstract

This paper describes our contribution in Opinion Target Extraction and Sentiment Polarity sub-tasks of SemEval 2016 ABSA task. A Conditional Random Field model has been adopted for opinion target extraction. A Logistic Regression model with a weighting schema of positive and negative labels has been used for sentiment polarity. Our submission for opinion target extraction is ranked second among the constrained systems which do not use additional resources and sixth over 19 submissions among the constrained and unconstrained systems in English restaurant reviews. Our submission for Sentiment Polarity is ranked eighth over 22 submissions on the laptop reviews.

## 1 Introduction

Classifying opinion texts at document or sentence levels is not sufficient for applications which need to identify the opinion targets. Even if the document is about one entity, many applications need to determine the opinion about each aspect of the entity. A user may express a positive opinion towards a restaurant, but he may have a negative opinion towards some aspects as the ambiance. Therefore, we need to identify the aspects and determine whether the sentiment is positive, negative or neutral towards each one. This task is called Aspect-Based Sentiment Analysis or Feature-Based opinion mining as called in the early work (Hu and Liu, 2004).

Aspect-Based Sentiment Analysis is composed of four subtasks:

### 1. Opinion Target Expression Extraction

Opinion Target Expression is a linguistic expression used in a given text to refer to an aspect of the reviewed entity. This subtask aims at identifying all the aspect terms present in a given set of sentences with pre-identified entities such as restaurants, laptops. An opinion target names a particular aspect of the target entity. For example:

"I liked the service and the staff, but not the food"

"The hard disk is very noisy"

The *service*, *staff* and *food* are opinion target expressions. *hard disk* is multi-word opinion target expression which will be treated as a single term.

### 2. Aspect Sentiment Detection

Each identified opinion target has to be assigned to one of the following polarity labels: positive, negative or neutral.

For example:

Input: "I hated their fajitas, but their salads were great"

Output: {fajitas: negative, salads: positive}

### 3. Aspect Category Detection

This subtask aims at identifying the aspect categories discussed in a given sentence from a predefined set of aspect categories such as

price and food. Aspect categories are typically coarser than the opinion targets, and they do not necessarily occur as terms in a given sentence.

For example, given the set of aspect categories of restaurant entity {food, service, price, ambiance}:

”The restaurant was too expensive”

The aspect category is {price}.

”The restaurant was expensive, but the menu was great”

The aspect categories are {price, food}.

#### 4. Aspect Category Polarity

Given a set of pre-identified aspect categories such as {food, price}, this subtask aims at determining the polarity of each aspect category. For example:

”The restaurant was too expensive”

{price: negative}

”The restaurant was expensive, but the menu was great”

{price: negative, food: positive}

In this paper, we focus on Opinion Target Extraction (OTE) and Sentiment Polarity towards a target or a category. The description of each subtask is provided by ABSA organizers (Pontiki et al., 2016). For OTE, a CRF model is proposed with several groups of features including syntactic and lexical features. For polarity detection, a logistic regression classifier is trained with the weighting schema for positive and negative labels and several groups of features are extracted including lexical, syntactic, semantic and sentiment lexicon features.

The rest of this paper is organised as follows. Section 2 outlines existing work in target extraction and polarity detection. Section 3 describes our system for opinion target extraction. Polarity detection is presented in Section 4. Section 5 shows the conclusion and the future work.

## 2 Related Work

Aspect-Based Sentiment Analysis consists of several subtasks. Some studies have proposed different methods for aspect detection and sentiment polarity analysis, others have proposed joint models in order to obtain the aspect and their polarities from the same model, these last models are generally unsupervised.

The early work on opinion target detection from on-line reviews presented by (Hu and Liu, 2004) used association rule mining based on Apriori algorithm (Agrawal and Srikant, 1994) to extract frequent noun phrases as product features. For polarity detection, they used two seed sets of 30 positive and negative adjectives, then WordNet has been used to find and add the synonyms of the seed words. Infrequent product features or opinion targets had been processed by finding the noun related to an opinionated word.

Opinion Digger (Moghaddam and Ester, 2010) also used the Apriori algorithm to extract the frequent opinion targets. The kNN algorithm is applied to estimate the aspect rating scaling from 1 to 5 stands for (Excellent, Good, Average, Poor, Terrible).

Supervised methods use normally Conditional Random Fields (CRF) or Hidden Markov models (HMM). (Jin and Ho, 2009) applied a HMM model to extract opinion targets using the words and their part-of-speech tags in order to learn a model, then unsupervised algorithm for determining the opinion targets polarity using the nearest opinion word to the opinion target and taking into account the polarity reversal words (such as not).

A CRF model was used by (Jakob and Gurevych, 2010) with the following features: tokens, POS tags, syntactic dependency (if the opinion target has a relation with the opinionated word), word distance (the distance between the word in the closest noun phrase and the opinionated word), and opinion sentences (each token in the sentence containing an opinionated expression is labeled by this feature), the input of this method is also the opinionated expressions, they use these expressions for predicting the opinion target polarity using dependency parsing for retrieving the pair target-expression from the training set. (Hamdan et al., 2014; Hamdan et al.,

2015a) also applied a CRF model with different features .

Unsupervised methods based on LDA (Latent Dirichlet allocation) have been proposed. (Brody and Elhadad, 2010) used LDA to figure out the opinion targets, determined the number of topics by applying a clustering method, then they used a similar method proposed by (Hatzivassiloglou and McKeown, 1997) to extract the conjunctive adjectives, but not the disjunctive due to the specificity of the domain.

(Lin et al., 2012) proposed Joint model of Sentiment and Topic (JST) which extends the state-of-the-art topic model (LDA) by adding a sentiment layer, this model is fully unsupervised and it can detect sentiment and topic simultaneously.

(Wei and Gulla, 2010) modeled the hierarchical relation between product aspects. They defined Sentiment Ontology Tree (SOT) to formulate the knowledge of hierarchical relationships among product attributes and tackled the problem of sentiment analysis as a hierarchical classification problem. Unsupervised hierarchical aspect Sentiment model (HASM) was proposed by (Kim et al., 2013) to discover a hierarchical structure of aspect-based sentiments from unlabeled online reviews.

### 3 Opinion Target Expression (OTE)

The objective of opinion target extraction is to extract all opinion target expressions in a restaurant review, opinion target could be a word or multiple words. This extraction consists of the following steps:

#### 1. Review Segmentation

This step segments each review into sentences. In restaurant dataset, we already have the sentences.

#### 2. Sentence Tokenizing

Each sentence is tokenized to get the terms. One can consider the spaces as separators or use a more complex tokenizer. We tokenize each sentence using NTLK tokenizer<sup>1</sup> which extracts the words, numbers and punctuations.

---

<sup>1</sup><http://www.nltk.org/api/nltk.tokenize.html>

#### 3. Sentence Tagging

Each term in the sentence should be tagged in order to be presented to a tagging classifier. We choose the IOB notation for representing each sentence in the review. Therefore, we distinguish the terms at the Beginning, the Inside and the Outside of opinion target expression. For example, for the following review sentence:

*"But the staff was so horrible to us."*

Where *staff* is opinion target. The tag of each term will be:

But:O the:O staff:B was:O so:O horrible:O  
to:O us:O.

#### 4. Feature Extraction

This is the main step of opinion target extraction. For representing each term, we extract the following features:

- The term itself.
- POS: We use NLTK parser<sup>2</sup> to attach a part of speech tag to each term.
- word shape: the shape of each character in the word (capital letter, small letter, digit, punctuation, other symbol)
- word type: the type of the word (upper-case, digit, symbol, combination )
- Prefixes (all prefixes having length between one to four).
- Suffixes (all suffixes having length between one to four).
- Stop word: if the word is a stop word or not.

In addition to the previous features, we extract for each term the following features:

- The two preceding and three subsequent terms of the actual term.
- The value of each two successive features in the the range -2,2 (the previous and subsequent two terms of actual term) for the following features: term, word POS, word

---

<sup>2</sup><http://www.nltk.org/book/ch05.html>

shape, word type. For example, for POS feature we extract:

pos[-2]—pos[-1]=DT—JJ  
pos[-1]—pos[0]=JJ—NN  
pos[0]—pos[1]=NN—,  
pos[1]—pos[2]=,—C

- We also extract the value of each three successive features in the the range -1,1 for the two features: term POS and term. For example, for the feature *term* we extract:

term[-2]—term[-  
1]—term[0]=a—good—place  
term[-1]—term[0]—term[1]=good—place—,

## 5. Training Method

we have used a Conditional Random Fields (CRF) which receives the feature representation of each term in each sentence and builds a tagging model in order to use it for predicting the tags of the new sentences.

### 3.1 Experiments

The data set is extracted from restaurant reviews, provided by SemEval 2016 ABSA organisers (Pontiki et al., 2016) where each review is composed of several sentences and each sentence may contain several OTEs. CRFsuite tool is used for this experiment. This tool is fast in training and tagging (Okazaki, 2007).

Our submission is ranked second among the constrained systems and sixth over all 19 systems with the F1 score. Table 2 shows the result of our system.

| Experiment | F1 Score |
|------------|----------|
| Our System | 66.545   |
| Baseline   | 44.071   |

Table 1. The results of OTE slot.

## 4 Sentiment Polarity

For a given set of aspect terms within a sentence, we determine whether the polarity of each aspect term is positive, negative or neutral. For example, the system should extract the polarity of *fajitas* and *salads* in the following sentence: "*I hated their fajitas, but their salads were great*", *fajitas*: negative and *salads*: positive.

This sub-task can be seen as sentence level or phrase level sentiment Analysis. We should determine the polarity, which could be positive, negative, neutral. We use the system described by (Hamdan et al., 2015b). Thus,We propose to use a logistic regression classifier with weighting schema of positive and negative labels with the following features:

### - Word n-grams Features

Unigrams and bigrams are extracted for each word in the text without any stemming or stop-word removing, all terms with occurrence less than 3 are removed from the feature space.

### - Sentiment Lexicon-based Features

The system extracts four features from the manually constructed lexicons (Bing Liu Lexicon (Hu and Liu, 2004) and MPQA subjectivity Lexicon (Wilson et al., 2005)) and six features from the automatic ones (NRC Hashtag Sentiment Lexicon (Mohammad, 2012), Sentiment Lexicon (Hamdan et al., 2015b) ). For each text the number of positive words, the number of negative ones, the number of positive words divided by the number of negative ones and the polarity of the last word are extracted from manual constructed lexicons. In addition to the sum of the positive scores and the sum of the negative scores from the automatic constructed lexicons.

### - Negation Features

The rule-based algorithm presented in Christopher Potts' Sentiment Symposium Tutorial is implemented. This algorithm appends a negation suffix to all words that appear within a negation scope which is determined by the negation key and a certain punctuation. All these words are added to the feature space.

### - Brown Cluster Features

Each word in the text is mapped to its cluster in Brown clusters, 1000 features are added to feature space where each feature represents the number of words in the text mapped to each cluster. The 1000 clusters is provided in Twitter Word Clusters of CMU ARK group which were constructed from approximately 56 million tweets.

### - Category Feature

We also added the category of each OTE as a feature to the feature space.

## 4.1 Experiments

We trained a L1-regularized Logistic regression classifier implemented in LIBLINEAR, which has given good results in several papers (Hamdan et al., 2015b) (Hamdan et al., 2015a). The classifier is trained on the training data set using the previous features with the three polarities (positive, negative, and neutral) as labels. A weighting schema is adapted for each class, we use the weighting option  $-w_i$  which enables a use of different cost parameter  $C$  for different classes. Since the training data is unbalanced, this weighting schema adjusts the probability of each label. Thus we tuned the classifier in adjusting the cost parameter  $C$  of Logistic Regression, weight  $w_{pos}$  of positive class and weight  $w_{neg}$  of negative class.

We used the 1/10 of training data set for tuning the three parameters in Laptop reviews, all combinations of  $C$  in range 0.1 to 4 by step 0.1,  $w_{pos}$  in range 1 to 8 by step 0.1,  $w_{neg}$  in range 1 to 8 by step 0.1 are tested. The combination  $C=0.3$ ,  $w_{pos}=1.2$ ,  $w_{neg}=1.9$  have been chosen. Table 2 shows the results of our system on the Laptop data set. Our system is ranked eighth over 22 submissions.

| Experiment     | Accuracy |
|----------------|----------|
| <b>Laptops</b> |          |
| Our system     | 74.282   |
| Baseline       | 44.071   |

Table 2. Results of sentiment polarity in laptops reviews.

## 5 Conclusion

We have built two systems for opinion target extraction of restaurant data set, and sentiment polarity analysis for laptops. We have used supervised tagger for OTE, trained a CRF model with several features. A Logistic regression classifier is used for sentiment polarity where we adopted a weighting schema.

# COMMIT at SemEval-2016 Task 5: Sentiment Analysis with Rhetorical Structure Theory

Kim Schouten and Flavius Frasincar

Erasmus University Rotterdam

P.O. Box 1738, NL-3000 DR Rotterdam, the Netherlands

## Abstract

This paper reports our submission to the Aspect-Based Sentiment Analysis task of SemEval 2016. It covers the prediction of sentiment for a given set of aspects (e.g., subtask 1, slot 2) for the English language using discourse analysis. To that end, a discourse parser implementing the Rhetorical Structure Theory is employed and the resulting information is used to determine the context of each aspect, as well as to compute the expressed sentiment in that context by weighing the discourse relations between words. While discourse analysis yields high level linguistic information that can be used to better predict sentiment, the proposed algorithm does not yet stack up to the high-performing machine learning approaches that are commonly exploited for this task.

## 1 Introduction

With sentiment analysis being at the forefront of research, many avenues are explored to find that one new algorithm that will outperform all others. This drive towards excellence is of no surprise given the high practical value this type of algorithms have and the added value they can yield for businesses and consumers alike. This is especially true for aspect-level sentiment analysis, where sentiment scores are assigned, not to a document or sentence, but to the various characteristics, or aspects, of the entity under consideration. Such a fine-grained analysis of, for instance, products or services, can provide many useful insights into consumer thinking.

The majority of the algorithms for aspect-level sentiment analysis is centered around the use of a machine learning classifier and involves tasks such as feature construction and parameter estimation. While the past has shown that this kind of algorithms have strong performance, other directions are also explored (Schouten and Frasincar, 2016). One of these is the concept-driven approach (Cambria et al., 2015), which functions at the semantic level, built upon a layer of natural language processing components. Another direction, which is the research we describe here, is using discourse analysis to improve sentiment classification.

Discourse analysis looks at how the various text segments interact with each other. For example, in “*So even though this laptop is ugly, bulky and way overpriced, I still like it.*”, the first half of the sentence gives an explanation for the second part of the sentence. As illustrated in the above example, knowing which parts of the text are ancillary and which parts of the text form the core of the sentence can play a vital role in classifying sentiment. In this case, the sentiment for the laptop in general is positive, even though all of the discussed aspects are negative. Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) describes the various discourse units and their relations, and multiple RST parsers exist that can extract these discourse elements (Marcu, 1997; Surdeanu et al., 2015).

This research shows how one can use RST to classify aspect sentiment. The basic principles of RST are explained in Section 2. The following section showcases some related work on RST, while Section 4 describes how our pipeline is set up. The algorithm

is evaluated in Section 5, followed by conclusions and future work in Section 6.

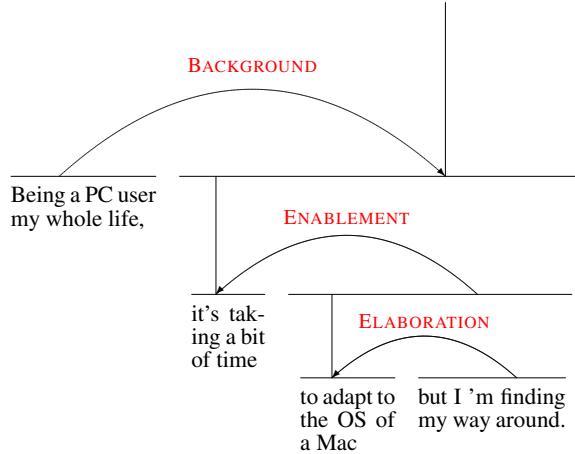

## 2 Rhetorical Structure Theory

When performing an RST analysis, the text is first split into clauses, which are called elementary discourse units (EDUs). These clauses form the basic building blocks of the discourse tree. The RST parser then postulates relations between the EDUs, selecting them from a predefined list of discourse relations. There are two basic types of relations: mononuclear and multinuclear relations. The former connects two discourse elements where one element is supporting the other, whereas the latter connects two or more discourse elements that do not have such a clear division of roles. For example, in '*I've only had mine a day but I'm already used to it...*', the part before 'but' is ancillary and is called the satellite. It supports the second clause, which is called the nucleus, by setting up a contrast. An example of a multinuclear relation is '*It is in the best condition and has a really high quality.*' In this sentence, both elements are nuclei since none of them is specifically supporting the other and they are on the same level instead. EDUs that are linked by a discourse relation together form a new clause that can be linked to another clause again. In this way, a hierarchical structure, which is called the discourse tree, can be formed that spans a whole document. In Figure 1, the discourse tree is shown for the following example.

'Being a PC user my whole life, it's taking a bit of time to adapt to the OS of a Mac but I 'm finding my way around.'

## 3 Related Work

One of the first approaches that applies RST to sentiment analysis is (Taboada et al., 2008). This work suggests to rank words within a satellite EDU differently from words that are within a nucleus EDU. Even such a simple use of discourse information already leads to a higher performance of their framework. Note that because only EDUs are used, this method only exploits information from the leafs of the discourse tree.

**Figure 1:** Full discourse tree of a simple review sentence (the curved lines denote a mononuclear relation between a nucleus and a satellite).

This is also true for the approach taken in (Heerschop et al., 2011), which uses the same split between words in a nucleus or words in a satellite. Additionally, they take the rhetorical relations these EDUs are in, into account. One of the outcomes of this research is that certain relations are more important for sentiment analysis than others. Hence, words that are in a EDU with an important relation should have a higher influence on the sentiment analysis than others. Another interesting idea was that some EDUs are in a contrasting relation and sentiment scores for words in these EDUs should be negated or flipped. In the described experiments,  $F_1$  increased with 15% compared to a baseline because of the exploitation of discourse information. Note that this approach performs sentiment analysis at the sentence level, while we are applying discourse analysis for aspect-level sentiment analysis.

Being closer to aspect-level, the method described in (Zirn et al., 2011) applies RST at the sub-sentence or clause level embedding it inside a Markov Logic Chain. The research mainly focuses on finding relations that negate the sentiment of a certain clause since this has a high impact on the total sentiment score. Compared to a Support Vector Machine baseline, the employed model shows a significant improvement.

## 4 Framework

In order to apply RST for aspect-level sentiment analysis, the discourse context of an aspect has to

be defined first, since this varies from aspect to aspect. Fortunately, we can exploit the discourse tree to select the relevant parts of the text with respect to a given aspect. Knowing the relevant parts of the sentence, the sentiment can be computed by having different weights on the various discourse relations and multiplying the sentiment scores for individual words through the relevant parts of the discourse tree, aggregating the partial scores to one final score that determines the sentiment class.

The first step consists of finding the leaf node(s) in the discourse tree that cover a given aspect. For explicit aspects, the exact position within the sentence is known (i.e., with the `from` and `to` values), so determining the relevant EDUs is straightforward. Sometimes, an aspect spans multiple EDUs. This is the case for some explicit aspects and for all implicit aspects, since the latter do not have a specific target (i.e., target is `NULL` and `from` and `to` are zero). When multiple EDUs are returned by this step, the following steps are performed for each EDU, and the final results are aggregated at the end.

Since satellites are complementing the information presented in the nuclei, it stands to reason that, when determining the sentiment of an aspect that is described in a nucleus, we also utilize the information in the satellite that supports that nucleus. On the other hand, when an aspect is described in a satellite, we do not need to include the information of its nucleus since nuclei do not add information to satellites. This information asymmetry helps us to define the context of an aspect. We can look at the discourse tree and, starting at the leaf containing the aspect, move up the tree. As long as we are encountering nuclei we need to go higher because the related satellites need to be included in the context. Hence, as soon as we arrive at a satellite node, that node will be the root of the context tree, since its related nucleus does not need to be included because of the reasons specified before. For the example in Figure 1, since the aspect ‘OS’ is in a nucleus, we go up to include its elaborating satellite, thereby arriving in a satellite node. Since the first encountered satellite node will be the root node of the context tree, we will not move up the discourse tree any further.

With the context tree available, each word is assigned a sentiment score, using the Stanford Senti-

ment Tool (Socher et al., 2013). The sentiment values are then combined using Formula 1.

$$sent(s_i) = \sum_{t_j \in s_i} sent(t_j) \times \prod_{r_n \in P_{s_i}} w_{r_n}, \forall s_i \in S_a. \quad (1)$$

where  $S_a$  is the set of leaf nodes of the context tree for aspect  $a$ ,  $sent(s_i)$  is the sentiment score corresponding to leaf node  $s_i \in S$ , and  $P_{s_i}$  denotes all edges on the path from the root node of the context tree to leaf node  $s_i$ . Furthermore,  $sent(t_j)$  is the sentiment score for word  $t_j \in s_i$  and  $w_{r_n}$  denotes the weight associated with the rhetorical role of edge  $r_n$ . These weights are obtained by running a Genetic Algorithm, optimizing for accuracy.

In the final step, all of the  $sent(s_i)$  values for a given aspect are added to arrive at a final sentiment score for each aspect, as shown in Formula 2.

$$sent(s_a) = \sum_{s_i \in S_a} sent(s_i) \quad (2)$$

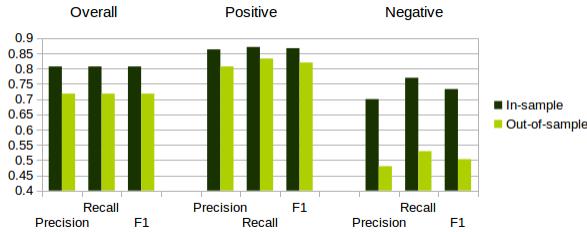

To map the sentiment score of an aspect to a class label, we use a threshold  $\epsilon$  to make the distinction between positive and negative classes. As suggested in (Heerschop et al., 2011), we compute the average sentiment score for all aspects that are positive as well as for all aspects that are negative. The  $\epsilon$  threshold is then set as the mean of those two values. This helps to avoid the sentiment bias in reviews. Note than in its current form, the algorithm is only capable of assigning a positive or a negative sentiment class to an aspect. Hence all neutral aspects will be misclassified.

## Implementation Notes

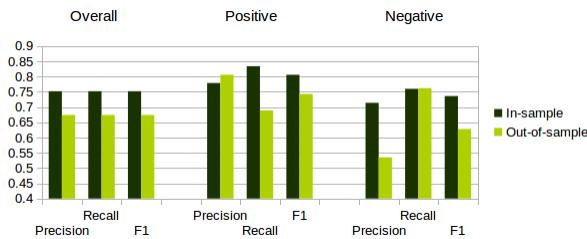

The above framework is implemented using the Stanford CoreNLP (Manning et al., 2014) pipeline, including the already mentioned sentiment component (Socher et al., 2013), together with the CLULAB (Surdeanu et al., 2015) discourse parser.

## 5 Evaluation

The evaluation is performed on a previously unseen test set by the organizers of the task. For a description of the used data sets, we refer to the task description paper (Pontiki et al., 2016). The results of this evaluation are shown in Table 1. The proposed algorithm is limited to predicting the senti-

**Figure 2:** Results on the restaurants data, specified per sentiment class.

**Figure 3:** Results on the laptops data, specified per sentiment class.

ment value only (i.e., slot 3 for subtask 1) and only operates on English.

|                          | Restaurants | Laptops |
|--------------------------|-------------|---------|
| In-sample                | 79.1%       | 77.3%   |
| 10-fold cross-validation | 76.1%       | 71.8%   |
| Official test data       | 71.8%       | 67.5%   |

**Table 1:** Results of the proposed algorithm on the two considered datasets. Note that the official results on the restaurant data set are slightly higher than in the official ranking due to a few parsing errors with HTML entities in the submitted file.

As can be seen in Table 1, the algorithm suffers from overfitting, which is caused by optimizing the weights of the various RST relation types. Interestingly, the positive class of the restaurants dataset appears to be unaffected by this overfitting, as its performance on the cross-validated training data is only 2% lower than the in-sample accuracy. This is in stark contrast to the negative class, which suffers a sharp decrease in performance when going from in-sample to cross-validation. However, even comparing the cross-validation results with the test data shows a gap in performance. This can be due to a number of reasons, where it is most likely that the test data is slightly different in terms of language usage than the training data.

Looking at the precision and recall scores for the

positive and negative class in Figures 2 and 3, we can see that on the restaurants data, the negative class is poorly predicted, with both a low precision and a low recall. The positive class, however, is performing only slightly worse than on the training data, with the biggest hit taken on the precision. For the laptops data, the situation is different. Here, both the positive and the negative class have a slightly higher recall than precision on the training data. Looking at the test data, however, shows that the algorithm predicts too many negative aspects, as the precision for the negative class plummets, but the recall stays roughly the same. For the positive class, the reverse is true: since it only predicts positive in a limited number of cases, the precision is high, but recall is much lower than on the training data.

Negative comments are more difficult to find, as evidenced by the shown performance scores, because of the greater range of expressions used for negative expressions. For example, besides using words with a known negative sentiment, people can express themselves using sarcasm or by describing some aspect and letting the reader conclude that that is sub-par.

## 6 Conclusions

This research shows how Rhetorical Structure Theory (RST) can be used for aspect-level sentiment analysis. Using discourse information when determining sentiment allows certain parts of the text to be stressed while others can be diminished in influence with respect to the sentiment computation. Optimizing the weights of the various relations with a Genetic Algorithm unfortunately leads to overfitting, reducing its effectiveness. Furthermore, we hypothesize that the rather straightforward way of multiplying sentiment through the context tree might be too simplistic. Hence, our suggestions for future work are to limit overfitting of the relation weights and to look for a more sophisticated approach to combining the sentiment scores within the context tree. A good avenue for future research is to investigate the dependence of RST methods on language usage, since the laptop data and restaurant data show such a different result when comparing in-sample and out-of-sample performance. Determining the context tree is also a subject for future research, as

we have not yet tried a full range of possibilities. Last, embedding the discourse information in a classifier like Support Vector Machines is worthy of investigation to see the effect of combining high level linguistic information with the power of statistical inference.

## Abstract

This paper describes our systems submitted to the Sentence-level and Text-level Aspect-Based Sentiment Analysis (ABSA) task (i.e., Task 5) in SemEval-2016. The task involves two phases, namely, Aspect Detection phase and Sentiment Polarity Classification phase. We participated in the second phase of both subtasks in laptop and restaurant domains, which focuses on the sentiment analysis based on the given aspect. In this task, we extracted four types of features (i.e., Sentiment Lexicon Features, Linguistic Features, Topic Model Features and Word2vec Feature) from certain fragments related to aspect rather than the whole sentence. Then the proposed features are fed into supervised classifiers for sentiment analysis. Our submissions rank above average.

## 1 Introduction

Aspect-Based Sentiment Analysis task (ABSA), i.e., task 5 in SemEval-2016, is an interesting task, which focuses on the sentiment analysis based on the target and certain categories. The organizers set up three subtasks, i.e., Sentence-level ABSA (i.e., Subtask 1), Text-level ABSA (i.e., Subtask 2), and Out-of domain ABSA (i.e., Subtask 3). For subtask 1 and 2, the training data in each domain is provided, while no labeled data is provided for subtask 3. Given an opinionated document in a domain, both subtask 1 and subtask 2 are grouped into two phases, i.e., Aspect Detection phase and Sentiment Polarity Classification phase. We participated in the second phase

of these two subtasks, aiming to identify the sentiment polarity for each given aspect which is made up of  $\langle E\#A, OTE \rangle$  in two domains.

Specifically, for Sentence-level ABSA, focusing on identifying all the opinion tuples (i.e.,  $\langle E\#A, OTE, polarity \rangle$ ) in each sentence of the reviews, the Aspect Detection phase contains two slots. The Slot1 is to identify every entity (i.e., E) and attribute (i.e., A) pair (also named as category, e.g., RESTAURANT-PRICES) according to given sentence, and the Slot2 focuses on detecting Opinion Target Expression (i.e., OTE or target in short). For example, in “*Pizza here is consistently good*”, the participants are required to recognize *Pizza* as OTE and FOOD#QUALITY as E#A. The second phase, i.e., Sentiment Polarity Classification (Slot3), is to determine the sentiment polarity (i.e., positive, negative, or neutral) for each aspect (i.e.,  $\langle E\#A, OTE \rangle$ ). As for Text-level ABSA, aiming at identifying the opinion tuples (i.e.,  $\langle E\#A, polarity \rangle$ ) expressed in each review, the Aspect Detection phase is to identify the E#A pairs and the second phase is to assign the sentiment label (positive, negative, neutral or conflict) for each detected E#A. The conflict label is assigned when the dominant sentiment of the opinion is not clear.

In previous work, (Kim et al., 2013) presented a hierarchical aspect sentiment model to classify the polarity of aspect terms from unlabeled online reviews. (Jiménez-Zafra et al., 2015) proposed a syntactic approach for identifying the words that modify each aspect. (Branavan et al., 2009; He et al., 2012; Mei et al., 2007) used topic or category information. (Saias, 2015) used a 3-class classifier and

some handcrafted features to perform ABSA. (Lin and He, 2009; Jo and Oh, 2011) presented LDA-based models, which incorporated aspect and sentiment analysis together to model sentiments towards different aspects. Unlike these work, which try to extract features from the whole sentence, we propose a method which just takes certain fragments related to the given aspect from the sentence into consideration to perform feature engineering for the ABSA task.

The rest of this paper is structured as follows. In Section 2, we describe our system in details, including motivation, preprocessing, feature engineering, evaluation metric and algorithm, etc. Section 3 reports data sets, experiments and result discussion. Finally, Section 4 concludes our work.

## 2 System Description

### 2.1 Motivation

At sentence-level ABSA, generally, a review consists of several sentences and one single sentence may contain mixed opinion tuples (i.e.,  $\langle OTE, E\#A, polarity \rangle$ ) towards different *OTE* or *E#A*. The goal of our system is to identify the polarity for each opinion tuple. We found that the given aspect is just related to certain fragments in corresponding sentence. Therefore, in order to extract features from the relevant fragments, we proposed a two-step method to acquire potential words related to given aspect as pending words for future feature extraction. This approach consists of two steps, i.e., *Segmentation Step*, which is to split each sentence into several fragments, and *Selection Step*, which selects out one or more fragments from sentence for each aspect.

Specifically, in the *Segmentation Step*, we used punctuation marks (i.e., {., ?!}) and conjunctions (i.e., {and, but}) to split the sentence into several *candidate fragments*. It is worth noting that the *OTE* is the entity or attribute words in reviews the users explicitly indicated. When there is no explicit mention of the entity, the *OTE* takes the value *NULL*. In restaurant domain, both *E#A* and *OTE* are provided in reviews, whereas only *E#A* are annotated and provided in the laptop domain, we assumed its *OTE* is *NULL*. Therefore, we adopted two strategies for *Selection Step*. In the case that the targets are provided,

we located the fragment which contains the target as *target fragment* and selected the words ranging from the prior *target fragment* (not include) to the current *target fragment* (included) as pending words. In another case that the targets are *NULL*, we automatically assigned a *target fragment* for it as follows. We firstly divided all sentences in training data into several subsets according to their attributes (i.e., *A* in *E#A*). If multiple attributes exist in the same sentence then the sentence is shared in corresponding subsets. Then we calculated the *tfidf* score for each word in each subset. Finally, we summed up the *tfidf* scores of all words in each fragment according to the attribute in given opinion. The fragment with top score is set as *target fragment*. After locating the *target fragment*, the approach to select the pending words is the same as the case that the targets are provided.

As for text-level ABSA, the opinion tuples (i.e.,  $\langle E\#A, polarity \rangle$ ) are endowed with each review rather than the sentence. Based on the statistic of the training data, we found that the labels of *E#A* in text-level are consistent with the most frequent polarity of the corresponding *E#A* in one review at sentence-level. Thus, for subtask 2 (i.e., text-level), we counted the number of positive, negative and neutral labels for each *E#A* in each review from the results of subtask 1. Then the most frequent polarity of each *E#A* is set as the label for corresponding *E#A* in each review in subtask 2.

For each domain, the participants are required to submit two runs, (1) *constrained*: only the provided data can be used; (2) *unconstrained*: any additional resources can be used. In this task, we adopted external resources, i.e., 8 sentiment lexicons and 100 billion words from Google News, to train the *Sentiment Lexicon* features and the *Word2vec* (Mikolov et al., 2013) feature. Thus, the difference between our two systems lies in these two features. For both systems, we also extracted many traditional types of features to build classifiers for classification.

### 2.2 Data Preprocessing

The original data is provided in XML format. So we first removed the XML tags from data and then transformed the abbreviations to their normal for-

mat. We used *Stanford Parser tools*<sup>1</sup> for tokenization, POS tagging and parsing. Then, the WordNet-based Lemmatizer implemented in NLTK<sup>2</sup> was adopted to lemmatize words to their base forms with the aid of their POS tags.

### 2.3 Feature Engineering

Four types of features extracted from the pending words are adopted to build the classifiers, i.e., Linguistic features, Sentiment Lexicon features, Topic Model features and Word2vec feature.

#### 2.3.1 Linguistic Features

**Word  $N$ -grams:** For all pending words, after transforming them into lowercase, we extracted the unigram, bigram, trigram and 4-gram as word  $N$ -grams features.

##### Lemmatized Word $N$ -grams:

Pending words were lemmatized by NLTK firstly, then we extracted four types of  $N$ -grams from the lemmatized form as Lemmatized Word  $N$ -grams, i.e., unigram\_L, bigram\_L, trigram\_L and 4-gram\_L.

**Word Nchars:** We recorded presence or absence of contiguous sequences of 3, 4, and 5 characters from pending words as  $N$ -chars features.

**POS:** We counted the number of nouns (the corresponding POS tags were *NN*, *NNP*, *NNS* and *NNPS*), verbs (*VB*, *VBD*, *VBG*, *VBN*, *VBP* and *VBZ*), adjectives (*JJ*, *JJR* and *JJS*) and adverbs (*RB*, *RBR* and *RBS*) in pending words as the pos feature.

**Allcaps:** It indicated the number of uppercase words in pending words.

**Elongated:** We recorded the number of the words contained the repeating characters (e.g., *sslowwwwww*) as the elongated feature.

**Punctuation:** Customers often use exclamation mark (!) and question mark (?) to express surprise or emphasis, so we recorded the number of exclamation and question marks in pending words as the punctuation features.

**Negation:** Negation comprised various kinds of devices to reverse the truth value of a proposition, thus the identification of negations is very essential. In our work, we collected 29 negations from Internet and designed this binary feature to indicate whether there is negation in pending words.

<sup>1</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

<sup>2</sup><http://nltk.org>

#### 2.3.2 Sentiment Lexicon Features

Giving the pending words, we first converted them into lowercase and then calculated five sentiment scores for each sentiment lexicon to construct *Sentiment Lexicon Features (SentiLexi)* (1) the ratio of positive words to pending words, (2) the ratio of negative words to pending words, (3) the maximum sentiment score, (4) the minimum sentiment score, (5) the sum of sentiment scores. We transformed the sentiment scores in all sentiment lexicons to the range of  $[-1, 1]$ , where “–” denotes negative sentiment. If the pending word does not exist in one sentiment lexicon, its corresponding score is set to zero. The following 8 sentiment lexicons are adopted in our systems: *Bing Liu opinion lexicon*<sup>3</sup>, *General Inquirer lexicon*<sup>4</sup>, *IMDB*<sup>5</sup>, *MPQA*<sup>6</sup>, *AFINN*<sup>7</sup>, *Senti-WordNet*<sup>8</sup>, *NRC Hashtag Sentiment Lexicon*<sup>9</sup>, *NRC Sentiment140 Lexicon*<sup>10</sup>.

#### 2.3.3 Topic Model Features

With the aid of *LDA-C tool*<sup>11</sup> with default parameter setting, we generate topic-related features from all training data as follows.

**Sent2Topic:** The *LDA* could generate the document distribution among predefined topics. We extracted this distribution as *Sent2Topic* feature.

**Top Topic word (TopTopic):** Since the topic probability of each word indicates its significance in corresponding topic, we set 20 topics and collect the top 25 words in each topic to build *TopTopic* feature.

#### 2.3.4 Word2vec Feature

**Google Word2vec (GoogleW2V):** We used the publicly available *word2vec* tool<sup>12</sup> to get word vectors with dimensionality of 300, which is trained on 100 billion words from Google News as *GoogleW2V*.

## 2.4 Evaluation Measure and Algorithm

To evaluate the performance of different systems, the official evaluation measure *accuracy* is adopted. We employ the *Logistic Regression* algorithm with the default parameter implemented in *liblinear* tools<sup>13</sup> to build the classifiers for its good performance in our preliminary experiments. The 5-fold cross validation is adopted for system development.

## 3 Experiment

### 3.1 Datasets

In restaurant domain, the opinion tuple is composed of target, category and polarity (i.e.,  $\langle OTE, E\#A, Polarity \rangle$ ). And in laptop domain, the *OTE* is not taken into account in opinion tuple (i.e.,  $\langle E\#A, Polarity \rangle$ ). The restaurant domain contains 6 entities (e.g., *AMBIENCE*, *DRINKS*, *FOOD*, *RESTAURANT*, etc) and 5 attributes (i.e., *GENERAL*, *PRICES*, *STYLE\_OPTIONS*, *QUALITY*, *PRICES*, etc). While in laptop, 22 entities (e.g., *BATTERY*, *SUPPORT*, *CPU*, *COMPANY*, etc.) and 9 attributes (e.g., *USABILITY*, *GENERAL*, *QUALITY*, etc) are tagged. Table 1 shows the statistics of the data sets used in our experiments.

| Data             | Reviews | Sentences | Opinions | Positive | Negative | Neutral | Conflict |
|------------------|---------|-----------|----------|----------|----------|---------|----------|
| Restaurant(SB1): |         |           |          |          |          |         |          |
| train            | 350     | 2,000     | 2,506    | 1,657    | 751      | 98      | 0        |
| test             | 90      | 676       | 859      | 611      | 204      | 44      | 0        |
| Laptop(SB1):     |         |           |          |          |          |         |          |
| train            | 450     | 2,500     | 2,908    | 1,634    | 1,086    | 188     | 0        |
| test             | 80      | 808       | 801      | 481      | 274      | 46      | 0        |
| Restaurant(SB2): |         |           |          |          |          |         |          |
| train            | 335     | 1,950     | 1,435    | 1012     | 327      | 55      | 41       |
| test             | 90      | 676       | 404      | 286      | 84       | 23      | 11       |
| Laptop(SB2):     |         |           |          |          |          |         |          |
| train            | 395     | 2,373     | 2,082    | 1,210    | 708      | 123     | 41       |
| test             | 80      | 808       | 545      | 338      | 162      | 31      | 14       |

**Table 1:** Statistics of training and test dataset of two subtasks in laptop and restaurant domains. *Positive*, *Negative*, *Neutral*, *Conflict* stand for the number of corresponding labels.

### 3.2 Experiments on Training data

For both laptop and restaurant domains, we adopted similar methods, i.e, employing rich features to build classifiers, and performed constrained systems and unconstrained systems respectively. Since *Sentiment lexicon* feature and *GoogleW2V* feature utilized the external data, we did not use these two types of features in the constrained system. As for

unconstrained systems, all features were employed. As for feature selection, a *hill climbing* algorithm is adopted to find out the contributions of different features, which is described as: keeping adding one type of feature at a time until no further improvement can be achieved. Table 2 shows the results of feature selection experiments for unconstrained and constrained systems in restaurant and laptop domains.

According to Table 2, it is interesting to find that (1) *3-char*, *4-char* and *negation* are beneficial to this task. The possible reason may be that there exists a lot of derivations in training data, e.g., *relax* and *relaxing*. Besides, the negator always reverses the sentiment polarity of corresponding review, which results in the good contribution of *negation* feature. (2) *SentiLexi* features are effective in two domains. In our preliminary experiments, we found that the *SentiLexi* features made great contribution to sentiment analysis task, which indicates that this type of features are indeed significant. (3) *POS* features are not quite effective in all systems. The possible reason may be that *POS* aims at identifying the subjective instances from objective ones, but the objective records just occupy a small proportion. (4) The majority of features are more valid in unconstrained system than that in constrained system. The possible reason may be that there are certain overlapped information between the *SentiLexi* features, the Word2vec feature and the other features.

In our preliminary experiments, we conducted the baseline system where features are extracted from the whole sentence without the consideration of *OTE* and *E\#A*. The result showed that the method described in section 2.1 outperformed the baseline. Thus, we used the strategy that extracting features from certain relevant fragments rather than the whole sentence for this task.

### 3.3 Results and Discussion on test data

Using the optimum feature set shown in Table 2 and the algorithm described in section 2.4, we trained separate models for each domain and evaluated them against the test set in SemEval-2016 Task 5. For both subtask 1 and 2, we constructed 4 systems for unconstrained and constrained systems in restaurant and laptop domains respectively.

From the Table 3, we find that: (1) The uncon-

<sup>13</sup><https://www.csie.ntu.edu.tw/~cjlin/liblinear/>

| Features          |             | Laptop Domain |             | Restaurant Domain |             |

## 4 Conclusion

In this paper, we extracted several types of features, i.e., *Linguistic* features, *SentiLexi* features, *Topic Model* features and *Word2vec* feature, and employed the Logistic Regression classifier to detect the sen-

timent polarity in given aspect for reviews. Moreover, we have demonstrated a two-step approach to acquire the pending words from the relevant fragments instead of the whole sentences for feature extraction. This enables the system to capture the relationship between the sentiment of the sentence and its opinion adherent. The results on test and training data showed the effectiveness of our method for the ABSA task. For the future work, it would be interesting to explore domain-specific sentiment lexicons to improve the performance and examine more advanced ways of using sentiment lexicons and word embedding features.

## Abstract

This paper describes our system for aspect-based sentiment analysis (ABSA). We participate in Subtask 1 (sentence-level ABSA), focusing specifically on aspect category detection. We train a binary classifier for each category. This year’s addition of multiple languages makes language-independent approaches attractive. We propose to utilize neural networks which should be capable of discovering linguistic patterns in the data automatically, thereby reducing the need for language-specific tools and feature engineering.

## 1 Introduction

Aspect-based sentiment analysis (ABSA) refers to the identification of specific entities and their aspects (aspect terms, opinion targets) in text and to the classification of their polarity. Typically, ABSA is applied to user reviews from various fields, such as consumer electronics, hotels or restaurants. In ABSA, we assume that the general target of evaluation has several aspects (e.g. food quality for restaurants) and we attempt to identify users’ opinions on these individual aspects. Unlike the more general task of sentiment analysis where the goal would be to classify the polarity of entire sentences (or even whole reviews), in ABSA, we need to take a more fine-grained approach and consider also the internal structure of the given sentences.

As for the sentence-level ABSA, the aim is to identify all opinion tuples present in the sentence, taking into account the context of the whole review.

In our work, we focus on identifying aspect term categories; these are composed of entities (e.g. FOOD) and their attribute labels (e.g. QUALITY or PRICE). Both the entities and the attribute labels were assigned based on predefined inventories.

We apply our method on several languages covering the following domains:

- Arabic: hotels
- Dutch: restaurants
- English: consumer electronics and restaurants
- French: restaurants
- Russian: restaurants
- Spanish: restaurants
- Turkish: restaurants

Our submission was the best system for Russian and Turkish but did not achieve noteworthy results in other domains/languages.

## 2 Related Work

The previous results for different ABSA SemEval tasks are discussed in Pontiki et al. (2014) and Pontiki et al. (2015). So far, most researchers in the field have focused on traditional machine learning approaches, such as various probabilistic methods (see Agarwal and Mittal (2016)), and/or employed deterministic methods, e.g. subjectivity lexicons (Taboada et al., 2011). Because more languages were added this year, approaches such as neural networks, which require less language-specific data and engineering, become attractive.

Neural networks have been used for sentiment analysis. Particularly, in last year’s SemEval Twitter sentiment classification task, several submissions applied convolutional networks (Toh and Su, 2015; Ebert et al., 2015). In our work, we use recurrent networks instead. Our motivation for this decision is that for aspect identification, syntactic relationships and long-distance dependencies may play a significant role and that such phenomena may be better modeled with a recurrent network. Furthermore, our recurrent network could easily be adapted to perform sequence labeling instead of sentence level classification – this would allow us to identify the exact position in the sentences where the aspect was mentioned.

### 3 System Description

Our system addresses Subtask 1 – sentence-level ABSA. Within the subtask, we focus on Slot 1, i.e. aspect category detection. For each sentence, our goal is to identify all aspect categories which are mentioned. Each category is composed of an entity E (e.g. FOOD or SERVICE) and its attribute A (e.g. QUALITY or PRICE). We do not decompose this definition and treat each category independently, effectively reducing the task to many binary classification subtasks (one for each E#A pair).

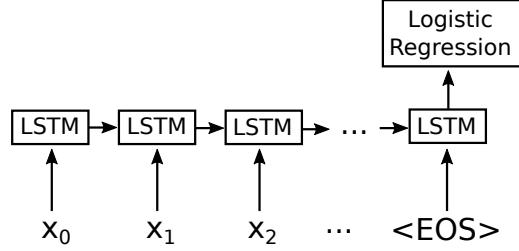

Each classifier in our system is a deep recurrent neural network with Long Short-Term memory cells (LSTM, Hochreiter and Schmidhuber (1997)). LSTMs have been designed to overcome the vanishing gradient problem present in standard recurrent neural networks. Their ability to remember information over many time steps should enable them to capture long-term dependencies in the data.

Our network encodes the input sentence word by word and at the end produces a binary classification decision based on the representation of the full sentence.

#### 3.1 Word Representations

We represent each word (token) on the input by its pre-trained word embedding (and we do not further optimize the embeddings when training the network).

For each language, we use the current dump of

**Figure 1:** Architecture of our network (a single binary classifier).

Wikipedia<sup>1</sup> as training data for the word embeddings. We use WikiExtractor<sup>2</sup> to extract plain text from the dump. We run a sentence splitter and we tokenize the sentences. Table 1 shows statistics of the data for each language.

| Language | Sentences (M) | Tokens (M) |
|----------|---------------|------------|
| English  | 97.0          | 2103       |
| French   | 26.2          | 633        |
| Spanish  | 20.5          | 505        |
| Russian  | 18.9          | 347        |
| Dutch    | 15.4          | 252        |
| Turkish  | 3.9           | 60         |
| Arabic   | 3.1           | 63         |

**Table 1:** Sizes of Wikipedia dumps for each language.

We train the representations using word2vec<sup>3</sup> with continuous bag of words as the underlying model. We set the embedding size to 200.

#### 3.2 Network Architecture

Our network is essentially a deep LSTM encoder followed by a logistic regression layer with two output classes (neurons). For each sentence, we go over the input word by word and provide the embeddings of the tokens to the input layer. The hidden LSTM layers maintain a state at each step which encodes the (partial) sentence. After the final token, we input an artificial end-of-sentence token which signals the network to output a classification decision on the final layer. Depending on the activation of the

<sup>1</sup><http://wikipedia.org/>, we retrieved the current dumps on January 6, 2016.

<sup>2</sup>[http://medialab.di.unipi.it/wiki/Wikipedia\\_Extractor](http://medialab.di.unipi.it/wiki/Wikipedia_Extractor)

<sup>3</sup><https://code.google.com/archive/p/word2vec/>

two output neurons, we either classify the instance as positive (i.e. containing the given E#A pair) or negative.

Figure 1 shows an illustration of the architecture. We initially experimented with a single LSTM layer but stacking several layers lead to improved accuracy. All of the networks used in the final submission share an identical architecture consisting of an input layer (word2vec embeddings, size 200) followed by three LSTM layers (64, 32 and 32 cells) and the final layer with two neurons. We did not experiment with tuning a decision threshold; we simply assign the class (positive or negative) which has the higher probability according to the network. We implement the networks in Chainer,<sup>4</sup> an open-source framework for neural networks.

### 3.3 Training

We evaluated several optimization algorithms and found that Adam (Kingma and Ba, 2014) lead to the fastest convergence. We also use gradient clipping as described in Pascanu et al. (2012): when the L2 norm of the gradients increases over a given threshold (which we set to 1), gradients are rescaled to fit within that norm. We also found dropout (Srivastava et al., 2014) to improve the results and we utilize it in all LSTM layers with the probability set to 0.5.

When training, we use cross-validation and measure held-out accuracy to detect overfitting. We found that even though training error (almost) monotonically decreases, held-out performance tends to be rather unstable. Moreover, many classes are rare and the held-out set may therefore only contain a handful of positive instances. We were not able to mitigate this instability which made it difficult to choose the final model.

Nonetheless, we decide how many training iterations to run based on cross-validation; we measure the average f-measure over the folds for each iteration and then choose the iteration with the highest average.

## 4 Results

In this section, we present and discuss the obtained results. We compare a number of systems for each language and domain.

<sup>4</sup><http://chainer.org/>

**Official Baseline.** We report the results of the official baseline (provided by the task organizers). The official baseline is an SVM classifier with bag-of-words features which assigns a positive label to a sentence if the predicted probability is above a certain threshold.

**Baseline.** We also implement our own baseline. We use a simple logistic regression model and, similarly to the submitted system, we train a binary classifier for each category. We only use bag of words as features; we do not include any other information (such as morphological analysis or subjectivity lexicon features). We use L2 regularization with weight 1 for all models. Our motivation for including this baseline is to provide a direct comparison with a simpler model trained in a similar way as the neural network.

**Submitted.** The system as submitted for the official evaluation. Due to the number of networks that we had to train, we were not able to fully optimize all of them before the submission deadline. In some cases, we therefore use models trained only on a handful of iterations over the training data.

**Optimized.** We report the results of the fully optimized system separately. These results were obtained after the deadline. In this case, all models were selected based on cross-validation as described in Section 3.3.

**Best.** To put the performance of our system into context of the state of the art, we also report the scores of the best system for each language and domain.

## 4.1 Discussion

We evaluate our system using the toolkit provided by the organizers of the task. Table 2 shows all our results. The best result for each data set (excluding the winning system) is marked in bold. Asterisks mark the cases where our system won.

Concerning baselines, we observe that our implementation is often substantially better than the official baseline. This does not hold for the restaurants domain in English and Turkish, and for laptops. For Turkish, we suspect that the size of the test set (144 sentences) plays a role – the scores can be unstable when test data is small. For laptops, we believe this can be attributed to the large number of possible categories in this domain; our classifiers do not use a

**Table 2:** F-measure of the baselines, the submitted system, the fully optimized system and the winning system for all domains and languages.

tuned threshold.

Our submitted systems do not always outperform the baselines. While we did win in Russian and Turkish, results in other data sets are less promising, with scores similar to the (stronger) baseline or even lower. This is a discouraging finding, especially considering the amount of additional data used in network training – word embeddings were trained on millions of sentences from Wikipedia.

However, we do observe some generalization in the outputs of the deep-learning models which is beyond the capabilities of the baseline models. For instance, our model correctly identifies the category FOOD#QUALITY in the sentence “Green Tea creme brulee is a must!”, even though this dish is not mentioned in the training data.

Our *optimized* networks do not always perform better than the submitted systems. Considering that we trained the submitted networks with fewer iterations (due to time constraints), we suspect that even with our model selection based on cross validation, overfitting may still have affected the results.

Overall, there are several possible explanations for the weak performance. Due to significant domain mismatch between Wikipedia and the data sets for the task, the trained word embeddings may not be suitable.<sup>5</sup>

Overfitting, and more generally, suboptimal setting of model (hyper)parameters, also most likely play a role.

The system design may also be problematic: we build a relatively large number of completely independent models (each doing binary classification for a single category) even though it seems clear that some parameter sharing should be possible. This problem is particularly prominent in data sets with

a large number of possible classes, such as the laptop domain. In these cases, many E#A pairs are very rare. Because we do not decompose the entity and attribute and we train separate models, our classifiers only observe a handful of positive training instances, which results in very unreliable models.

## 5 Conclusion

We described our submission to the ABSA shared task. Our system won in two categories but overall does not outperform a simple baseline solution. We believe that more careful training of the networks is required and that we may need to revise the system design. On the other hand, the deep-learning model does show some generalization power, so this direction seems promising.

### 5.1 Future Work

In the future, we are planning to try other possible network architectures. In particular, instead of our many binary classifiers we could train a single network (for each language/domain) where the final layer would have as many neurons as there are categories. This could simplify the training and perhaps make the model more robust. Especially for domains with many possible sentence labels (such as laptops), this could improve the system performance.

A natural extension of this approach would be to design the network to predict the entity and attribute separately; this could also allow for some parameter sharing between different classes.

We would also like to further investigate the issue of hyperparameter tuning and model selection.

Finally, a direct comparison with convolutional networks could also be interesting.

<sup>5</sup>We would like to thank the reviewers for this observation.

# UWaterloo at SemEval-2016 Task 5: Minimally Supervised Approaches to Aspect-Based Sentiment Analysis

Olga Vechtomova and Anni He

University of Waterloo, Canada

{ovechtmova, anni.he}@uwaterloo.ca

## Abstract

This paper describes our system for Aspect-Based Sentiment Analysis (ABSA), task 5 of SemEval 2016. To conduct sentence level ABSA, we employed minimally supervised approaches for each type of extracted information. The system uses Word2Vec to derive word semantic similarities, and relies on external review corpora as training data. The results of the 2016 evaluation are discussed and suggestions for improvements are given.

## 1 Introduction

In this paper, we describe our system for Aspect-Based Sentiment Analysis (ABSA), Task 5 of SemEval 2016. The task involves classifying consumer reviews into existing aspect category labels (slot 1), identifying the opinion target expression (OTE) corresponding to the aspect category label (slot 2), then assigning sentiment polarity expressed about the aspect category (slot 3). The aspect category (slot 1) consists of two parts: Entity (e.g. food, ambience, restaurant) and Attribute (e.g. price, quality).

Our system tackles the problem in three stages addressing each slot individually for the restaurant domain and laptop domain (slot 3 only). The strengths of the system include no lexicon resources and minimal amount of labeled corpora. For the aspect category identification and OTE extraction, the approach is semi-supervised utilizing Word2Vec models (Mikolov et al., 2013) to derive word semantic similarities. The lists of words ranked by their semantic similarities to each entity and each attribute are generated for the aspect category identification.

For the polarity assignment, we build from the approach of (Vechtomova et al., 2014) using corpora of consumer-rated electronics and restaurant reviews. The method does not require any sentiment labels at the word or sentence level or sentiment lexicons.

The paper describes each stage of the system in detail in section 2. In section 3, results of the system are presented and conclusions are drawn in section 4.

## 2 System Description

### 2.1 Corpora

At different stages of our system we used various resources we automatically generated from two corpora, described below. In both of these corpora we used only the original text of the review and the overall review ratings assigned by the consumer.

For the Restaurant domain, we used a corpus of 157,865 restaurant reviews from one of the major business review websites (Vechtomova, 2014). The collection contains reviews for 32,782 restaurants in the United States. The average number of words per review is 64.7. We will refer to this corpus as the Restaurant corpus throughout the paper.

For the Laptop domain, we used a subset of the Amazon corpus (Jindal and Liu, 2008), containing 138,504 reviews of products in the category Consumer Electronics. We will refer to this corpus as the CE corpus throughout the paper.

### 2.2 Aspect Category Detection

For this slot, the goal is to identify all entity and attribute pairs expressed by the given review sentence.

Prior to the two-stage entity and attribute identification pipeline, we obtain ranked lists of words for each entity type (entity ranked lists) and some of the attribute labels (attribute ranked lists). Extraction of OTEs by the process described in section 2.3 must be done prior to the feed into the category identification step.

We participated in Slot 1 in the Restaurant domain only. The entity ranked lists are generated from a Word2Vec model trained on the Restaurant corpus with a vocabulary size of 22118 words. The ranked lists are generated using a semi-supervised approach by using OTEs from the 2015 ABSA Restaurant training set as seed words. A list of top  $n$  similar words ( $n=500$ ) is computed for each seed word by cosine similarity, then the lists are merged to form one ranked list per entity. The top  $n$  similar words parameter is chosen empirically to be sufficiently large relative to the vocabulary size in order to generate a fair-sized merged list. A weight of 5 is applied to the seed words to boost their rank in the merged list. The similarity scores in the merged lists are normalized to a range of [0,1]. When the entity ranked lists are utilized in the entity identification step, we apply a similarity threshold of 0.05 to discard any words below the threshold. The trained Word2Vec model only detects single words, therefore the ranked lists contain no multiword phrases.

The entity identification is based on the previously extracted OTEs for each review sentence and the generated entity ranked lists from Word2Vec. For each identified OTE of each sentence, its cosine similarity score is obtained from each entity ranked list. The entity with the highest similarity to the OTE is assigned. The OTE is further tokenized if it is a MWU. Each token goes through the same entity assignment as above, then the entity with the highest similarity is assigned to the entire MWU-OTE. If the OTE does not appear in any of the ranked lists, then the OTE is discarded, and no entity or attribute is assigned.

In order to identify the attribute component of the entity-attribute pair, we first generate a set of seed words from the ABSA 2015 training set. This process is done for each entity category that has more than one attribute (e.g. FOOD, DRINKS). For every entity-attribute pair (e.g. FOOD#PRICES) we parse all sentences in the training set that are labeled with

this pair, and extract all words that have JJ (adjective) and VBN (verb, past participle) POS tags, have frequency greater than one, and have one of the following relationships with at least one noun or pronoun: adjectival modifier, relational clause modifier, nominal subject or passive nominal subject. These attribute seed words are then used to obtain a ranked list of words (attribute ranked list) using Word2Vec in a similar process as the entity ranked lists.

After an entity is identified, attributes are assigned based on the information from the review sentence. Each review sentence is tokenized, singularized with stop words removed. Intersection of all the tokens is computed with each attribute ranked list. The attribute with the highest similarity is assigned. If none of the ranked list attributes are assigned, then the attribute with the highest prior probability in the ABSA 2015 training set is assigned.

### 2.3 Extraction of Opinion Target Expressions

We approach the problem of opinion target extraction with a semi-supervised method. The opinion target expression (OTE) is Slot 2 in the ABSA task, and is only set for the Restaurant domain.

First, seed words are extracted for each Entity from the set of opinion target expressions in the ABSA 2015 training dataset. These are ranked by frequency, and top  $n$  are used. We evaluated different values for  $n$ , with 5 showing the best results on the ABSA 2015 test data. For each seed word we generate a ranked list of words using Word2Vec models, and create a merged entity ranked list as explained in Section 2.2.

The next stage in the OTE extraction process is identification of the boundaries of nominal multi-word units (MWUs) representing OTEs in the sentences. We use an algorithm developed by (Vechtomova, 2014) that builds MWUs in a bottom-up manner. Each sentence in the dataset is parsed using Stanford dependency parser (De Marneffe et al., 2006). The process begins by identifying all single nouns, which are governors in at least one syntactic dependency relation. By following a set of syntactic rules, we merge each of these nouns with the adjacent words (e.g. adjectives, other nouns) in an iterative manner, one at a time. The merging proceeds in two stages: in the first stage, the algorithm iteratively merges pairs of words that have either ad-

jectival modifier (e.g. salty fish), nominal compound modifier (e.g. garden salad), or possession modifier (e.g. Chef’s choice) dependency relationship. In the second stage, it iteratively merges pairs of words that have a prepositional modifier (e.g. fish with rice) or a conjunct (e.g. fish and chips) relationship. In addition to applying syntactic rules, before each merge, the algorithm calculates Normalized Pointwise Mutual Information (NPMI) between two strings to be merged. Only if all the syntactic rules are satisfied and the NPMI is above the specified threshold, the two strings are merged. The algorithm is described in detail in (Vechtomova, 2014). The output of this stage is a set of nominal MWUs (which may include single nouns) for each sentence.

Finally, the system calculates a score for each MWU–Entity pair by summing the scores of the matching words in the corresponding entity ranked list. If an MWU has a score ( $s$ ) of zero in all categories, it is discarded. If the score is  $0 < s < 0.1$ , the target is changed to NULL. If  $s \geq 0.1$ , it is retained as OTE.

## 2.4 Polarity Identification

We address the problem of polarity detection with an approach that only uses the texts of consumer reviews and overall review ratings assigned by consumers. The attractiveness of the method is that it does not require any sentiment lexicons or sentiment labels at the word or sentence levels. We extend a method described in (Vechtomova et al., 2014). Due to the growing popularity of online product/business reviewing, there exist vast repositories of reviews in many categories of consumer products and businesses. Most of the online review sites require users to rate products numerically on some scale (e.g. a 5-star rating scheme in Amazon). We leverage these resources in our methods. The Restaurant corpus that we used has ratings on a 10-point scale, while the CE corpus, on a 5-point scale. For the Restaurant domain we generate a set of negative reviews by pooling all reviews with ratings of 1 and 2, and a set of positive reviews by pooling all reviews with the rating of 10 from the Restaurant corpus. In the Laptop domain, reviews with ratings 1 and 2 were used for the negative set, while reviews with the rating of 5 for the positive set.

In summary, the process consists of the following

steps. First, two vectors of context features are created for each adjective or verb ( $w$ ) that has a dependency relationship with a noun or personal pronoun. One vector  $posV$  is built based on all occurrences of  $w$  in the positive set, and the second vector  $negV$  is built based on its occurrences in the negative set. Next, polarity of the occurrence of  $w$  in a previously unseen sentence  $s$  is determined by building a vector  $evalV$  based only on the context of  $w$  in  $s$ , and computing a pairwise similarity of  $EvalV$  to  $posV$  and  $negV$ .

In more detail, the following steps are performed on each of the two sets: positive and negative. Each sentence in a positive/negative set is processed by using a dependency parser in the Stanford CoreNLP package. In each sentence, we first locate all nouns or personal pronouns ( $n$ ). Then, for each  $n$ , its dependency triples with adjectives and verbs ( $w$ ) are extracted, where the dependency relation is either an adjectival modifier, nominal subject, passive nominal subject, direct object or relative clause modifier. An example of a dependency triple is  $nsubj(pizza, hot)$ , where pizza is a governor, while hot is a dependent. We also identify dependency relations of adjectival complements, clausal complements and open clause complements and merge them with the nominal subject relationship sharing the same verb, e.g.  $nsubj(menu, looks)$  and  $acomp(looks, great)$  are merged into  $nsubj\_acomp(menu, look\_great)$ .

We also created a set of rules to determine whether the context containing an instance of  $w$  is negated or not. For each occurrence of  $w$  the following information is recorded: negation (1 –  $w$  is negated; 0 –  $w$  is not negated); dependency relation of  $w$  with  $n$ ;  $w$  lemma (output by Stanford CoreNLP). These three pieces of information form a pattern  $p$ , e.g., “negation=0; amod; better”. A context feature vector ( $PosV$  and  $NegV$ ) is built for each  $p$ , as follows: for each instance of  $w$  matching this pattern in the corpus (positive or negative, respectively) we extract all dependency relations containing it. Each of them is transformed into a context feature  $f$  of the form: “lemma; Part Of Speech (POS); dependency relation”. For instance, if adjective “hot” occurs in a dependency triple  $advmod(hot, too)$ , the following feature is created to represent “too” and its syntactic role (adverbial modifier) with respect to “hot”: “too, RB, advmod”. We also build

| Pattern                        | Context   |
|--------------------------------|---|
| NEGATION=0,<br>nsubj, cold, JJ | also, RB, advmod<br>be, VBZ, cop<br>bread, NN, nsubj<br>horrible, JJ, conj_and<br>it, PRP, nsubj<br>not, RB, conj_and<br>particularly, RB, advmod<br>quickly, RB, advmod<br>tired, JJ, conj_and |

**Table 1:** Example of a Pattern and its Context Features.

composite features by joining up to four dependency relations by traversing the dependency graph.

For each  $f$  we record its frequency of co-occurrence with  $p$  (used as TF in Eq. 1). Table 1 contains an example of a pattern and a subset of its context features. The same algorithm is used to build a feature vector ( $\text{Eval}V$ ) for each pattern extracted from each sentence in the ABSA test dataset.

Next, for each pattern  $p$  found in the test sentence, we compute pairwise similarity between its  $\text{Eval}_p$  vector and  $\text{pos}V_p$  and  $\text{neg}V_p$  respectively. For the purpose of computing similarity we evaluated two similarity functions: BM25 Query Adjusted Combined Weight (QACW) (Sparck Jones et al., 2000) and TF.IDF. QACW was first used to compute term-term similarity in (Vechtomova and Robertson, 2012). The  $\text{Eval}V_p$  is treated as the query, while  $\text{pos}V_p$  and  $\text{neg}V_p$  as documents ( $V_p$  in Eq. 1)

$$\text{Sim}(\text{Eval}V_p, V_p) = \sum_{f=1}^F \frac{\text{TF}(k_1 + 1)}{K + \text{TF}} \times \text{QTF} \times \text{IDF}_f \quad (1)$$

Where:  $F$  – the number of features that  $\text{Eval}V_p$  and  $V_p$  have in common;  $\text{TF}$  – frequency of feature  $f$  in  $V_p$ ;  $\text{QTF}$  – frequency of feature  $f$  in  $\text{Eval}V_p$ ;  $K = k_1((1b) + b\text{DLAVDL})$ ;  $k_1$  – feature frequency normalization factor;  $b$  –  $V_p$  length normalization factor;  $\text{DL}$  – number of features in  $V_p$ ;  $\text{AVDL}$  – average number of features in the vectors  $V$  for all patterns  $p$  in the training set (positive or negative). The  $b$  and  $k_1$  parameters were set to 0.1 and 50 respectively, as these showed best performance on the ABSA 2016 Restaurant training dataset. The  $\text{IDF}$  (Inverse Document Frequency) of the feature  $f$  is calculated as  $\text{IDF}_f = \log(N/n_f)$ , where,  $n_f$  – number of vectors  $V$  in the training set (positive or negative) containing  $f$ ;  $N$  – total number of vectors  $V$  in the training set.

Finally, if  $\text{Sim}(\text{Eval}V_p, \text{pos}V_p) > \text{Sim}(\text{Eval}V_p,$

$\text{neg}V_p)$ , we assign positive polarity to the given instance of  $p$  in the test sentence, otherwise, negative.

Polarity detection in ABSA is done as a Phase B evaluation, i.e. after the Phase A goldset (containing OTEs and Entity-Attribute pairs) is released. The next steps differ for the Restaurant and Laptop domains, since the former has OTEs, while the latter does not.

For the Restaurant domain, for each OTE in the goldset, the method determines the majority polarity based on all  $p$  that contain the OTE or any of its words if the OTE is an MWU. If there is equal number of positive and negative cases, then neutral polarity is assigned. If no word matching OTE or any of its constituents is found by our method, then average polarity is calculated based on the current sentence. This method was also used for cases with NULL OTEs. If no words have been extracted by our method for the given sentence, then average polarity based on the entire review is calculated.

For the Laptop domain, we tried two methods. In Method 1 (submitted), the average polarity is calculated based on the entire sentence, and if no opinion words have been extracted for the given sentence, then we assign the average polarity calculated based on the entire review. In Method 2, for each Entity type in the goldset (e.g. Battery, Memory) we first built a set of related words using Word2Vec given the entity name as the seed word. Top 500 words ranked by cosine similarity to the seed word were used. For each Entity-Attribute pair in each sentence of the Phase A goldset, we first determine if any opinion target extracted by our method matches a word in the ranked list for the corresponding entity. If it does, then we assign its polarity to the corresponding Entity-Attribute tuple(s) for that sentence. If no matching word for an entity is found, then we calculate polarity based on all words that did not match any other category. If no such words exist, we default to Method 1.

### 3 Results

In this section we present results of the runs on the ABSA 2016 training and test datasets.

Tables 2 through 6 show results for entity-attribute identification and OTE extraction. The training set performs better than the test set in all

| <b>Dataset</b> | <b>Precision</b> | <b>Recall</b> | <b>F-Measure</b> |

| TRAIN 2016     | 0.6331           | 0.6676        | 0.6499           |
| TEST 2016      | 0.6100           | 0.6457        | 0.6273           |

**Table 3:** Slot 1 results (restaurant) evaluating on entity only.

three evaluations. This can be attributed to the fact that the entity/attribute ranked lists were built using Word2Vec models generated from the 2015 training set which is a subset of the 2016 training set.

Motivation of the ranked lists process stems from the minimal amount of annotated training data. It is hypothesized that the OTEs from the training data provide strong signals for entity labels. For example, if the OTE is “waiter”, then the entity is most likely “SERVICE”. Once the entity is identified, attribute labels are assigned using tokenized words in the sentence besides the OTE. It is thought that the other words in the sentences are better predictors for attribute labels. For example, the review sentence “the food was not worth the price” has OTE “food” and the entity-attribute label “FOOD#PRICES”. The attribute label can easily be determined from the word price ranked at the top of the #PRICES attribute ranked list. There are several consequences impacting the performance of the system as a result of the two-stage design as explained below.

A comparison can be made between the results for entity-attribute pair identification (Table 2) and entity-only identification (Table 3) to show progression of the system performance between the two stages. The system performs more than 10% better in the entity-only case for both test and train datasets. This is expected because attribute identification using tokenized words as features from the review sentence is less reliable than using the OTE as a single feature.

Another weakness of the system is in the aspect category identification for NULL OTEs. The en-

| <b>Dataset</b> | <b>Precision</b> | <b>Recall</b> | <b>F-Measure</b> |
|----------------|------------------|---------------|------------------|

| TEST 2016      | 0.4804           | 0.7026        | 0.5707           |

**Table 5:** Slot 2 (Opinion Target Expression) results (restaurant dataset).

| <b>Dataset</b> | <b>Precision</b> | <b>Recall</b> | <b>F-Measure</b> |
|----------------|------------------|---------------|------------------|
| TRAIN 2016     | 0.3582           | 0.3934        | 0.3750           |
| TEST 2016      | 0.3240           | 0.3667        | 0.3440           |

**Table 6:** : Slots 1&2 results (restaurant dataset).

ity/attribute ranked lists procedure is not designed for NULL targets due to the lack of OTEs. Currently the NULL target sentences require a different process whereby words in the sentence are tokenized and compared to both the entity ranked lists and attribute ranked lists to identify the label pair. The system evaluated without the NULL targets shows about a 4% improvement in F-measure for the test and train datasets. To improve the system, the NULL target aspect category identification may need to use additional features from the previous and following sentences of the review.

Table 5 shows the results of the evaluation for Slot 2 (OTE). While recall is good, the precision is not high. A better method of computing similarity between a candidate OTE and the Entity categories is needed. Also, a better method to detect NULL targets is needed. Out of 198 NULL OTEs in the test gold set, our method missed 164. As expected, the combined results of slots 1& 2 is rather poor as shown in Table 6.

Our approach to polarity identification showed promising results. QACW performed slightly better on both the training and test Restaurant datasets. As can be seen from Table 7, Method 1 in the laptop polarity task performed better than Method 2. This is likely due to the fact that using one word per entity as seed is not sufficient to generate a good set of entity-related words. In the future, it will be good to explore how to generate a better set of seed words semantically representing the entity.

In our submission for the Laptop Slot 3, we did not use features based on adjectival, clausal and open clausal complements merged with the nominal subject modifier, e.g. *nsubj\_acomp(menu, look\_great)* (for the description of features see Section 2.4). When we added these relations to the

| TEST 2016 – LAPT TF.IDF, Method 2             | 0.7066   |

**Table 7:** Slot 3 (polarity) results.

| Dataset/Method                    | Accuracy |
|-----------------------------------|----------|
| TRAIN 2016 – LAPT TF.IDF Method 1 | 0.7634   |
| TEST 2016 – LAPT TF.IDF Method 1  | 0.7316   |

**Table 8:** Slot 3(polarity) generated by adding adjectival, clausal and open clausal complements to the feature set.

feature set, the performance improved by 2.9% and 2.6% on the training and test datasets respectively (see Table 8).

One of the major reasons why the polarity method did not perform better is that we adapted a method that was designed for identifying two categories (positive and negative) to the ABSA task, which has three categories (positive, negative and neutral). This is evident when we break down the results by polarity category: the F-measure in the Restaurant domain for Positive, Negative and Neutral categories is 0.8815, 0.6439 and 0.1194 respectively. For the Laptop it is 0.8004, 0.5727 and 0 respectively. Further work is needed on better identification of neutral cases.

## 4 Conclusion

In this paper, we described our system for aspect-based sentiment analysis used for aspect category identification, extraction of opinion target expression and polarity identification. Our polarity identification method only leverages available consumer reviews with the associated overall review ratings assigned by the consumer. It does not require any sentiment lexicons or sentiment annotations in the texts of the reviews. The polarity identification and

OTE extraction showed promising results among other systems having performed within one percent of the mean scores of all participating systems in the restaurant and laptop domains. To advance our system, we identified weaknesses of the aspect category identification and hopeful next steps to improve the results by refined treatment of NULL target sentences.

## Abstract

This paper describes a weakly supervised solution for detecting stance in tweets, submitted to the SemEval 2016 Stance Task. Our approach is based on the premise that stance can be exposed as positive or negative opinions, although not necessarily about the stance target itself. Our system receives as input n-grams representing opinion targets and common terms used to denote stance (e.g. hashtags), and use these features, together with the sentiment detection solutions, to automatically compose a large training corpus. Then, it applies a supervised learning algorithm to develop a stance prediction model.

## 1 Introduction

Sentiment analysis involves the automatic identification of opinions, feelings, evaluations, attitudes and emotions expressed by people in the written language. Popular lines of work in this field are opinion mining (Liu, 2012) and emotion mining (Mohammad, 2016). Stance detection is a less explored problem, addressed as part of SemEval-2016 (International Workshop on Semantic Evaluation 2016), Task 6<sup>1</sup>. Stance detection is defined in this task as the automatic determination from text whether its author is in favor of the given target, against the given target, or whether neither inference is likely.

The present work describes the solution developed for Task 6-b, which involves the unsupervised stance detection in tweets based solely in their content. The target is Donald Trump, a possible republican presidential candidate, for which two sets of

non-annotated tweets were supplied: a domain corpus with 78,156 tweets and a test corpus with 707 tweets for task evaluation purpose. Another set of annotated tweets for stance detection was available as part of Task 6-a (supervised stance detection), which included 639 tweets about another possible candidate, Hillary Clinton. We used this annotated data to develop the proposed method, due to the similarity of problems. Details of the Task 6 can be found at (Mohammad et al., 2016).

The identification of stance can be complex even for humans (Walker et al., 2012), and our strategy was to address it partly as an opinion mining problem. Stance can be exposed as positive or negative opinions, but not necessarily about the target of the stance problem. For instance, when the opinion target is a politician, the target may be his/her agenda for health or education, members of the same party, or opponents. In addition, stance detection faces challenges common to sentiment analysis in general, such as use of vocabulary and slang specific of the media, orthography errors, sarcasm, etc.

We developed a weakly supervised method for detecting stance in tweets. Our method requires some side-related targets and key stance n-grams, which are used, together with sentiment detection solutions, to automatically label tweets with regard to a stance. The automatically labeled tweets are then used to train a classifier to detect stance in tweets, resulting in a stance prediction model.

The remaining of the paper describes the obtained results, the proposed solution and the experiments developed.

Table 1: Trump Corpus: Confusion Matrix and Metrics

## 2 Results

Task 6-b evaluated the proposed solutions according to the mean F-score of *Against* and *Favor* stances, considering the test dataset. Among 9 participants, the solution proposed by our team was the second runner-up, with a mean F-score of 42.43. Table 1 displays the confusion matrix related to the test dataset, together with the respective precision, recall and F-score metrics. The precision obtained for all classes are relatively similar, ranging from 38.18% (*Favor*) to 41.9% (*None*). However, it is clear that our solution tends to classify instances as *Against*, which explains why only the recall of this stance displays a good value (68.9%).

These results can be explained by the fact that our approach is more effective in identifying *Against* tweets when they are related to Trump or related targets, but fails to recognize endorsements to Trump when they are expressed as criticisms to his opponents. In addition, our system relies on the identification of sentiment, and the performance for identification of negative sentiment was clearly superior, compared to the detection of positive and neutral tweets, as discussed in more detail in Section 4.2. The particularly low recall obtained for the *None* class, which assumes lack of sentiment, might have influenced the other results.

## 3 The Process

Our system was developed on the premise that the stance towards a politician could be detected by analysing opinions of people tweeting explicitly about him, his party, his supporters or opponents, as well as subjects that he endorses or criticizes. As a weakly supervised solution, our system receives as input n-grams representing opinion targets (e.g. variations on the name of Trump, or his opponents), and terms frequently used to denote stance (e.g. hashtags, derogatory terms). Tweets

expressing opinions according to these characteristics could be used to automatically compose a large training corpus for a supervised approach, such that a stance prediction model could be produced. This eliminates the burden of manual annotation.

For that purpose, we developed a process for automatically detecting stance in tweets that converts a stance detection problem into a polarity detection problem, according to the following steps:

1. Stance Features Identification;
2. Rule-based Automatic Annotation of a Training Corpus;
3. Creation of a Stance Prediction Model Using Supervised Learning;
4. Stance Prediction of Unlabeled Tweets.

### 3.1 Stance Features Identification

The first step in the process was to identify n-grams that typically would indicate a stance in the domain corpus. We developed a program to extract n-grams (uni-gram, bi-grams and tri-grams) from the domain corpus, and rank them by frequency. Then, we manually inspected the most frequent n-grams (top 200), selecting the ones that directly or indirectly were related to the stance target. We divided these n-grams into two categories: *side-related targets* and *stance keywords*. Side-related targets are expressions used as the target of an opinion. Variations of “Donald Trump” (e.g. “Donald”, “Trump”) and his party are examples of the *Favor* side, whereas variations of the name of his opponents (e.g. Hilary Clinton) and subjects that compose this political platform (e.g. immigrants) are instances of the *Against* side. Table 2 shows all the side-related targets selected for Trump.

Stance keyword n-grams consist of expressions that enable to assign a stance even when the opinion target is implicit. For example, the unigram “Apprentice”, name of the TV show presented by Trump, was used in ironic tweets denoting an against stance about him, whereas the hashtag #stophillary would represent a favor stance towards Trump. Table 3 displays the stance all keyword n-grams selected for Trump.

### 3.2 Automatic labeling of a Training Corpus

The goal of this step is to automatically label tweets, so as to compose a training dataset to develop a

| Side    | Side Related Targets   |
|---------|--|
| FAVOR   | realdonaldtrump, donaldtrump, donald trump, donald, trump, republican, republicans   |
| AGAINST | hillaryclinton, hillary clinton, hilary clinton, hillary, hilary, clinton, clintons, hill, democrats, democrat, bill clinton, obama, mexicans, mexican, latino, latinos, elchap, chapo, immigrant, immigrants, immigration, mexico |

**Table 2:** Side Related Targets

| Side    | Key Stance N-grams  |
|---------|---|
| FAVOR   | stop hillary, stophillary   |
| AGAINST | love wins, lovewins, apprentice, dontvotefortrump, mr trump, racist |

**Table 3:** Key Stance N-grams

stance prediction model using supervised learning. We devised a set of rules that represent our premise about opinions characterizing the stance, displayed in Table 4. Only clearly expressed stances are considered for the training dataset (FAVOR, AGAINST and NONE), otherwise they are disregarded.

Rules 1 and 2 assume the use of stance keywords to denote positive/negative opinions, whereas rules 3-6 consider the combination of a side-related target and the positive/negative polarity of the sentiment contained in the text. Rule 7 assumes that it is unlikely that tweets without sentiments represent a stance (NONE).

We developed a program to generate for each tweet of the corpus the following features:

- Presence of at least one favor stance keyword n-gram;
- Presence of at least one against stance keyword n-gram;
- Presence of at least one favor-related target n-gram;
- Presence of at least one against-related target n-gram;
- Tweet polarity;

The program scans all tweets in the domain corpus tweets, and generates a new dataset with these features. It verifies the presence of key stance n-grams and side related targets, and evaluates tweet polarity by submitting the tweet text to three sentiment analysis APIs. Once the stance features are generated for each tweet, the rules are applied. Tweets are included in the training corpus if rules 1,

| Rule   | Stance        |
|--|---------------|
| 1 - KEY-FAVOR<br>Presence of a favor keyword n-gram with no against keyword n-gram   | FAVOR         |
| 2 - KEY-AGAINST<br>Presence of an against keyword n-gram with no favor keyword n-gram  | AGAINST       |
| 3 - FAVOR-POSITIVE<br>Presence of a favor-related side target with no against-related side target and positive tweet polarity    | FAVOR         |
| 4 - FAVOR-NEGATIVE<br>Presence of a favor-related side target with no against-related side target and negative tweet polarity    | AGAINST       |
| 5 - AGAINST-POSITIVE<br>Presence of a against side related target with no favor-related side target and positive tweet polarity  | AGAINST       |
| 6 - AGAINST-NEGATIVE<br>Presence of an against-related side target with no favor-related side target and negative tweet polarity | FAVOR         |
| 7 - NEUTRAL<br>Neutral tweet polarity  | NONE          |
| Other cases  | DISCARD TWEET |

**Table 4:** Rules used for automatic labeling

2, 3, 4, 5, 6 or 7 hold, or discarded otherwise. The resulting training dataset is composed by the original tweet texts, and the label automatically assigned to the tweet.

With the goal of increasing the precision of tweet polarity identification, we combined the results of three off-the-shelf sentiment analysis APIs, namely HP Haven On Demand<sup>2</sup>, IBM Alchemy<sup>3</sup> and Vivekn<sup>4</sup>. Each API returns the polarity property as a label (i.e. negative, positive or neutral) and the respective score property. The developed program first verifies if Haven's score and Alchemy's score are equal to zero, a condition that defines a tweet as neutral. Otherwise, the program combines the APIs by adding the three scores. The result is a negative tweet if the calculated value is negative, and positive otherwise. This particular combination was based on experiments on the use of these APIs, which are described in more details in Section 4.2.

Table 5 displays the distribution of tweets per rule considering both Trump and Hillary datasets. With regard to Trump corpus, although there were 78,156 tweets in the domain corpus supplied for the task,

<sup>2</sup><https://www.havenondemand.com/>

<sup>3</sup><http://www.alchemyapi.com/>

<sup>4</sup><http://sentiment.vivekn.com/docs/api/>

| Rule                 | Hillary    | Trump         |
|----------------------|------------|---------------|
| 1 - KEY-FAVOR        | 10         | 1             |
| 2 - KEY-AGAINST      | 96         | 1,383         |
| 3 - FAVOR-POSITIVE   | 63         | 2,295         |
| 4 - FAVOR-NEGATIVE   | 127        | 7,369         |
| 5 - AGAINST-POSITIVE | 6          | 0             |
| 6 - AGAINST-NEGATIVE | 25         | 4             |
| 7 - NEUTRAL          | 41         | 2,201         |
| Other cases          | 271        | 6,709         |
| <b>Total</b>         | <b>639</b> | <b>19,952</b> |

**Table 5:** Domain Corpus Tweets X Rule

it was possible to apply the rules only to 19,952 tweets due to quota restrictions for the free usage of Alchemy. Most tweet labeled as *Against* were detected using Rules 4 and 2, whereas most *Favor* labels were assigned due to Rule 3. It is possible to see that most tweets in Trump’s corpus were focused on Donald Trump himself and target representing support to him, and therefore, the bias related to opinions related to opposition targets, as represented by rules 5 and 6, could not be explored. The training sets resulting from application of the rules were unbalanced, with a dominance of *Against* instances. Hillary training set was composed of 229 *Against* (62%), 98 *Favor* (27%) and 41 *None* instances (11%). Trump training set was composed of 8,752 *Against* (66%), 2,300 *Favor* (17%) and 2,201 *None* instances (17%).

### 3.3 Creation of a Stance Prediction Model Using Supervised Learning

The goal of this step is to develop a stance predictive model by submitting the training dataset automatically labeled to a classification algorithm.

The training corpus generated in previous step is composed of the original tweet text and the stance label. We pre-processed the texts and submitted them to a classification algorithm for a three class problem: *Favor*, *Against* and *None*. We adopted the Weka platform (version 3.7.11) (Hall et al., 2009), and an SVM classification algorithm (SMO) available in this environment with the default parameters.

The following actions were performed during pre-processing: a) convert all tweet texts to lower case; b) replace all mentions for tweet profiles by the “a\_mention” unigram, except those containing the text of a side-related target (e.g. “realdon-

| Actual    |         | Predicted |       |       |        |
|-----------|---------|-----------|-------|-------|--------|
|           |         | Against   | Favor | None  | Recall |
| Precision | Against | 290       | 46    | 25    | 80.33  |
|           | Favor   | 45        | 55    | 12    | 49.11  |
|           | None    | 113       | 23    | 30    | 18.07  |
|           |         | 64.73     | 44.35 | 44.78 |        |
| F-score   |         | 71.69     | 46.61 | 25.75 |        |

**Table 6:** Hillary Corpus: Confusion Matrix and Metrics

aldtrump”); c) submit the text to the *Stringtoword-vector* function available in Weka for textual feature extraction and creation of the training dataset. We chose the following parameters for feature extraction: a) extraction of alphabetic unigrams and bigrams; b) removal of stopwords; c) no limitation on the number of n-grams extracted; and d) binary representation of features (i.e. presence or absence).

### 3.4 Stance Prediction of Unlabeled Tweets

The last step of the process is to predict the stance for any tweet, using the model trained in the previous step. For the Semeval task, we applied the predictive model to the provided test set, composed of 707 instances, obtaining the results displayed in Table 1.

As an experiment, we also tested the approach on the Hillary dataset provided in Task 6-a, but limited to the tweets that were discarded during the creation of the training set. The results are displayed in Table 6, which are significantly better, compared to Trump’s. In both results, it is clear that performance for the *None* class is the weakest point of our solution. Very few neutral tweets are recognized as such (recall of 16.92% and 18.07% for the Trump and Hillary datasets, respectively), compromising the precision of both *Favor* and *Against* stances.

## 4 Experiments

We made two main experiments as the basis for the proposed solution: a) verification of the impact of proposed rules with regard to the performance of the predictive model, using the Hillary labeled dataset, and b) verification of the precision of the off-the-shelf sentiment detection APIs used. These are described in the remaining of this section.

| Rules         | Class         | Automatic labeling |        |         | Predictive Model |        |         | Combined  |        |              |
|---------------|---------------|--------------------|--------|---------|------------------|--------|---------|-----------|--------|--------------|
|               |               | Precision          | Recall | F-score | Precision        | Recall | F-score | Precision | Recall | F-score      |
| (a) 1.2.7     | Against       | 85.41              | 79.61  | 82.41   | 52.45            | 95.35  | 67.67   | 58.05     | 90.86  | 70.84        |
|               | Favor         | 40.00              | 33.33  | 36.36   | 0.00             | 0.00   | 0.00    | 40.00     | 3.57   | 6.55         |
|               | None          | 36.59              | 46.88  | 41.10   | 21.74            | 3.73   | 6.37    | 31.25     | 12.05  | 17.39        |
|               | Weighted Avg. | 71.08              | 68.71  | 69.66   | 33.43            | 51.02  | 37.22   | 47.92     | 55.09  | 45.69        |
| (b) 3.4.5.6.7 | Against       | 78.20              | 66.24  | 71.72   | 58.30            | 70.59  | 63.86   | 65.26     | 68.70  | 66.94        |
|               | Favor         | 48.86              | 65.15  | 55.84   | 17.39            | 26.09  | 20.87   | 35.03     | 49.11  | 40.89        |
|               | None          | 36.59              | 38.46  | 37.50   | 50.82            | 24.41  | 32.98   | 45.10     | 27.71  | <b>34.33</b> |
|               | Weighted Avg. | 64.62              | 61.83  | 62.63   | 50.79            | 49.60  | 48.21   | 54.72     | 54.62  | 53.90        |
| (c) All rules | Against       | 81.22              | 77.18  | 79.15   | 47.49            | 86.67  | 61.36   | 64.73     | 80.33  | <b>71.69</b> |
|               | Favor         | 47.96              | 66.20  | 55.62   | 30.77            | 19.51  | 23.88   | 44.35     | 49.11  | <b>46.61</b> |

Table 7: Experiments with Hillary dataset

#### 4.1 Experiments on the Rules to Detect Stance

We experimentally developed our method using the Hillary labeled corpus provided for Task 6-a, given that both stance targets are politicians in campaign. To perform this test and assess the performance of our method, we automatically labeled the Hillary training corpus, and applied the predictive model only to the instances that were not filtered by any of the rules. Table 7 displays the results obtained according to the rules used to prepare the training dataset. We compared three different scenarios:

- (a) Stance Keywords rules (rules 1 and 2) combined with the neutral rule (rule 7);
- (b) Side-related target and polarity rules (3 to 7 rules);
- (c) All rules;

We measured the precision, recall and F-measure of the instances that were included in the training dataset (columns *Automatic labeling*), predicted instances according to the trained model (columns *Predictive Model*), and the whole set of instances labeled either using the rules or the predictive model (columns *Combined*). Scores are detailed per class and weighted average.

With regard to automatic labeling, the best weighted F-score was obtained by the set of stance keyword rules (a), i.e. 69.66, despite the poor result for the *Favor* class. However, our objective was to improve detection of *Against* and *Favor* stances, even at the expense of a less favorable result for the *None* class. Thus the set of all rules (c), which presents the second better F-score, is more interest-

ing because it yields good scores for both *Favor* and *Against* stances.

Considering the predictive model, even if the training set is less accurate using only the rules involving sentiment about a side-related target (b), the respective model yields more accurate predictions (i.e. weighted F-measure of 48.21%). However, considering the *Against* and *Favor* classes, again the set of all rules (c) produced a slightly better result.

Finally, when considering the combination of the instances labeled by the rules and the ones by the predictive model, the best results are displayed for the set of all rules (c), considering both the weighted F-measure, and the scores for the *Against* and *Favor* classes. Thus, the set of all rules presents more balanced results throughout the 2 phases of the process, yielding the best final result.

It should be noticed that the results summarized in Tables 1 and 6 for Trump and Hillary corpora, respectively, were produced differently. The test set provided for Task-b was labeled using the predictive model only, whereas the Hillary results were produced using the combined approach of rules and predictive model. Considering that Trump corpus was much bigger, compared to Hillary's, we assumed for the task that the results of the predictive model would be more accurate. By applying the combined approach over Trump test set instead, the result would be slightly better (43.8%, using the same evaluation criterion adopted for the task).

#### 4.2 The Sentiment Analysis APIs

We started the development of our solution using only Haven On Demand API but, after some tests,

we noticed issues on the precision of the polarity detection step, which is key in our process. Indeed, it can be seen in Table 5 that an elevated number of tweets is filtered by sentiment rules.

| API         | Class    | Precision | Recall | F-Score      |
|-------------|----------|-----------|--------|--------------|
| Alchemy     | Negative | 64.39     | 78.42  | 70.71        |
|             | Neutral  | 17.82     | 26.34  | <b>21.26</b> |
|             | Positive | 39.23     | 15.89  | 22.62        |
| Haven       | Negative | 46.42     | 51.28  | 48.73        |
|             | Neutral  | 16.84     | 17.20  | 17.02        |
|             | Positive | 55.97     | 46.73  | 50.93        |
| Vivekn      | Negative | 57.99     | 56.62  | 57.30        |
|             | Neutral  | 13.39     | 17.20  | 15.06        |
|             | Positive | 36.20     | 31.46  | 33.67        |
| Combination | Negative | 64.84     | 78.42  | <b>70.99</b> |
|             | Neutral  | 31.46     | 15.05  | 20.36        |
|             | Positive | 61.56     | 61.37  | <b>61.47</b> |

**Table 8:** APIs Comparison

Using a polarity annotated dataset also in the political domain<sup>5</sup> (Mohammad, 2016), we compared the performance of the 3 chosen APIs, and their combination. Results are displayed in Table 8. It can be seen that the best results for negative and neutral texts are yielded by Alchemy API, whereas Haven on Demand provides a better result for positive tweets. The major benefit obtained by the combination of the three APIs was a significant better performance with regard positive texts, given that the results for negative and neutral texts are quite similar to the use of Alchemy alone. These results reveal that all solutions perform better in the detection of negative sentiment.

The performance in sentiment identification seems to have a straightforward relationship with the results obtained in stance identification. According to Table 5, the rules that combine sentiment with Favor-related side are the most representative ones, not to mention that the only rule for identifying lack of stance is related to neutral sentiment. It is interesting to note that very similar figures can be found when we compare the F-measure of the *Combination* of solutions in Table 8, and the *Automatic labeling* scores obtained for the sentiment rules (b) in Table 7, particularly Negative/Against (70.99% and 71.72%), and Positive/Favor (61.47% and 55.84%) F-measure scores.

<sup>5</sup><http://www.purl.org/net/PoliticalTweets2012>

## 5 Conclusions and Future Work

The results obtained by the participants of SemEval Task 6 reveal that stance identification is a hard problem, for which available solutions still need to evolve. For the non-supervised task, the best result achieved the mean F-score of 56.28%, which still is not a good performance in itself. The publication of the gold standard for the task, together with the labeled datasets available for Task 6-a, will allow us to improve the process, focusing mainly in strategies for increasing the performance with regard to the Favor and None stances. Among the strategies are the improvement of polarity detection for the positive and neutral classes, increasing the automatic generated training corpus by overcoming the dependency on Alchemy (subject to quota limitations), and the investigation of a revised set of rules. Another approach would be to label instances based on social information like Twitter profiles, and the exploration of conversation threads and the connections among profiles available in the Twitter platform. We also intend to test our process using other domain corpora to explore whether the approach adopted and its underlying premise can be generalized to stance identification on other subjects.

## Abstract

In this paper, we develop a convolutional neural network for stance detection in tweets. According to the official results, our system ranks 1<sup>st</sup> on subtask B (among 9 teams) and ranks 2<sup>nd</sup> on subtask A (among 19 teams) on the twitter test set of SemEval2016 Task 6. The main contribution of our work is as follows. We design a "vote scheme" for prediction instead of predicting when the accuracy of validation set reaches its maximum. Besides, we make some improvement on the specific sub-tasks. For subtask A, we separate datasets into five sub-datasets according to their targets, and train and test five separate models. For subtask B, we establish a two-class training dataset from the official domain corpus, and then modify the softmax layer to perform three-class classification. Our system can be easily re-implemented and optimized for other related tasks.

## 1 Introduction

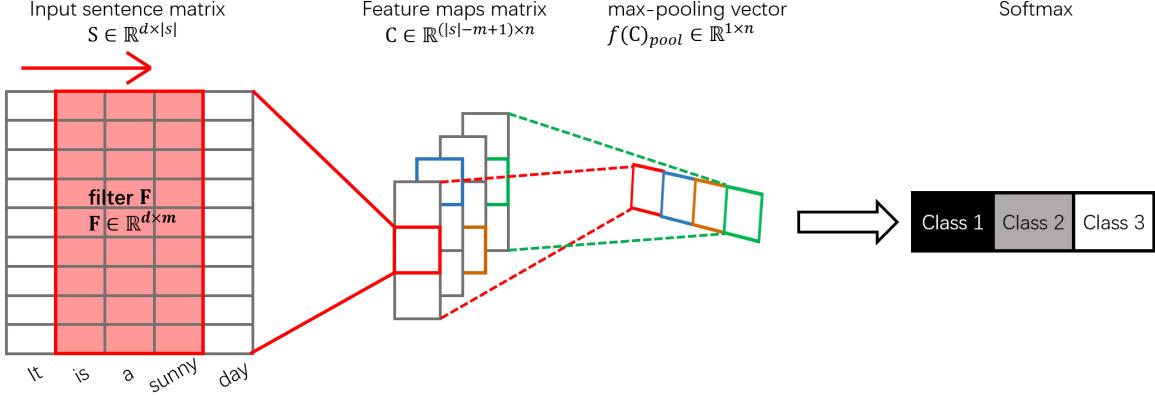

There are several requirements for stance detecting applications on the internet. However it is unpractical for humans to classify massive amounts of tweets. Twitter stance detection aims to automatically determine the emotional tendency of tweets. To classify tweets polarity, mainstream approaches are based on Pang (Pang et al., 2002), like regression problem, using machine learning algorithm to build classifiers from tweets with manually annotated polarity to classify the polarity of a tweet(Jiang et al., 2011; Hu et al., 2013; Dong et al., 2014). In this direction, most studies focus on designing effective

features to obtain better classification performance (Pang and Lee, 2008; Liu, 2012; Murakami and Raymond, 2010). For example, Mohammad (Mohammad and Turney, 2013) implements some sentiment lexicons and several manually-selected features. To leverage massive tweets containing positive and negative emoticons for automatically feature learning, Tang (Tang et al., 2014) proposes to learn sentiment-specific word embedding. We transfer this method to detect tweets stance.

In this paper, we develop a specific convolutional neural network learning model for stance detection. Firstly, we learn word embedding from Google News database as the input of our system. Afterwards, we train the CNN model with the SemEval2016 Task 6 dataset. Finally, we design a "vote scheme" using the softmax results to predict the label of test set. We also make some task specific improvement. For subtask A, we separate datasets into five sub-dataset, and train and test five separate models. For subtask B, we establish a two-class training dataset from the official domain corpus based on several special expressions. We evaluate our deep learning system on the test set of SemEval2016 Task 6. Our system ranks 1<sup>st</sup> on subtask B and 2<sup>nd</sup> on subtask A. The good performance in the Task 6 evaluation verifies the effectiveness of our model and schemes.

## 2 Architecture overview

The architecture of our convolutional neural network is mainly inspired by the architecture proposed by Kim, which performs well and efficiently in sentence classification tasks (Kim, 2014). The reason

**Figure 1:** Main architecture of our convolutional neural network.

why we base on Kim’s model is that there is much in common between stance detection task and sentence classification task when the amount and the distribution of dataset is rather reasonable. Our architecture is shown on Fig. 1.

In the following, we give a brief introduction of the main components of our network architecture in the connecting order: look-up table, input matrix, convolutional layer, activation function, pooling layer and softmax layer. We also describe the approach to train this model.

## 2.1 Look-up table

Look-up table is a huge word embedding matrix. Each column of the table, which is  $d$ -dimensional, corresponds to a word. Word embedding in the look-up table are pre-trained vectors published by word2vec team (Mikolov et al., 2013)<sup>1</sup>. These vectors are trained on part of Google News dataset (about 100 billion words).

## 2.2 Input matrix

An input matrix  $S$ ,  $S \in \mathbb{R}^{d \times |s|}$ , is the representation of an input sentence:  $[w_1, w_2, \dots, w_{|s|}]$ .  $|s|$  is the length of the sentence,  $w_i$  is the corresponding  $d$ -dimensional vector found in look-up table. If this word does not exist in the look-up table, make it a zero vector or a vector whose components are numbers randomly generated in a given range.

<sup>1</sup><https://code.google.com/archive/p/word2vec/>

## 2.3 Convolutional layer

The goal of the convolutional layer is to extract patterns, so that some common abstractive representation can be found among the dataset. Pattern means specific sequential words in a sentence. Patterns can be extracted by different filter matrixes  $F$  which are discriminatively sensitive to different patterns.

More formally, the convolution operation  $\odot$  between an input sentence matrix  $S \in \mathbb{R}^{d \times |s|}$  and a filter  $F \in \mathbb{R}^{d \times m}$ , where  $m$  is an assigned width, is defined as follow:

$$c_i = \sum (S_{[:,i:i+m-1]} \odot F),$$

where  $1 \leq i \leq |s| - m + 1$ .  $S_{[:,i:i+m-1]}$  is a matrix slice of size  $m$  along the columns and  $\odot$  is the element-wise multiplication. Both  $S$  and  $F$  have the same  $d$  rows. As shown on Fig. 1, filter  $F$  slides along the column dimension of  $S$  generating vector  $c$ :  $[c_1, c_2, \dots, c_{|s|-m+1}]$ , named feature map.

So far we have introduced how to compute a convolution between the input sentence matrix and a single filter. To get a richer representation of the dataset, we apply  $n$  filters on every input sentence matrix to compute feature maps matrix  $C$ ,  $C \in \mathbb{R}^{(|s|-m+1) \times n}$ . Note that every input sentence matrix has a corresponding  $C$  matrix and every column of matrix  $C$  corresponds to a convolution result between a filter and this input sentence matrix.

In practice, we also add a bias vector  $b \in \mathbb{R}^n$  to every row of matrix  $C$  element-wise to train a more appropriate model.

## 2.4 Activation function

To fit the non-linear boundaries better, convolutional layer is always followed by a non-linear activation function  $f()$  in practice.  $f()$  is applied element-wise on feature maps matrix  $C$ . Among the most popular choices of activation functions: sigmoid, tanh (hyperbolic tangent) and ReLU (rectified linear), we finally choose ReLU, since it is rather simple and sometimes more efficient<sup>2</sup>.

## 2.5 Pooling layer

For the purpose of simplifying the information in the output from the convolutional layer (passed through the activation function), pooling layer is used. We adopt the max-pooling method, which is choosing the maximum value from every column of  $f(C)$  ( $f()$  is the ReLU operation), to form a condensed representation vector. More formally, after the max-pooling operation,  $f(C) \in \mathbb{R}^{(|s|-m+1) \times n} \rightarrow pool(f(C)) \in \mathbb{R}^{1 \times n}$ , which is also shown on Fig. 1.

## 2.6 Output layer: softmax

The fully connected softmax layer is for classification. To a K-class dataset, the probability distribution of j-th class is as follows:

$$P(y = j|x, s, b) = \text{softmax}_j(x^T w + b)$$

$$= \frac{e^{x^T w_j + b_j}}{\sum_{k=1}^K e^{x^T w_k + b_k}},$$

where  $x$  is the input vector (the vector produced by pooling layer in our network),  $w_k$  and  $b_k$ , having the same dimensionality as the input vector  $x$ , are weight vector and bias vector of the k-th class respectively.

Softmax layer calculates the probability of each class and then chooses the class having the maximum value as the predict label.

## 2.7 Approach to train the network

The parameters trained by our network are as follows:

$$\theta = \{W; F; b; w_k; b_k\},$$

---

<sup>2</sup>Rough experiment have been done on the training set with different activation functions, since these experiment are not that thoughtful, the result will not be shown in experiment session.

where  $W$  is the word embedding of all words in dataset, including those found in the look-up table and those randomly assigned;  $F$  is the set of all the filters;  $b$  is the bias vector in the convolutional layer;  $w_k$  and  $b_k$  are the weight and the bias vector of k-th class in the softmax layer.

We use backpropagation algorithm to optimize these parameters and we adopt Adadelta (Zeiler, 2012) update rule to automatically tune the learning rate. We also opt our network by another two methods: l2-norm regularization terms for the parameters to mitigate overfitting issues and dropout scheme (Srivastava et al., 2014), which is to set the chosen value zero, to prevent feature co-adaptation.

## 3 Improvement for stance detection

In this session, we briefly introduce our improvement on the CNN architecture we described above. The improvement is task specific.

**Vote scheme.** We validate our model by cross validation method. For the models of subtask A and subtask B, we design ten parallel epochs, whose validation sets are randomly selected from the training set and non-overlap.

Different from general network, we design a "vote scheme" for prediction instead of predicting when the accuracy of validation set reaches its maximum. In each epoch, we choose some iterations deliberately to predict the test set. Then, when this epoch ends, for every sentence in the test set, we appoint the label which appears most frequently in these predictions as the result of this epoch. Finally, when ten epochs end, we vote within results of these ten epochs by the same method described above to determine the final labels.

By performing multiple times independently and voting twice, we get a rather robust mechanism for predicting.

**"divide and conquer" scheme.** For subtask A, we separate both training and test datasets respectively into five sub-datasets according to their targets, and then train and test five separate models with these divided datasets. The contrast experiment between this "divide and conquer" model and the model trained by the integral dataset is shown in Session 4.

**"2-step" scheme.** For subtask B, in the condition

| Corpus                      | Favor | Against | None | Total |
|-----------------------------|-------|---------|------|-------|
| Training Dataset            |       |         |      |       |
| Subtask A                   | 753   | 1,394   | 766  | 2,913 |
| Subtask A-Atheism           | 92    | 304     | 117  | 513   |
| Subtask A-CC <sup>1</sup>   | 212   | 15      | 168  | 395   |
| Subtask A-FM <sup>2</sup>   | 210   | 328     | 126  | 664   |
| Subtask A-HC <sup>3</sup>   | 118   | 393     | 178  | 689   |
| Subtask A-LofA <sup>4</sup> | 121   | 354     | 177  | 652   |

| Subtask B                   | 148   | 299     | 260  | 707   |

<sup>1</sup> Target "Climate Change is a Real Concern".

<sup>2</sup> Target "Feminist Movement".

<sup>3</sup> Target "Hillary Clinton".

<sup>4</sup> Target "Legalization of Abortion".

**Table 1:** Task 6 dataset.

that the official corpus is unlabeled whereas training set is necessary for our supervised model, we come up with a solution having two steps: 1. Build a two-class training dataset; 2. Modify the softmax layer to perform three-class classification on the two-class training dataset.

According to some expressions and hashtags revealing a distinct tendency, for example, "go trump" and "#MakeAmericaGreatAgain" reveal favor tendency whereas "idiot" and "fired" reveal against tendency, we finally establish a two-class training dataset, which has about 2000 favor tweets and about 3000 against tweets, from the domain corpus for subtask B (Mohammad et al., 2016). Then, we modify the softmax layer. For a test sentence, if the absolute value of the subtraction between the probability values of the two classes is less than a randomly selected real number  $\alpha$  ( $\alpha \in [0.05, 0.1]$ ), predict this sentence as "None" stance. Otherwise, predict it the class having the greater probability value.

## 4 Experiments and evaluation

**Dataset.** For subtask A, the training set is the official training data for Task A (Mohammad et al., 2016). For subtask B, the training set is described in Session 3. Details about datasets are shown in Table 1.

**Parameters setup.** Word embedding matrix is

| Corpus                         | "Divide" <sub>1</sub><br>Model | "Integral" <sub>1</sub><br>Model |
|--------------------------------|--------------------------------|----------------------------------|
| subtask A-all                  | 0.6733                         | 0.6498                           |
| subtask A-Atheism <sup>2</sup> | 0.6334                         | 0.5652                           |
| subtask A-CC <sup>2</sup>      | 0.5269                         | 0.5379                           |
| subtask A-FM <sup>2</sup>      | 0.5133                         | 0.5377                           |
| subtask A-HC <sup>2</sup>      | 0.6441                         | 0.6172                           |
| subtask A-LofA <sup>2</sup>    | 0.6109                         | 0.6098                           |

<sup>1</sup> Official metric:  $(F_{\text{favor}} + F_{\text{against}}) / 2$ .

<sup>2</sup> Abbreviation of targets. Those have been described in the footnote of Table 1.

**Table 2:** Contrast experiment results on subtask A. "Divide" refers that those results come from five separate model trained by five target corpus. "Integral" refers that those results come from one model trained by integral subtask A corpus.

described in Session 2.1, the dimensionality  $d$  is 300. We design three different width filters, 100 in width 3, 100 in width 4 and 100 in width 5, which means that there are 300 filters in total. We choose ReLU as activation function and we use max-pooling. L2-norm regularization term is set to 1e-6, the probability of dropout is set to 0.5. Bias vector  $b$ , as well as  $w_k$  and  $b_k$  in softmax layer are all set to zero vectors.

**Test result.** We perform contrast experiments on subtask A. The results of the "divide and conquer" model and its contrast integral model, as well as the five separate models are shown in Table 2. The description of these models is in Session 3. We can see from Table 2 that "divide and conquer" model does not always have a better performance. However, since the words using in the sentences which belong to the same target are expected to be more similar, the "divide" model still performs much better on some dataset (e.g. Atheism). The "divide and conquer" model is the one we submit for evaluation.

**Official ranking.** Part of the official rankings for both subtask A and B are summarized in Table 3. As we can see our model performs well on both subtasks. Our model ranks 2<sup>nd</sup> on subtask A, whose official metric is only 0.5% lower than the first team. On subtask B our model ranks 1<sup>st</sup>, and the official metric is 56.28%, about 10% higher than the second team.

| Team                         | Official Metric <sup>1</sup> | Rank |
|------------------------------|------------------------------|------|

## 5 Conclusions

We develop a specific convolutional neural network system for detecting twitter stance in this paper. We give a detailed description of our model and specific adaptation for different subtasks. Among 28 submitted systems, our system obtains good rank on both subtask A and subtask B on the test set of SemEval2016 Task 6. Our system has good scalability for other related tasks.

## 6 Future work

Due to the tight schedule, there are still many aspects need to explore. For example, why the Google news word2vec performs well in this context? How much does this word embedding improve the score compared with randomly initial word embedding? Is the more suitable word embedding exists? What's more, the vote scheme is somewhat curt, we should do more experiment to validate its robustness. Our code is available in github for anyone who has a interest in further exploration<sup>3</sup>.

## Abstract

This paper describes the University of Sheffield’s submission to the SemEval 2016 Twitter Stance Detection weakly supervised task (SemEval 2016 Task 6, Subtask B). In stance detection, the goal is to classify the stance of a tweet towards a target as “favor”, “against”, or “none”. In Subtask B, the targets in the test data are different from the targets in the training data, thus rendering the task more challenging but also more realistic. To address the lack of target-specific training data, we use a large set of unlabelled tweets containing all targets and train a bag-of-words autoencoder to learn how to produce feature representations of tweets. These feature representations are then used to train a logistic regression classifier on labelled tweets, with additional features such as an indicator of whether the target is contained in the tweet. Our submitted run on the test data achieved an F1 of 0.3270.

## 1 Introduction

Stance detection is the task of assigning stance labels to a piece of text with respect to a topic, i.e. whether a piece of text is in favour of “abortion”, neutral, or against. Previous work considered target-specific stance predictors in debates (Walker et al., 2012; Hasan and Ng, 2013) or news (Ferreira and Vlachos, 2016).

The variety of topics discussed on Twitter calls for developing methods that can generalise to any target, including targets not seen in the training data, which is the focus of Subtask B in Task 6 of SemEval 2016 (Mohammad et al., 2016). A further challenge is that

the targets are not always mentioned in the tweets, which distinguishes this task from target-dependent sentiment analysis (Zhang et al., 2015; Zhang et al., 2016), and open-domain target-dependent sentiment analysis (Mitchell et al., 2013; Vo and Zhang, 2015).

The SemEval Stance Detection task is further related to that of textual entailment (Dagan et al., 2005; Bowman et al., 2015; Lendvai et al., 2016), i.e. we judge if a hypothesis (tweet in our task) entails, contradicts or is neutral towards a textual premise (target in our task). However, the premises in typical RTE datasets offer a richer context than the stance detection targets, i.e. they are full sentences instead of topic labels such as “atheism”. Simple baselines such as textual overlap can achieve an F1 of  $>0.5$  (Bowman et al., 2015), whereas for stance detection such baselines would not perform well, as the target is only mentioned in about half the tweets.

In our approach we learn a 3-way logistic regression classifier to perform stance detection. Apart from the standard bag-of-words features commonly used in sentiment analysis, we also use features from a trained bag-of-words autoencoder similar to the one used by Glorot et al. (2011). In our experiments we show that the bag-of-words autoencoder trained on a large amount of unlabelled tweets about the targets can help generalise to unseen targets better; on our development set it achieves an 8% increase over our best baseline. Further, tweets which contain the target are easier to classify correctly than tweets which do not contain the target. Such information can be useful for stance detection and we experiment with different ways of integrating it, finding that including a binary feature “targetContainedIn-

“Tweet” outperforms including features extracted by applying the autoencoder to the target.

## 2 Method Description

At the core of our stance detection approach is a classifier trained on tweets stance-labelled with respect to a target. For this purpose we used the logistic regression classifier from scikit-learn with L2 regularisation (Pedregosa et al., 2011)<sup>1</sup>. In what follows we describe the various feature representations we used and the data pre-processing. Resources to reproduce our experiments are available on Github<sup>2</sup>.

The stages of our approach are: a) unlabelled tweets about the targets; b) preprocess the data; c) train a bag-of-word autoencoder on all task data and unlabelled collected tweets, d) apply the autoencoder to all labelled training tweets to get a fixed-length feature vector; add a “does target appear in tweet” feature; and e) train a logistic regression model and apply it to the test tweets.

### 2.1 Autoencoder Training

After tweets are tokenised, a bag-of-word autoencoder is trained on them. To do so, a vocabulary of the 50000 most frequent words is constructed. The input to the autoencoder is a vector  $input\_dim$  for each training example of size 50000. Each index  $i$  in  $input\_dim[i]$  corresponds to a word in the vocabulary,  $input\_dim[i]$  is 1 if the tweet contains the corresponding word in the vocabulary and 0 otherwise. During autoencoder training, an encoder, i.e. embedding function is learned which maps input of size  $input\_dim$  to an embedding of size  $output\_dim$ , as well as a decoder which reconstructs the input. We apply the encoder to the training and test data to obtain features of size  $output\_dim$  for supervised learning and disregard the decoder. While it would be possible to train an encoder which preserves word order, i.e. an LSTM (Li et al., 2015), we opt for a simpler bag-of-word autoencoder here, following Glorot et al. (2011).

The architecture of the autoencoder is as follows:  $input\_dim$  is 50000, it has one hidden layer of di-

mensionality 100, and  $output\_dim$  is of size 100. A dropout of 0.1 is added to the hidden layer (Srivastava et al., 2014). The autoencoder is trained with Adam (Kingma and Ba, 2014), using the learning rate 0.1, for 2600 iterations. In each iteration, 500 training examples are selected randomly.

Additional tweets are collected: 395212 tweets, tweeted between 18 November and 13 January, collected with the Twitter Keyword Search API<sup>3</sup> using up to two keywords per target (hillary, clinton, trump, climate, femini, aborti). Note that Twitter does not allow for regular expression search, so this is a free text search disregarding possible word boundaries.

### 2.2 Feature Extraction

The autoencoder is applied to the labelled data to get an 100-dimensional feature vector. For the final run, it was only applied to the tweets, but we also experiment with applying it to the target (see Section 3.2).

One additional binary feature is used for the final run, `targetInTweet`, which indicates if the name of the target is contained in the tweet. The following mapping was used for this purpose: ‘Hillary Clinton’ → ‘hillary’, ‘clinton’; Donald Trump → ‘trump’; ‘Climate Change is a Real Concern’ → ‘climate’; ‘Feminist Movement’ → ‘feminist’, ‘feminism’; ‘Legalization of Abortion’ → ‘abortion’, ‘aborting’. Further features, which are not used for the final run, are discussed in Section 3.2.

### 2.3 Preprocessing

Twitter-based tokenisation is performed with twokenize<sup>4</sup>. Afterwards, tokens are normalised to lower case and stopwords are filtered, using the nltk<sup>5</sup> English stopword list, punctuation characters, plus Twitter-specific stopwords. The latter is manually created and consists of: “rt”, “#semst”, “thats”, “im”, “s”, “...”, “via”, “http”. The first seven have to be an exact token match, the last one has to match the beginning of a token. Finally, phrases are detected, using an unsupervised method that creates 2-grams of commonly occurring expression such as “hillary clinton”, “donald trump”, “hate muslims”

<sup>1</sup>[http://scikit-learn.org/stable/modules/generated/sklearn.linear\\_model.LogisticRegression.html](http://scikit-learn.org/stable/modules/generated/sklearn.linear_model.LogisticRegression.html)

<sup>2</sup><http://github.com/sheffieldnlp/stance-semeval2016>

<sup>3</sup><https://dev.twitter.com/rest/public/search>

<sup>4</sup><https://github.com/leondz/twokenize>

<sup>5</sup><http://www.nltk.org>

(Mikolov et al., 2013)<sup>6</sup>. The phrase detection model is trained on all tweets except the test tweets. At application time, if two subsequent tokens are identified as a phrase, those tokens are merged to one token (i.e. “donald”, “trump” → “donald\_trump”).

### 3 Experiments

#### 3.1 Experimental Setup

Our development setup is to train on all labelled tweets for the targets “Climate Change is a Real Concern”, “Feminist Movement” and “Legalization of Abortion”, then evaluate on “Hillary Clinton” tweets. The motivation for this is that Hillary Clinton is the most semantically related target to the Task B test target Donald Trump, since both entities are persons and politicians. For final submission we tuned all settings with this setup, then retrained on all data and applied the model to the test data.

#### 3.2 Methods

Our goal is to determine if including the target is beneficial and if so, how best to include the it. To this end, the following features are evaluated:

- Aut-twe: the autoencoder is applied to the tweet only
- Aut-twe.tar: the autoencoder is applied to the tweet and the target, the target features are concatenated with the tweet features
- Aut-twe\*tar: the autoencoder is applied to the tweet and the target, and the outer product of the tweet and target features is used
- InTwe: A boolean “targetInTweet” feature

We evaluate the impact of traditional sentiment analysis gazetteer features, extracted by assessing appearance of each word of the tweet in the gazetteers:

- Emo: emoticon recognition<sup>7</sup> One gazetteer/binary feature for each of: happy, sad, happy+sad, not\_available
- Aff: WordNet Affect gazetteer features, one binary feature for each of: anger, disgust, fear, joy, sadness, surprise (Strapparava and Valitutti, 2004)<sup>8</sup>

|                   | AGAINST | 0.5701 | 0.7964 | 0.6645 |
|                   | Macro   |        |        | 0.4121 |

**Table 1:** Stance Detection results, reported on the development set. The best results are achieved with Aut-twe+inTwe.

In addition we experiment with substituting the bag of word autoencoder with a word2vec model trained on the same data. We trained a skip-gram model with a dimensionality of 300, 10 min words and a context of 10 with the gensim implementation of word2vec<sup>9</sup>. Word vectors are combined by multiplication to get a fixed-length sentence-level vector. We also report a bag-of-words baseline, which disregards the unlabelled data and extracts unigram and bigram bag-of-word features from the training data. For the word2vec models as well as the bag-of-words baseline, the same preprocessing as for the autoencoder approach is used.

### 4 Results

Results are reported in Tables 1 and 2 for all the experiments above, using the dev setup (Hillary Clinton) and the test setup (Donald Trump). Overall re-

<sup>9</sup><https://radimrehurek.com/gensim/models/word2vec.html>

|                   | AGAINST | 0.4107 | 0.8763 | 0.5592 |
|                   | Macro   |        |        | 0.3246 |

**Table 2:** Stance Detection results, reported on official test. The submitted run is Aut-twe+InTwe.

sults for dev are significantly better than for test, and F1 for AGAINST is consistently higher than for FAVOR. Performance increases for test with respect to baselines are much smaller than for dev. The best results for the dev set are achieved with Aut-twe+inTwe, and it was chosen for the final run on the test set. However, the best results on the test set are achieved with Aut-twe+inTwe+Emo, which is almost on par with the BoW baseline.

The feature that contributes positively to both dev and test performance is inTwe. It was introduced because almost all tweets in the training data that contain the target either FAVOR or are AGAINST the target, but are rarely neutral towards the target. 363 out of 656 Hillary Clinton dev tweets contain the target, and 309 out of 689 Donald Trump test tweets contain the target. We observed that there is a significant difference in performance between tweets containing the target and tweets which do not contain the target (see Tables 3 and 4).

| inTwe | Stance  | P      | R      | F1     |
|-------|---------|--------|--------|--------|
| Yes   | FAVOR   | 0.2830 | 0.1456 | 0.1923 |
|       | AGAINST | 0.7072 | 0.7237 | 0.7154 |
|       | Macro   |        |        | 0.4538 |
| No    | FAVOR   | 0.0714 | 0.0714 | 0.0714 |
|       | AGAINST | 0.4361 | 0.8529 | 0.5771 |
|       | Macro   |        |        | 0.3243 |

**Table 3:** Stance Detection results, reported on dev, split by tweets containing the target and not containing the target. The run used is Aut-twe+inTwe.

| inTwe | Stance  | P      | R      | F1     |
|-------|---------|--------|--------|--------|
| Yes   | FAVOR   | 0.7778 | 0.0486 | 0.0915 |
|       | AGAINST | 0.5201 | 0.8931 | 0.6574 |
|       | Macro   |        |        | 0.3745 |
| No    | FAVOR   | 0.0000 | 0.0000 | 0.0000 |
|       | AGAINST | 0.3333 | 0.8286 | 0.4754 |
|       | Macro   |        |        | 0.2377 |

**Table 4:** Stance Detection results, reported on test, split by tweets containing the target and not containing the target. The run used is Aut-twe+inTwe.

Adding autoencoder features for the target did not improve results for dev. For test, tweet features aggregated with target features slightly outperform target features on their own. As for traditional sentiment analysis features, Emo improves macro F1 for test, but not dev, and Aff does not improve macro F1 for either of them.

## 5 Conclusions and Future Work

To conclude, we showed that it is important to detect if the target is mentioned in the tweet, and that a bag-of-word autoencoder can help to detect stance towards unseen targets. Further, developing a stance detection method for new targets without any labelled training data is challenging - we found that there are some discrepancies between what features perform well for a development versus a test set. In future work we will investigate how to better incorporate the target for stance detection, as this target-dependence is crucial in capturing that the same tweet can have different stance with respect to different targets that are not mentioned in the tweet.

## Abstract

We present the IUCL system, based on supervised learning, for the shared task on stance detection. Our official submission, the random forest model, reaches a score of 63.60, and is ranked 6th out of 19 teams. We also use gradient boosting decision trees and SVM and merge all classifiers into an ensemble method. Our analysis shows that random forest is good at retrieving minority classes and gradient boosting majority classes. The strengths of different classifiers wrt. precision and recall complement each other in the ensemble.

## 1 Introduction

Stance detection is a difficult task since it often requires reasoning in order to determine whether an utterance is in favor of or against a specific issue. In the shared task (see Mohammad et al. (2016) for details about the shared task), we interpret it as a variant of sentiment analysis and adopt an approach that combines shallow lexical features with an ensemble of different supervised machine learning classifiers. Previous work has shown that using “arguing” features based on an arguing lexicon along with modal verbs and targets identified via syntactic rules (Somasundaran and Wiebe, 2010); finding polarized relations between aspects and topics (Somasundaran and Wiebe, 2009); adding semantic frames (Hasan and Ng, 2013) and contextual features (Anand et al., 2011) generally improve results. Since some of these features do not generalize across targets (Anand et al., 2011), and since we have an additional challenge in processing Twitter data, we rely on unigram features and word vectors. This means that our

approach is incapable of handling sarcasm or humor. Instead, it provides a robust basis on which we can later add more informative features.

Our approach consists of classifiers with a bag of words (unigrams) or with word vectors as features. We use three separate classifiers (SVMs, random forest, gradient boosting decision trees) and an ensemble classifier (TiMBL). Our official submission is the random forest classifier with word unigrams.

## 2 Methods

We use the data sets provided by the SemEval-2016 shared task 6 (Mohammad et al., 2016).

### 2.1 Preprocessing

Preprocessing mostly consists of tokenization. During tokenization, we normalize capitalization, and all punctuation signs are separated except for @ and #, as these symbols indicate hashtags and handles. We extract frequency counts of each token in the entire corpus and in each stance (Favor, Against, None) per target for use in the feature selection process.

We experimented with TWEEBOPARSER (Kong et al., 2014), a dependency parser specifically designed for Twitter data, to extract dependency relations among words. We extract POS tags, multi-word expressions, and dependency triples from the parses. However, due to the feature sparsity, none of them improved over unigrams. Thus, they are not used in the final systems.

### 2.2 Features

One of the major decisions in developing a machine learning system for stance detection lies in

| Model         | Features                   |
|---------------|----------------------------|
| GBDT          | GloVe word vectors         |
| random forest | unigrams + IG              |
| SVM           | unigrams + IG              |
| ensembleG     | three classifiers + global |
| ensembleNG    | three classifiers only     |

**Table 1:** Summary of features for each model. The random forest model constitutes our official submission.

the choice of features and of feature representations. Detecting stance in political tweets can be regarded as a form of sentiment analysis for short text, and we assume that different stances of tweets are partially expressed by the choice of words. For example, not mentioning any words that express a polarized attitude indicates that a tweet is most likely a None stance. Tweets are relatively short documents, we use bag of words (unigrams) since in this case bigrams and trigrams are likely to be too sparse to be informative. Another possibility would be to follow approaches in sentiment analysis and use sentiment lexicons. However, such lexicons are normally general purpose resources, and domain specific information is not included. In contrast, we need such domain specific knowledge, for example to capture the fact that “dear lord” is an indication of a negative stance towards the target Atheism while it may have a different meaning when it occurs for the target Hillary Clinton. Since unigrams include a high number of irrelevant features and also constitute a rather impoverished representation, we use feature selection as well as word vectors in our experiments.

Table 1 summarizes the features used for each of our models. We use information gain (IG) for feature selection on unigrams. Global refers to global features (see section 2.2.3). The three classifiers are GBDT, random forest, and SVM; the ensemble uses their output (predicted label and its probability).

### 2.2.1 Feature Selection

There are issues resulting from the large number of bag-of-words features: 1) Not all words are good indicators for stance; some words occur evenly across the data set. 2) Rare words, which are less likely to occur in the test data, do not contribute much. To alleviate these problems, we perform feature selection using information gain (IG). IG esti-

mates the amount of information a word gives for the decision on the stance. We choose IG because it has been shown to be robust across different sentiment analysis data sets and across different skewing ratios, compared to other feature selection methods (Liu et al., 2014). Note that different from its use in decision trees, we use IG as an external filter to select a subset of features, before and independent of any classifiers.

### 2.2.2 Word Vector Features

One limitation of bag-of-words features is that they are very sparse, and they cannot handle out-of-vocabulary words properly. Since tweets are relatively short, and the amount of official training data is small, it is likely that the out-of-vocabulary rate is high. Thus we also build models using word vectors, which represent each word with a vector of continuous values. Word vectors have been shown to capture the similarity among words and thus alleviate data sparseness (Collobert et al., 2011).

We have experimented with two different word vector models, word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). We have used the pre-trained word2vec obtained from the Google News dataset, which contains a 300-dimensional vector representation for 3 million words and phrases<sup>1</sup>, and the pre-trained GloVe, which is obtained from 2 billion tweets and has a 250-dimensional vector representation for 1.2 million words and phrases<sup>2</sup>.

To construct a representation for a tweet, we look up a word in the word vectors model, then average all vectors for words to produce a vector representation for the tweet. For example, to represent a 15 word tweet using word2vec, we first obtain a 300-dimensional vector for each word, then average all 15 vectors. This means that the word order is lost and the representation constitutes a “bag of vectors”.

**Comparing Word Vectors** We have performed a comparison of both word vector variants in a 5-fold cross validation experiment on the training data. Table 2 summarizes the results. We can see that GloVe performs consistently better than word2vec except for Feminist where word2vec is 0.6% better than

<sup>1</sup><https://code.google.com/archive/p/word2vec/>

<sup>2</sup><http://nlp.stanford.edu/projects/glove/>

| Target   | Word2vec | GloVe |
|----------|----------|-------|
| Abortion | 61.4     | 62.4  |
| Atheism  | 62.6     | 66.4  |
| Climate  | 69.9     | 71.1  |
| Feminist | 53.8     | 53.2  |
| Hillary  | 59.5     | 61.1  |

**Table 2:** Comparing word2vec and GloVe.

GloVe. We assume that this performance gap is mainly caused by the domain difference from which the word vectors are obtained: We used GloVe pre-trained on tweets and word2vec pre-trained on news. This leads to a higher number of out-of-vocabulary words for the word2vec model. In other words, GloVe provides a broader coverage for this data set.

### 2.2.3 Global Features

The bag-of-words features used in the classifiers (see section 3) assume that the words are considered independently. However, in many situations, it is the distributions of positively and negatively oriented words that determine the final stance of a tweet. A low coverage of words from these two distributions is a strong indicator for None stance as well. This is especially important for the ensemble classifier. For this reason, we have developed two additional features for the ensemble, which capture information from these two distributions: one feature for positive orientation and one for negative orientation. The feature is a numeric score, representing the association of a tweet with positive or negative stance respectively. The positive orientation is calculated based on the following equation:

$$score_T^{pos} = \frac{1}{|T|} \sum_{w \in T} \frac{freq(w) \text{ in POS}}{\sum_{w' \in V} freq(w') \text{ in POS}}$$

where  $T$  is a tweet,  $|T|$  is the tweet length excluding stop words.  $V$  is the entire vocabulary.  $freq(w)$  is the frequency count of  $w$  in the following set.  $POS$  is the set of all positive tweets. This score measures for each word (its lemma) the association with positive stance, sums up all words in the tweet, and normalizes the score by the tweet length. The score for the negative orientation is calculated accordingly.

The None orientation is not calculated since it is already represented by the absence of positively or

negatively oriented words. I.e., we assume that if a tweet has low positive and negative orientations, it indicates a None stance.

### 2.3 Adding Manually Annotated Data

We mined additional tweets for each of the five targets in Nov. 2015 by searching for hashtags relevant to the targets. These tweets are not included in the final systems since they increased the class imbalance. We will investigate better options for including the data in the future. Hashtags for Abortion include #abortion, #abortionrights, and #prolife; Atheism includes #atheism, #atheist, and #theist; Climate includes #actionclimate and #climatechange; Feminist includes #feminism, #feminist, #heforshe, and #womensrights; and Hillary includes #HillaryClinton.

Tweets were then annotated for stance, following the guidelines used for the annotation of the official shared task data<sup>3</sup>. Two annotators participated in the annotation process. The number of additional tweets ranged between 260 and 2,400 per target.

## 3 Classifiers

Since there is little research on determining the best fitting bias for stance detection, we explore three different classifiers for the stance classification, support vector machines (SVM), random forest, and gradient boosting decision trees (GBDT). For all three classifiers, we use the implementations in Scikit-Learn (Pedregosa et al., 2011).

We choose SVM because it is the most widely used machine learning model for text classification and sentiment analysis (e.g., (Pilászy, 2005)).

Additionally, it has been shown to be robust with high dimensional features (e.g., (Joachims, 1998)). Random forest is adopted because of its capability of reducing overfitting by performing sampling on data points and on feature subspaces. GBDT is selected because it works well with continuous numerical features such as word vectors.

We train individual classifiers for each target. Parameters are optimized in a 5-fold cross-validation over the training data. SVM and random forest are trained on different numbers of selected unigrams

<sup>3</sup>See <http://alt.qcri.org/semeval2016/task6/data/uploads/stance-question.pdf>.

for each target: 1,700 for Abortion, 1,535 for Atheism, 1,381 for Climate, 1,749 for Feminist, and 1,704 for Hillary. GBDT is trained on the word vectors: 300 dimensions for word2vec and 250 dimensions for GloVe. Additional experiments are performed with a standard feed-forward neural network on word vectors. These showed better performance on the training set for some targets, but overall, GBDT prove to be more reliable.

**SVM** Our initial experiments using cross validation on training data showed that linear kernel performed better than non-linear ones, and that the LinearSVC implementation (one-vs-rest strategy for multi-class) outperformed SVC (one-vs-one strategy). The optimal parameters differ for each target: 0.015-0.3 for the slack variable; standard hinge or squared hinge for the loss function; and L2 norm for the penalty term.

**Random Forest** The parameters for random forest are: 50, 70, or 90 for the number of trees; 500 or All for the number of features to consider when looking for the best split; 200, 500, or unlimited for the maximum depth of trees.

**GBDT** The gradient boosting decision trees (GBDT) classifier is used in combination with word vector features. Our initial experiments showed that GBDT handles word vector features better than SVM and random forest. The optimal parameter range for different targets are: 80-100 for number of estimators; 0.05-0.3 for learning rate; false for warm start; and 0.5-1.0 for subsample ratio.

**Ensemble Classifier** Since initial experiments with the three classifiers showed considerable differences across targets and stances, we investigate whether an ensemble classifier would benefit from aggregating their predictions. For the ensemble classifier, we choose a memory-based learner, TiMBL, because of the need to operate on a small set of rather abstract features: stance predictions and confidence scores from the three classifiers along with the global features (see section 2.2.3).

We use TiMBL (Daelemans et al., 2009) version 6.4.2, and perform 5-fold jackknifing to generate the training set for this ensemble classifier. Parameter optimization is performed on the five folds. The best parameters are different in each target: 7-29

| Team    | Official Metric |

for the number of neighbors; default minority voting for class voting in most cases; Modified Value Distance, Jeffrey divergence, and cosine distance for distance metric; and gain ratio for feature weight in most cases.

## 4 Results

### 4.1 Official Result

Since the ensemble classifier was not completed in time for submission, we had to decide which individual classifier to submit. The random forest model is selected based on a five-fold cross validation on the training set. This system reaches a score of 63.60 (macro-averaged F), as shown in table 3, the sixth best result out of 19 participating systems. This result is approximately 4 percent points lower than that of the highest performing system.

### 4.2 Additional Results

#### 4.2.1 Overview of All Classifiers

Table 4 shows the results of the three individual classifiers as well as of the two ensemble model variants, one combining only the individual classifiers' outputs (EnsembleNG), the other one (EnsembleG) including also the global features (see section 2.2.3). These results show that the GBDT approach using GloVe reaches the highest result (64.64) among the individual classifiers. The random forest classifier, which constitutes our official submission is about 1 percentage point lower (63.60), and the

**Table 5:** Detailed comparison. Best accuracies of individual classifiers are shown in italics, best overall results in bold. (F = macro-averaged F over Favor and Against; official score.)

SVM classifier is about 1.5 percentage points below that (61.93). A closer look at the ensemble variants shows that using the global features has a detrimental effect across all targets, most likely because this information is too coarse. The other ensemble classifier improves over GBDT by 1.5 percentage points (66.14). This shows that we can benefit from important information from all individual classifiers.

#### 4.2.2 Further Analysis

While the official scorer averages the results over all five targets, we are interested in whether our classifiers show a stable performance across targets, and why the ensemble model benefits from combining all individual classifiers. For this reason, we modified the scorer so that it would calculate accuracy, precision, and recall for individual stances per target separately. The results are shown in table 5. The official metric is the macro-averaged F-measure on Favor and Against while accuracy is equivalent to the micro-averaged F-measure based on all classes.

The results show a more diverse picture: For the individual classifiers, GBDT reaches the highest ac-

curacies for the targets Climate and Feminist, random forest for Atheism and Hillary, and they tie for Abortion. For the ensembles, the version without global features reaches higher accuracies for Abortion, Climate, and Hillary, the version with global features has a higher accuracy for Feminist, and they tie for Atheism.

EnsembleNG, which reaches the best score across all targets, only reaches the best score for two targets: Abortion and Feminist. It reaches lower results than the best individual classifier for 3 targets: Atheism, Climate, and Hillary. However, since the best results for the latter 3 targets are reached by different individual classifiers (random forest for Atheism and Hillary; GBDT for Climate), we assume that the ensemble provides the best compromise.

In order to obtain a better understanding of the differences in performance of classifiers across targets, we have analyzed the distribution of stances per target. Table 6 shows the distribution in training and test data. If we combine the information from table 5 with the stance distributions, we notice that a major advantage of the random forest classifier is its

| Data Set | Stance  | Abortion | Atheism | Climate | Feminist | Hillary |
|----------|---------|----------|---------|---------|----------|---------|
| Train    | Favor   | 18       | 18      | 54      | 32       | 17      |
|          | Against | 55       | 59      | 4       | 49       | 57      |
|          | None    | 27       | 23      | 42      | 19       | 26      |
| Test     | Favor   | 17       | 14      | 73      | 20       | 15      |
|          | Against | 67       | 73      | 7       | 64       | 58      |
|          | None    | 16       | 13      | 20      | 16       | 27      |

**Table 6:** Class distribution across targets in percentage.

high recall on the None stance, which is generally (one of) the minority class(es). For the second minority class (Favor for Abortion, Atheism, Hillary, and Feminist; and Against for Climate), the picture is less clear: For Climate, none of the classifiers manage to identify any of the Against tweets. For Abortion and Feminist, random forest also shows a high recall for Favor, but for Atheism and Hillary, its precision is considerably higher. In contrast, GBDT reaches a higher recall for the majority class (with Atheism as the only exception). SVM generally has precision and recall values between or below the other classifiers. The only exception is the target Feminist, where SVM reaches the highest precision for all three stances.

One hypothesis that could be drawn from the analysis above is that the GBDT model is better suited for finding examples of the majority classes while random forest is better at finding minority class examples. However, when we compare the targets Abortion and Atheism, the class distribution is similar, but the performance of the two classifiers is vastly different: For Abortion, GBDT reaches higher recall for the majority class (Against) and higher precision for Favor. For Atheism, it has a higher precision for the majority class and a higher recall for Favor. The reasons for these different behaviors need to be determined in future work.

## 5 Conclusion

In this shared task, we regard stance detection as a special case of sentiment analysis, using supervised classifiers and bag of unigrams and word vectors as features. Our submitted system is based on a random forest classifier because of its capability to handle overfitting and to generalize over the test data. Since the amount of available training data is small, random forest’s ability to sample data points and fea-

ture subspaces reduces data sparsity. The submitted system has an official score of 63.60 and ranked 6th out of 19 teams.

We also experimented with other single models (SVM and GBDT) and with an ensemble model built on a memory-based classifier. The GBDT model using GloVe word vectors reaches a higher score of 64.64, which may be a result of the word vectors’ capability to capture similarities among words, which helps in dealing with out-of-vocabulary words. The ensemble model that aggregates information from the three individual classifiers reaches the highest performance of 66.14. Our hypothesis is that different strengths (e.g., good performance for minority/majority classes) from individual models complement each other in the ensemble.

However a closer look at the performance of all classifiers and ensembles across individual targets shows that no system reaches consistently good results across all targets. The best performing ensemble (EnsembleNG) outperforms individual classifiers only for Abortion and Feminist; for the other targets, random forest or GBDT reach higher accuracies. Some of the variation in system performance can be explained by the class imbalance present in the data sets for the different targets, but further work is required to identify other factors.

Finally, it is worth pointing out that our approach to stance detection utilizes very surface oriented features. To boost performance, we may need to develop methods that incorporate inference, entailment, and world knowledge, for example, to handle cases such as “keep H. out of the white house”.

## Abstract

In this paper, we compare feature-based and Neural Network-based approaches on the supervised stance classification task for tweets in SemEval-2016 Task 6 Subtask A (Mohammad et al., 2016). In the feature-based approach, we use external resources such as lexicons and crawled texts. The Neural Network based approach employs Convolutional Neural Network (CNN). Our results show that the feature-based model outperformed the CNN model on the test data although the CNN model was better than the feature-based model in the cross validation on the training data.

## 1 Introduction

To solve supervised short text classification tasks, there are two major approaches; feature-based and Neural Network based approaches. In traditional feature-based approaches, we extract various features from a text. The features are usually constructed from n-grams (e.g., bigrams) of the texts and external resources such as lexicons and unlabeled corpora.

In Neural Network based approaches, a number of models for text classifications exist; for example, Feed-Forward Neural Network model using an average of embeddings of target word sequences as the input layer (Iyyer et al., 2015), Recursive Neural Network (Socher et al., 2011; Socher et al., 2013), and Convolutional Neural Network (CNN) (Johnson

and Zhang, 2015; dos Santos and Gatti, 2014; Kim, 2014).

In this paper, we compare feature-based and Neural Network based approaches on the supervised stance classification task for tweets, SemEval-2016 Task 6 Subtask A (Mohammad et al., 2016). The feature-based approach classifies tweets using logistic regression model. The features are extracted using external knowledge such as Senti-WordNet (Esuli and Sebastiani, 2006) and a collection of crawled tweets, in addition to unigrams or bigrams in the target tweet. For the Neural Network approach, we implement CNN based on Kim (2014). As the input embeddings, we use word embeddings trained by Continuous Bag-Of-Words (CBOW) model (Mikolov et al., 2013) on Wikipedia articles.

The experimental results show that the CNN based approach performed the best in the cross validation on the training data. However the tendency was opposite on the test data probably because the CNN model overfitted to the training data. In contrast, the feature-based approach was more robust, leveraging the external knowledge.

## 2 Datasets

We use the dataset of the SemEval-2016 Task 6 Subtask A, which is a supervised tweet classification task for five topics. There are three stances to classify; NONE, FAVOR, AGAINST. Table 1 shows the topics and distributions of the training data.

| Topic                            | FAVOR | AGAINST | NONE |
|----------------------------------|-------|---------|------|
| Atheism                          | 92    | 304     | 117  |
| Climate Change is a Real Concern | 212   | 15      | 168  |
| Feminist Movement                | 210   | 328     | 126  |
| Hillary Clinton                  | 112   | 361     | 166  |
| Legalization of Abortion         | 105   | 334     | 164  |

**Table 1:** Distributions of the labels for each topics in the training data.

To classify tweets into their stances, we consider two configurations: *Three-way Polarity Classifier* which detects three stance labels at once, and a combination of *Topic Classifier* and *Two-way Polarity Classifier*. Topic Classifier judges the relevance of a tweet to the topic, in other words, whether a stance label is NONE or not (FAVOR/AGAINST). Two-way Polarity Classifier then labels FAVOR or AGAINST for tweets that were not judged as NONE by the Topic Classifier.

### 3 Feature-Based Approach

#### 3.1 Preprocessing Tweets

We remove reply and mention expressions (@UserName) in tweets to prevent overfitting, and keep flags indicating whether tweets contain them or not. We also remove hashtags based on the following rules to prevent overfitting.

**Rule 1.** Hashtags embedded in the sentence with capitals or digits at non-initial letters  
e.g., #WeLoveJapan, #Pray4all

**Rule 2.** Hashtags at the end of a tweet  
e.g., #SemST, #2014, #LylicTweet

**Rule 1** removes hashtags that are too long or unpopular. **Rule 2** removes hashtags that do not contain a stance. Remaining hashtags such as #hillary and #god may provide important features to detect the stances.

We also expand shortened forms such as “I’m” and “can’t” based on simple rules. Finally, we obtain part-of-speech (POS) tags and dependency trees of tweets by using Stanford CoreNLP<sup>1</sup>.

#### 3.2 Features

**Reply (R):** If a tweet has a flag that indicates a reply or mention expression, we gener-

| Topic                            | Query  | # tweets |
|----------------------------------|--|----------|
| Atheism                          | “atheism”  | 24124    |
| Climate Change is a Real Concern | “climate”, “climate change”                                    | 22703    |
| Feminist Movement                | “feminist”, “feminism”, “feminist movement”, “gender equality” | 131677   |
| Hillary Clinton                  | “hillary”, “clinton”, “hillary clinton”                        | 980080   |
| Legalization of Abortion         | “abortion”   | 54846    |

**Table 2:** Crawled tweets used for HighPMI Features. This table shows search queries and the number of tweets we collected for each topic.

| Topic                            | Keywords               |
|----------------------------------|------------------------|
| Atheism                          | “atheism”              |
| Climate Change is a Real Concern | “climate”, “change”    |
| Feminist Movement                | “feminist”, “feminism” |
| Hillary Clinton                  | “hillary”, “clinton”   |
| Legalization of Abortion         | “abortion”             |

**Table 3:** Seed keywords for each topic for TargetSentiment and HighPMI features.

ate R=is\_reply or R=is\_mention as a feature. This feature may be effective because a reply or mention may provides a clue for detecting a stance.

**BagOfWords (BoW):** For detecting stances, words in a tweet are very informative. We include all unigrams of lemmas in a tweet as features. (e.g. BoW=think, BoW=not)

**BagOfDependencies (BoD):** Dependency relations such as adjectival modifier and negation are important for detecting stances. We include all dependency relations in a tweet as features. (e.g. BoD=hate=>i, BoD=like=>not)

**BagOfPOSTag (BoP):** We also extract features from POS tags. For example, if a tweet contains several interjections, the user probably has a negative opinion to the topic. We include all unigrams of POS tags in a tweet as features. (e.g. BoP=NOUN, BoP=UH)

**SentiWordNet (SWN):** Content words in a tweet may express some sentiment, which indicates stances and emotions of the user. We use SentiWordNet (Esuli and Sebastiani, 2006) for introducing sentiment of a word. It assigns positive/negative/objective scores to each word. In sentiment classification task, Pang et al. (2002) introduce SentiWordNet features. Following their work, we include sentiment polarity features for nouns, verbs,

| - BoD        | <b>0.5672</b> | 0.5097                                | 0.5895               | <b>0.5561</b>      | <b>0.5746</b>                  | <b>0.6276</b> |
| - BoP        | 0.5525        | 0.5248                                | 0.5785               | 0.5527             | 0.5034                         | 0.6169        |
| - SWN        | 0.5357        | 0.5168                                | 0.5760               | 0.5475             | 0.5308                         | 0.6162        |
| - SWS        | 0.5316        | 0.5248                                | 0.5783               | 0.5520             | 0.5342                         | 0.6174        |
| - TS         | 0.5327        | 0.5248                                | 0.5882               | 0.5502             | 0.5349                         | 0.6200        |
| - P          | 0.5360        | 0.5248                                | 0.5834               | 0.5520             | 0.5406                         | 0.6204        |
| Best         | 0.5672        | 0.5642                                | 0.5208               | 0.5883             | 0.5208                         | 0.6297        |

**Table 5:** Ablation Test of Topic + 2-way Polarity Classifier on 10-fold cross validation using the feature-based approach. The scores were measured in a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

adjectives and adverbs in the tweet based on the following rules.

1. For a given word, look up the top item in SentiWordNet and obtain a negative and positive score of the word.
2. If the negative score is equal to the positive score, no features are generated.
3. If the negative score is larger than the positive score, generate a negative polarity feature, otherwise generate a positive polarity feature. (e.g. SWN=love=>p, SWN=hate=>n)

**SentiWordSubject (SWS):** This feature focuses on sentiment expressed by subjective pronouns such as “I” or “we”, which may indicate emotions or stances of the user of a tweet. We obtain a sentiment polarity from the word modifying a subjective pronoun in a tweet, and include it as a feature. A sentiment polarity is obtained by SentiWordNet using the same rules for SWN features. (e.g. SWS=I=love=>p, SWS=We=hate=>n)

**TargetSentiment (TS):** We also consider sentiment or emotion for the topics. Jiang et al. (2011)

add words modifying target words as features. Similarly, we extract words modifying target words in a tweet, and include sentiment polarity features using the same rules in SWN features.

We calculate similarities between words and seed keywords using word embeddings. If the similarity is higher than 0.7, we use it as the target word. Table 3 shows the seed keywords for each topic.

For example, given a tweet “We hate feminist”, we extract “hate” that modifies the target word “feminist”. Then we get a feature TS=n using the same rules in SWN features. (e.g. TS=p, TS=n)

**HighPMI (P):** We crawled tweets containing target words, and collected words cooccurring with seed keywords (Table 3) in all crawled tweets for each topic. Table 2 shows query words and the number of crawled tweets for each topic. Then we calculate Point-wise Mutual Information (PMI) for all words. If the word in a tweet is in top 300 of the PMI, we generate a feature. This feature detects a tweet containing words related to the topic. This feature may be effective to classify whether NONE or not. (e.g. P=humanist, P=meninist)

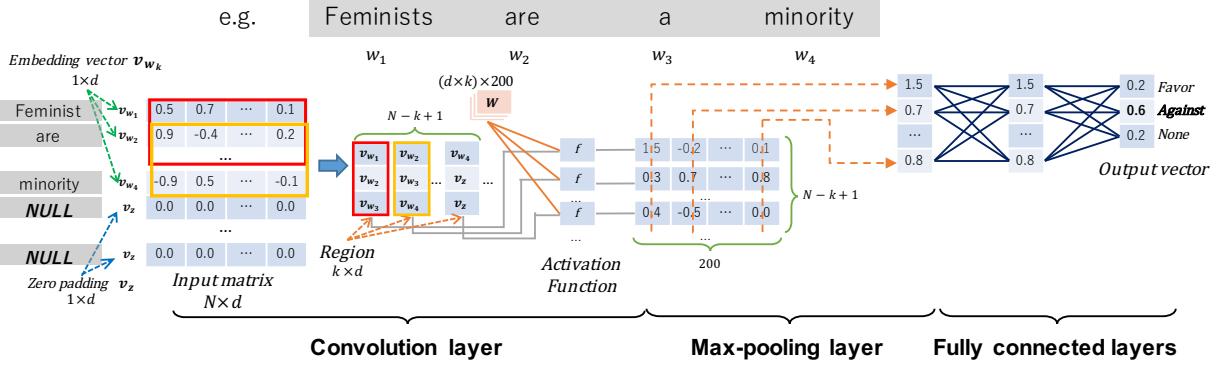

Figure 1: Overview of our CNN model.

### 3.3 Evaluation

#### 3.3.1 Experimental Setups

We used L2 logistic regression as the classification algorithm, and measured the classification performance on 10-fold cross validation using the Clas-sias package (Okazaki, 2009). We evaluated each model by a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

#### 3.3.2 Comparison of Classifier Combinations

We compared Three-way Polarity Classifier with the combination of Topic Classifier and Two-way Polarity Classifier. Table 3.1 shows the performances of these two classifier configurations. We confirmed that the combination of Topic Classifier and Two-way Polarity Classifier outperformed Three-way Polarity Classifier. Therefore, we used the combination of Topic Classifier and Two-way Polarity Classifier hereafter.

#### 3.3.3 Ablation Test

Through this experiment, we explore the contribution of individual features explained in Section 3.2. Table 5 shows the results of ablation tests. These results show that SWN features were the most effective to classify the stances. Sentiment of the tweet is one of the keys for stance classification. In contrast, BoD features degraded the classifier. We experimented further ablation tests with the feature set except for degraded features in the ablation test. These experiments revealed the best feature sets {BoW, BoP, R, SWN, P} (denoted ‘Best’ in Table 5).

## 4 CNN Based Approach

### 4.1 Method Overview

In recent years, Convolutional Neural Network (CNN) models have achieved remarkable results in various fields of research, such as computer vision and speech recognition. In the field of natural language processing, CNN models are also used for text classification tasks (Johnson and Zhang, 2015; dos Santos and Gatti, 2014), sentiment analysis (Kim, 2014), etc.

Following Kim (2014), we constructed CNN models to detect stances, as shown in Figure 1. They consist of one convolution layer with one max-pooling layer, and a three-layered feedforward network with softmax at the end to predict a distribution over classes. The convolution layer has 200 kernel windows whose sizes are  $k \times d$ , where  $k$  is the number of words in a window and  $d$  is the dimension size of the word embeddings. We denote an input tweet  $s$  as a sequence of words  $w_1, w_2, \dots, w_n$ , and their embeddings  $v_{w_1}, v_{w_2}, \dots, v_{w_n}$ . We use Chainer<sup>2</sup> for creating neural networks. To create a fixed-size input matrix for the implementation on Chainer, we added zero-padding vectors into the end of a sentence so that each input matrix will be  $N \times d$  matrix, where  $N$  is the upper bound of the length of a sentence.

As we mentioned in Section 2, we consider both **Three-way Polarity Classifier** and a combination of **Topic Classifier** and **Two-way Polarity Classifier**. We also try to find out the best hyper parameter  $k$  and activation functions.

<sup>2</sup><http://chainer.org/>

| Classifier    | Activation Functions | Atheism       | Climate Change is a Real Concern | Feminist Movement | Hillary Clinton | Legalization of Abortion | Total         |
|---------------|----------------------|---------------|----------------------------------|-------------------|-----------------|--------------------------|---------------|
| 3-way         | sig                  | <b>0.6770</b> | 0.4118                           | 0.5958            | 0.5681          | 0.4814                   | 0.6664        |

| Topic + 2-way | sig                  | 0.6751        | 0.4080                           | 0.5969            | 0.6061          | 0.5528                   | 0.6381        |
|               | relu                 | 0.5736        | 0.5710                           | 0.5990            | 0.6391          | 0.5455                   | 0.6365        |
|               | sig                  | 0.5826        | <b>0.5774</b>                    | 0.5974            | <b>0.6402</b>   | 0.5425                   | <b>0.6713</b> |
|               | relu                 | 0.6688        | 0.4017                           | <b>0.6005</b>     | 0.6090          | <b>0.5612</b>            | 0.6398        |

**Table 6:** Comparison of 3-way Polarity Classifier with Topic + 2-way Polarity Classifier on 10-fold cross validation using CNN based approach. The scores were measured in a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

| Kernel Size (k) | Atheism       | Climate Change is a Real Concern | Feminist Movement | Hillary Clinton | Legalization of Abortion | ALL topics    |
|-----------------|---------------|----------------------------------|-------------------|-----------------|--------------------------|---------------|
| 2               | <b>0.6390</b> | 0.5743                           | 0.6189            | <b>0.6490</b>   | <b>0.5611</b>            | <b>0.6831</b> |
| 3               | 0.5826        | <b>0.5774</b>                    | 0.5974            | 0.6402          | 0.5425                   | 0.6713        |
| 4               | 0.5746        | 0.5746                           | <b>0.6276</b>     | 0.6354          | 0.5398                   | 0.6755        |

**Table 7:** Tuning of window size per word  $k$  on 10-fold cross validation using CNN based approach. The scores were measured in a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

## 4.2 Experimental Setups

We trained 300 dimensional word embeddings using Word2Vec<sup>3</sup> with Wikipedia articles<sup>4</sup> (3950598 articles in total)<sup>5</sup>. We set  $N$  to 100, which exceeds the maximum length of all tweets. We use  $(300 \times k) \times 200$  matrix as  $W$  and three fully connected layers that consist of 200-50-3 units (Three-way Polarity Classifier) or 200-50-2 units (Topic Classifier or Two-way Polarity Classifier).

We measured the performance on 10-fold cross validation. We evaluated each model by a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

## 4.3 Evaluation

### 4.3.1 Comparison of Classifier Combinations

We compared Three-way Polarity Classifier with the combination of Topic Classifier and Two-way Polarity Classifier with  $k = 3$ . We tried using all possible combinations of sigmoid and relu functions in the CNN models.

Table 6 shows the performances of the classifiers.

The table indicates that the combination of Topic Classifier and Two-way Polarity Classifier outperformed Three-way Polarity Classifier. We confirmed that the combination of these classifier has been found effective for not only the feature-based approach, but also for the CNN-based approach.

We also achieved the best score when we use sigmoid function for Topic Classifier and relu for Two-way Polarity Classifier.

### 4.3.2 Tuning of Window Size $k$

We searched for the best value of the hyperparameter  $k$  with the highest model in Section 4.3.1. Table 7 shows that the model obtained the highest score with window size  $k = 2$ . The results show that bigram is appropriate for stance detection on the training data.

### 4.3.3 Visualization of the CNN Model

In this section, we visualize the CNN model that achieved the highest score in Section 4.3.2. To visualize the CNN model, we define a *region score* as the number of dimensions that are selected by the max-pooling layer per region. Figure 2 shows a heat map reflecting the region score.

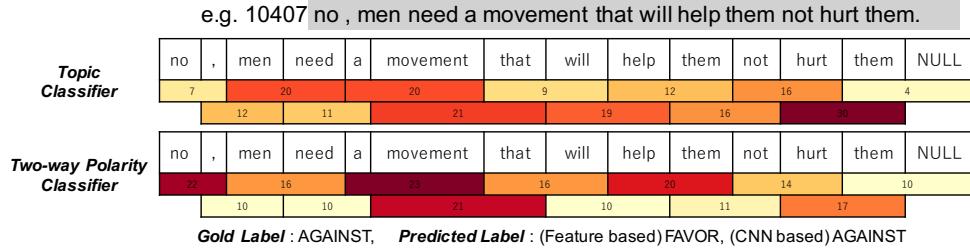

The figure provides several observations.

- Topic related words such as *movement* received a high score in both Topic classifier and Two-way Polarity Classifier. This shows that each

<sup>3</sup><https://code.google.com/archive/p/word2vec/>

<sup>4</sup><https://dumps.wikimedia.org/enwiki/20151201/enwiki-20151201-pages-articles.xml.bz2>

<sup>5</sup>We used the following options: -size 300 -window 5 -sample 1e-4 -negative 5 -hs 0 -cbow 1 -iter 3

**Figure 2:** Visualization of the CNN model. A bigram region in deep color receives high *region score*, which indicates that the convolution layer highly focuses on the region.

| Method                | Train         |               | Test                                   |                      |                    |                                |               |
|-----------------------|---------------|---------------|--|----------------------|--------------------|--------------------------------|---------------|
|                       | Total         | Atheism       | Climate Change<br>is a<br>Real Concern | Feminist<br>Movement | Hillary<br>Clinton | Legalization<br>of<br>Abortion | ALL topic     |
| Feature-Best          | 0.6297        | <b>0.5973</b> | 0.3891                                 | <b>0.5487</b>        | <b>0.5360</b>      | <b>0.5796</b>                  | <b>0.6426</b> |
| CNN-Best (Submission) | <b>0.6831</b> | 0.5890        | <b>0.3951</b>                          | 0.5241               | 0.3981             | 0.3775                         | 0.6221        |
| Majority Baseline     | 0.5411        | 0.4210        | 0.4212                                 | 0.3910               | 0.3683             | 0.4030                         | 0.6522        |

**Table 8:** Comparison of Feature-based Model and CNN Model on test data. The scores were measured in a macro average of micro-F1 scores of FAVOR and AGAINST for each topic and all topics.

CNN model automatically detects the topic words.

- Nouns, verbs and adjectives that appear in SentiWordNet received a higher score in both classifiers. In addition, their scores have some associations with cooccurrence with the topic word.
- Negation words such as *not* and *can't* received high scores in Polarity Classifier, but they received less scores in Topic Classifier.

## 5 Overall Results

We compared feature-based models with CNN models and the majority baseline in the test data. The feature-based models used Topic + Two-way Polarity Classifiers and the best feature sets mentioned in Section 3.3.3. The CNN models used Topic + Two-way Polarity Classifiers and the best hyperparameters mentioned in Section 4.3. The majority baseline labeled the test data as the stance that was most prevalent in the training data.

Table 8 shows a macro average of micro-F1 scores of FAVOR and AGAINST for two models in the test data and the cross validation results. As a comparison, we also show the majority baseline in Table 8.

We found that the feature-based model outperformed the CNN model in the test data, although the

CNN model was better in the cross validation on the training data. We think that the feature-based model was more robust, including broad external knowledge such as SentiWordNet and crawled tweets. In contrast, the CNN model obtained a lower score on the test data than on the cross validation.

## 6 Conclusion

We compared the feature-based and the CNN based approaches on SemEval-2016 Task 6 Subtask A. The CNN based approach performed the best in the cross validation on the training data although the feature-based approach outperformed the CNN model on the test data. We also visualized the CNN model to reveal what was focused on. We found that the CNN model automatically detected the topic words and effective words to detect the stances.

## Abstract

This paper describes our system participating in the SemEval 2016 task: Detecting stance in Tweets. The goal was to identify whether the author of a tweet is in favor of the given target or against. Our approach is based on a maximum entropy classifier, which uses surface-level, sentiment and domain-specific features. We participated in both the supervised and weakly supervised subtasks and received promising results for most of the targets.

## 1 Introduction

Stance detection has been defined as automatically detecting whether the author of a piece of text is in favor of the given target or against it. In the third class, there are the cases, in which neither inference is likely. It can be viewed as a subtask of opinion mining and it stands next to the sentiment analysis. The significant difference is that in the case of sentiment analysis, systems determine whether a piece of text is positive, negative, or neutral. However, in stance detection, systems are to determine the author's favorability towards a given target and the target even may not be explicitly mentioned in the text. Moreover, the text may express positive opinion about an entity contained in the text, but one can also infer that the author is against the defined target (an entity or a topic). This makes the task more difficult, compared to the sentiment analysis, but it can often bring complementary information.

There are many applications which could benefit from the automatic stance detection, including infor-

mation retrieval, textual entailment, or text summarization, in particular opinion summarization. Twitter was selected as the source of the text because of its popularity and because people express stance implicitly or explicitly there.

We first shortly introduce the task in Section 2 and the available dataset.<sup>1</sup> In Section 3, we describe our preprocessing, the implemented approach and system's features. It is followed by the setup for each analysed topic and a discussion of official results (Section 4).

## 2 Task Description

The **Detecting Stance in Tweets** task<sup>2</sup> (Mohammad et al., 2016) had two independent subtasks: supervised and weakly supervised stance identification.

The supervised task (subtask A) tested stance towards five targets: *Atheism*, *Climate Change is a Real Concern*, *Feminist Movement*, *Hillary Clinton*, and *Legalization of Abortion*. Participants were provided 2814 labeled training tweets for the five targets. An example tweet annotated as IN FAVOR: *These pics of #pornstars with/without makeup? Just perpetuating the myth that women need makeup to be considered pretty.* (the *Feminist Movement* target, ID: 1017).

A detailed distribution of stances for each target is given in Table 1. The distribution is not uniform and there is always a preference towards a certain stance (e.g., 59% tweets about *Atheism* are labelled as AGAINST).

<sup>1</sup>Details can be found in the overview paper (Mohammad et al., 2016).

<sup>2</sup><http://alt.qcri.org/semeval2016/task6/>

It naturally reflects the real-world scenario, in which a majority of people tend to one of the stances. This is also depending on the source of the data. For example, in the case of *Legalization of Abortion*, we can assume that the distribution will be significantly different in religious communities than in atheistic communities.

For the weakly supervised task (subtask B), there were no labelled training data but participants could use a large number of tweets related to the single target: *Donald Trump*. Example: *There are so many reasons to dislike #HillaryClinton but Half Human and Half Orangutan #DonaldTrump takes it to next level.* (ID: 589371241204711424).

Due to Twitter legal requirements, the dataset for subtask B contained only tweet ids and participants had to download those tweets using the provided script. The dataset contains 78256 tweet ids generated by searching for the tags #DonaldTrump and #trump2016. Unfortunately, some of those tweets did not exist at the download time, as their authors removed them. Our dataset contained 69454 tweets.

| Topic                            | FAV          | AG           | NONE         | TOT |
|----------------------------------|--------------|--------------|--------------|-----|
| Atheism                          | 92<br>(18%)  | 304<br>(59%) | 117<br>(23%) | 513 |
| Climate Change is a Real Concern | 212<br>(54%) | 15<br>(4%)   | 168<br>(43%) | 395 |
| Feminist Movement                | 210<br>(32%) | 328<br>(49%) | 126<br>(19%) | 664 |

Table 1: Training data statistics. FAV = IN FAVOR, AG = AGAINST, and NONE = neither inference.

### 3 The Approach Overview

We decided to build a classical supervised learning system, in particular, we used a maximum entropy classifier (Loper et al., 2002). The classifier was trained separately for each topic. For the subtask B - weakly supervised system (*Donald Trump*) we used the *Hillary Clinton* training data, which we considered as the closest. We also added some enhancements we discuss later.

We first analysed hashtags in the training corpus. We automatically identified those that predict the stance well for each topic. These hashtags strongly correlate with one of the stance classes. For example, if the tweet contains hashtag *#benghazi* (the *Hillary Clinton* target), the stance is always AGAINST. We picked hashtags which appear at least in 10 tweets and at least 90% of these tweets are annotated with a particular stance.

The important hashtags are listed in Table 2.

We also gathered from Twitter additional data (via Twitter API) based on these automatically detected hashtags (#benghazi, #stophillary2016, etc.). This additional data was not used directly during the training phase but we created a set of dictionaries (ADSD) out of them.

| Topic                            | Hashtag                                   | Stance                                   |
|----------------------------------|---|--|
| Atheism                          | #freethinker<br>#islam                    | IN FAVOR<br>AGAINST                      |
| Climate Change is a Real Concern | #climate<br>#mission<br>#peace<br>#tip    | IN FAVOR<br>IN FAVOR<br>NONE<br>IN FAVOR |
| Feminist Movement                | #feminists<br>#spankafeminist             | AGAINST<br>AGAINST                       |
| Hillary Clinton                  | #benghazi<br>#lol<br>#stophillary2016     | AGAINST<br>AGAINST<br>AGAINST            |
| Legalization of Abortion         | #alllivesmatter<br>#ccot<br>#prolifeyouth | AGAINST<br>AGAINST<br>AGAINST            |

Table 2: Hashtags analysis.

### 3.1 Preprocessing

Preprocessing starts the pipeline. Each of the following steps was applied to every tweet.

1. All URLs are replaced by keyword *URL*,
2. multiple exclamation marks are replaced by *MULTIPLEEXCLAMATIONS*,
3. multiple question marks are replaced by *MULTIPLEQUESTIONMARKS*,
4. Twitter usernames like @peter\_krejzl are replaced by *NAME*,
5. links to images (pic.twitter.com) are replaced by *IMGURL*,

6. hashtag `#sems` is removed,
7. initial tag `RT` is removed,
8. English stopwords are removed,<sup>3</sup>
9. only letters are preserved, the rest of the characters is removed,
10. for the *Donald Trump* target, we used training data from the *Hillary Clinton* target but we removed the following words from the tweets: *hillary, hilary, clinton*.

### 3.2 Features

A basic set of features was created from the preprocessed text. Unigrams perform quite well in the task (Somasundaran et al., 2009), so we used it as a baseline for all targets. The model is based on TF-IDF and uses not more than 750 features (first 750 words from the vocabulary). This is used for all five topics. Then, we implemented a set of other features that could be turned on or off for each topic.

We built a set of features from **hashtags** in Table 2. In maximum 50 unigram and bigram features were generated from the hashtags using the TF-IDF weighting.

Anand et al. (2011) showed that **initial n-grams** are useful features. Our system supports initial unigrams to initial trigrams, the maximum number is 50 features. However, from our experiments with the training dataset, we found useful only initial unigrams, and initial bigrams for the *Hillary Clinton* target (turned on for *Donald Trump* as well).

Another surface feature was **tweet length** (in words) after preprocessing.

**Part-of-speech** tags were generated from the preprocessed tweet and we built unigram and bigram data model using TF-IDF, limited to 50 features.<sup>4</sup>

**General Inquirer** (GI)<sup>5</sup> (General-Inquirer, 1966) provides dictionaries useful for example for sentiment analysis. We used a subset of the dictionary, in particular columns: *Positiv, Negativ, Hostile, Strong, Pleasure, Pain*.

---

<sup>3</sup>We used stopwords available in the `nltk.corpus` python library.

<sup>4</sup>We used *Nltk* part-of-speech tagger.

<sup>5</sup><http://www.wjh.harvard.edu/~inquirer/>

### Entity-centered sentiment dictionaries

(ECSD): We used another resource borrowed from the sentiment analysis: dictionaries created mainly for the purpose of entity-related polarity detection (Steinberger et al., 2012). We used both the highly positive and positive terms<sup>6</sup> as IN FAVOR features and highly negative / negative terms as AGAINST features.

In some topics like *Legalization of abortion* or *Atheism* any **reference to a bible** (e.g., *Romans 12:2*) is also a very good indicator. We add additional binary feature based on the presence of a bible reference.<sup>7</sup>

**Domain Stance Dictionary** (DSD) Based on the training data analysis of each topic, we created a list of key words that tend to indicate a particular stance. We first generated a list of candidates: for each topic, we took words with ratio  $frequency - in - topic / frequency - in - the - training - data > 0.6$  and  $frequency - in - topic > 1$ . If a word occurred at least 4 times more frequently in ‘IN FAVOR’ tweets than in ‘AGAINST’, it was added to the ‘IN FAVOR’ candidates’ list. We repeated the same approach to produce ‘AGAINST’ candidates. The lists were then filtered manually and it resulted in strong stance-predictive keywords lists. All the lists together contain 221 words, an average list had 22 words. For instance, for the *Legalization of Abortion* topic, the following words or hashtags suggest the AGAINST stance: *unborn, womb, prolife, conception, precious, chooselife, kills, abortionismurder, destroys, itsnotonitsnotsafe, manslaughter, eliminated, cannibalism, heartbeat, ...* We used the number of words from each dictionary the tweets contain as features.

### Additional Domain Stance Dictionary (ADSD):

In the case of the *Legalization of Abortion* and *Hillary Clinton* topics, we created additional two dictionaries per topic. It was a similar exercise to DSD, but we used the additional tweets gathered through Twitter API as an input. For example, the AGAINST dictionary for *Hillary Clinton* contains: *attack, benghazihearings, blamed, blood, BloodOn-HerHands, corrupt, irritated, Killary, ....*

---

<sup>6</sup>There are two levels of intensity for both polarities.

<sup>7</sup>Simple python regular expression `(\d+):(\d+)`.

Both the DSD and ADSD dictionaries contain terms that strongly indicate a particular stance. They were used to modify the final output towards the particular stance and override the classifier result. For each tweet we count the number of words from each positive or negative DSD/ADSD. If there are more words from the positive dictionary then the whole tweet is deemed FAVOR and vice versa. If the counts of positive and negative words are equal then the override logic is not used. We also noticed (during the development phase) that the classifier was overridden only few times in the Task A, while more times in the Task B. We think it is due to the different training data used for the Donald Trump task.

## 4 Configuration and Results

During the development phase, we used 10-fold cross-validation to test all combinations of features. Each particular dataset was split randomly. For each experiment we measured average F1-score on IN FAVOR and AGAINST classes, the same metric as the official one (Mohammad et al., 2016). This way we identified an optimal set of features for each topic, listed in Table 3.

| Topic    | Features   |
|----------|--|
| Atheism  | Unigrams, Bible reference, DSD   |
| Climate  | Unigrams, Hashtags, POS, DSD   |
| Feminism | Unigrams, Hashtags, DSD  |
| Hillary  | Unigrams, Hashtags, Initial unigrams, Initial Bigrams, ECSD, DSD, DSDA |
| Abortion | Unigrams, Bible reference, DSD, DSDA                                   |
| Trump    | Unigrams, Hashtags, Initial Unigrams, Initial Bigrams, ECSD, DSD, DSDA |

Table 3: Features per topic used for the submission.

Table 4 shows results on the development set. We reached the best improvement over the baseline for *Hillary Clinton*, followed by *Feminism* and *Atheism*. However, detecting a correct stance for these targets seemed to be the most difficult.

Official results of the SemEval task are summarized in Table 5. There were 19 participating systems for subtask A and 9 for subtask B. We per-

formed well for *Abortion* (2nd), *Climate* (3rd) and *Hillary Clinton* (4th) targets in comparison with the other participating systems, we received an average rank for *Atheism* and *Feminism*. The overall rank was 9th.

In the weakly supervised subtask (*Donald Trump*), we were ranked 4th, only the top system was significantly better. The difference between performances on the *Hillary Clinton* and *Donald Trump* topics (.5982 vs. .4202) indicate the difference in complexity between the subtasks.

It seems that although Clinton and Trump are competitors on political stage, Clinton’s training data brought useful features for Trump as well (criticizing or praising a politician), although in many cases the overriding strategy corrected the classifier’s prediction.

| Topic    | Baseline<br>(uni-<br>grams) | Features<br>(no<br>over-<br>ride) | Features<br>+ over-<br>ride | Diff<br>against<br>base-<br>line |
|----------|-----------------------------|-----------------------------------|-----------------------------|----------------------------------|
| Atheism  | .5579                       | .6314                             | .6314                       | +13%                             |
| Climate  | .6250                       | .6589                             | .6590                       | +5%                              |
| Feminism | .4722                       | .5424                             | .5443                       | +15%                             |
| Clinton  | .4460                       | .5386                             | .5386                       | +21%                             |
| Abortion | .6250                       | .6749                             | .6749                       | +8%                              |

Table 4: Development results per topic with features turned on/off (K-10 fold validation).

| Topic      | UWB<br>(Rank) | Avg. sys-<br>tem | Best sys-<br>tem |
|------------|---------------|------------------|------------------|
| Atheism    | .5788 (8)     | .5510            | .6725            |
| Climate    | .4690 (3)     | .4219            | .5486            |
| Feminism   | .5182 (10)    | .5155            | .6209            |
| Hillary    | .5982 (4)     | .5248            | .6712            |
| Abortion   | .6198 (2)     | .5472            | .6332            |
| Sub-task A | .6342 (9)     | .6202            | .6782            |
| Sub-task B | .4202 (4)     | .3737            | .5628            |

Table 5: Official results of the SemEval task. There were 19 submissions for subtask A and 9 submissions for subtask B.

## 5 Conclusion

The paper describes our participation in the Tweets stance detection task of SemEval 2016. Our submission was based on a maximum entropy classifier with mainly surface-level, sentiment and domain-specific features. The system was among the top systems for three of the five targets from the supervised task. Without the labeled tweets, the weakly supervised scenario, our position was fourth (from nine). Currently, we investigate in more detail how to gather more training data automatically.

## Abstract

This paper describes our approach for the *Detecting Stance in Tweets* task (SemEval-2016 Task 6). We utilized recent advances in short text categorization using deep learning to create word-level and character-level models. The choice between word-level and character-level models in each particular case was informed through validation performance. Our final system is a combination of classifiers using word-level or character-level models. We also employed novel data augmentation techniques to expand and diversify our training dataset, thus making our system more robust. Our system achieved a macro-average precision, recall and F1-scores of 0.67, 0.61 and 0.635 respectively.

## 1 Introduction

Stance detection is the task of automatically determining whether the authors of a text are against or in favour of a given target. For instance, take the following sentence: "It has been such a cold April, so much for global warming." This sentence's author is most likely against the concept of global warming (i.e., does not believe in it). The work presented here is specifically targeted towards detecting stance in tweets. The noisy and idiosyncratic nature of tweets make this a particularly hard task.

Automatic identification of stance in tweets has practical applications for a range of domains. For instance, it can be used as a sensor to measure the attitude of Twitter users on various issues, such as: political issues, candidates, brand names, TV shows, etc.

There has been extensive research done on modelling and automatic detection of stance in political arenas (e.g., debates) (Thomas et al., 2006) and on online forums (Somasundaran and Wiebe, 2009; Murakami and Raymond, 2010). However, as we alluded to earlier, the peculiar nature of tweets make techniques that have been developed for other platforms unsuitable. The field closest to this work is the field of Twitter sentiment classification, where the task is to detect the sentiment of a given tweet, usually as positive, negative, or neutral. Nonetheless, it is important to note that there are substantial differences between sentiment classification and stance detection. Sentiment classifiers determine the polarity of a given tweet, without considering any targets (see Vosoughi et al. (Vosoughi et al., 2015) for an example of a Twitter sentiment classifier). For instance, consider the tweet: "I love Donald Trump", this tweet has a positive sentiment, and the author of the tweet has a positive stance towards Donald Trump, but it can also be inferred that the author is most likely against or at best neutral towards Bernie Sanders. In this paper, we present a system for automatic detection of stance in Tweets.

## 2 Our Approach

We trained a different model for each of the five targets. Models for some of the targets used character-level convolutional neural networks(CNN), while other used word-level models. In one particular target (Hillary Clinton), a combination of character-level and word-level models was used. Though Character-level models are robust to the idiosyncratic and noisy nature of tweets, they require a larger dataset compared to word-level models. Our

choice between the models was informed by validation performance (as explained in section 5). The character and word-level models are explained in the section below.

## 2.1 Character-Level CNN Tweet Model

Character-level CNN (CharCNN) is a slight variant of the deep character level convolutional neural network introduced by Zhang et al (Zhang and LeCun, 2015), based on the success of CNNs in image recognition tasks (Girshick et al., 2014) (Hinton et al., 2012). In this model, we perform temporal (one-dimensional) convolutional and max-pooling operations. Given a discrete input function  $f(x) \in [1, l] \mapsto \mathbb{R}$ , a discrete kernel function  $k(x) \in [1, m] \mapsto \mathbb{R}$  and stride  $s$ , the convolution  $g(y) \in [1, (l - m + 1)/s] \mapsto \mathbb{R}$  between  $k(x)$  and  $f(x)$  and pooling operation  $h(y) \in [1, (l - m + 1)/s] \mapsto \mathbb{R}$  of  $f(x)$  is calculated as:

$$g(y) = \sum_{x=1}^m k(x) \cdot f(y \cdot s - x + c) \quad (1)$$

$$h(y) = \max_{x=1}^m f(y \cdot s - x + c) \quad (2)$$

where  $c = m - s + 1$  is an offset constant. In our implementation of the model, the stride  $s$  is set to 1.

This model is illustrated in Figure 1. We adapted this model for the size limit of tweets (140 characters). The character set includes English alphabets, numbers, special characters and unknown character. There are 70 characters in total, given below:

```
abcdefghijklmnopqrstuvwxyz
0123456789-, . ! ? : ' "
\|_#$%^&^*~`+-=<>()[]{}{}
```

Each character in the tweet can be encoded using one-hot vector  $x_i \in \{0, 1\}^{70}$ . Hence, a tweet is represented as a binary matrix  $x_{1..150} \in \{0, 1\}^{150 \times 70}$  with padding wherever necessary, where 150 is the maximum number of characters in a tweet plus padding and 70 is the size of the character set. Each tweet, in the form of a matrix, is now fed into a deep model consisting of four 1-d convolutional layers. A convolution operation employs a filter  $w$ , to extract  $l$ -gram character feature from a sliding window of  $l$  characters at the first layer and learns abstract textual features in the subsequent layers. This filter

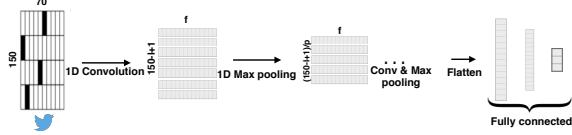

Figure 1: Illustration of CharCNN Model

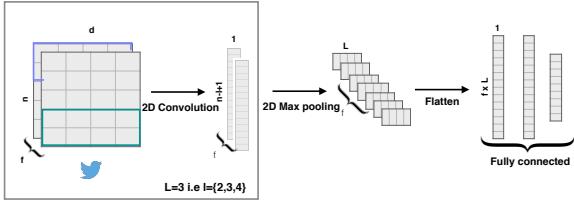

$w$  is applied across all possible windows of size  $l$  to produce a feature map. A sufficient number ( $f$ ) of such filters are used to model the rich structures in the composition of characters. Generally, with tweet  $s$ , each element  $c_i^{(h,F)}(s)$  of a feature map  $F$  at the layer  $h$  is generated by:

$$c_i^{(h,F)}(s) = g(w^{(h,F)} \odot \hat{c}_i^{(h-1)}(s) + b^{(h,F)}) \quad (3)$$

where  $w^{(h,F)}$  is the filter associated with feature map  $F$  at layer  $h$ ;  $\hat{c}_i^{(h-1)}$  denotes the segment of output of layer  $h-1$  for convolution at location  $i$  (where  $\hat{c}_i^{(0)} = x_{i...i+l-1}$  — one-hot vectors of  $l$  characters from tweet  $s$ );  $b^{(h,F)}$  is the bias associated with that filter at layer  $h$ ;  $g$  is a rectified linear unit and  $\odot$  is element-wise multiplication. The output of the convolutional layer  $c^h(s)$  is a matrix, the columns of which are feature maps  $c^{(h,F_k)}(s)|k \in 1..f$ .

The output of the convolutional layer is followed by a 1-d max-overtime pooling operation (Collobert et al., 2011) over the feature map and selects the maximum value as the prominent feature from the current filter. Pooling size may vary at each layer (given by  $p^{(h)}$  at layer  $h$ ). The pooling operation shrinks the size of the feature representation and filters out trivial features like unnecessary combination of characters (in the initial layer). The window length  $l$ , number of filters  $f$ , pooling size  $p$  at each layer can vary for each classification task.

The output from the last convolutional layer is flattened and passed into a series of fully connected layers. The output of the final fully connected layer (sigmoid or softmax) gives a probability distribution over categories in our classification task. For regularization we apply a dropout (Hinton et al., 2012) mechanism after the first fully connected layer. This prevents co-adaptation of hidden units by randomly setting a proportion  $\rho$  of the hidden units to zero (Generally, we set  $\rho = 0.5$ ). CharCNN can be robust to misspellings and noise, provided there is sufficiently large dataset to train the model.

**Figure 2:** Illustration of Word-Embedding Convolutional Model

## 2.2 Convolutional Word-Embedding Model

The convolutional embedding model (see Figure 2) assigns a  $d$  dimensional vector to each of the  $n$  words of an input tweet resulting in a matrix of size  $n \times d$ . Each of these vectors are initialized with uniformly distributed random numbers i.e.  $x_i \in \mathbb{R}^d$ . The model, though randomly initialized, will eventually learn a look-up matrix  $\mathbb{R}^{|V| \times d}$  where  $|V|$  is the vocabulary size, which represents the word embedding for the words in the vocabulary.

A convolution layer is then applied to the  $n \times d$  input tweet matrix, which takes into consideration all the successive windows of size  $l$ , sliding over the entire tweet. A filter  $w \in \mathbb{R}^{h \times d}$  operates on the tweet to give a feature map  $c \in \mathbb{R}^{n-l+1}$ . We apply a max-pooling function (Collobert et al., 2011) of size  $p = (n - l + 1)$  shrinking the size of the resultant matrix by  $p$ . In this model, we do not have several hierarchical convolutional layers - instead we apply convolution and max-pooling operations with  $f$  filters on the input tweet matrix for different window sizes ( $l$ ).

The vector representations derived from various window sizes can be interpreted as prominent n-gram word features for the tweets. These features are concatenated to give a vector of size  $f \times L$ , where  $L$  is the number of different  $l$  values which is further compressed to a size  $k$  before passing it to a fully connected softmax or a sigmoid layer whose output is the probability distribution over different categories of our classification task.

## 3 Model Training

We trained the CharCNN model and the Word-Embedding convolutional model for different targets and selected the best model for each of them. In our task, the tweets are classified into three categories: Favor, Against, and None. We defined the ground truth vector  $p$  as a one-hot vector. The com-

monly used hyperparameters for the convolutional layers of our CharCNN are:  $f = 256$ ,  $l = 7$  (first two layers) and  $l = 3$  (other 3 layers). The sizes of the fully connected layers in our CharCNN model are 1,024 and 512.

Similarly, the commonly used hyperparameters of the Convolutional Word-Embedding model are:  $l = 2, 3, 4$ ,  $f = 200$ ,  $d = 300$ ,  $k = 256$ . Softmax layer takes the output from the penultimate layers of the corresponding models, thereby generating a distribution over the three classes in our task. The class with the maximum probability is the label for the given input tweet.

To learn the parameters of the model we minimize the cross-entropy loss as the training objective using the Adam Optimization algorithm (Kingma and Ba, 2014). It is given by

$$CrossEnt(p, q) = - \sum p(x) \log(q(x)) \quad (4)$$

where  $p$  is the true distribution (1-of-C representation of ground truth) and  $q$  is the output of the softmax. This, in turn, corresponds to computing the negative log-probability of the true class. Each of the classifiers were trained for approximately 8-10 epochs.

In order to deal with the imbalance in the data, we used a simple balancing technique: to choose a sample on each training step, we randomly picked a class and then randomly selected a tweet associated with this class.

## 4 Training Set Expansion

We expanded the training set by collecting additional tweets for each target-stance pair from the Twitter historical archives. To form a query for the historical API, we automatically selected 40 representative hashtags for each target-stance pair and manually filtered the resulting hashtags lists. The total amount of additional tweets was 1.7 million. Since number of collected tweets vastly exceeded the size of the official dataset, we decided to abstain from using the latter for training and instead use it for validation purposes. For some targets (mentioned in the section 5.2), we augmented the collected set with tweets obtained by replacing some words and phrases with similar ones, using Word2Vec.

## 4.1 Identifying Representative Hashtags

We found hashtags well-suited for forming a data expansion query. Hashtags are commonly used to represent a “topic” or “theme” of a tweet and thus often convey information of both the target and the stance (e.g. #stophillary2016).

We measured the strength of association between a hashtag and a particular target-stance pair by computing mutual information between them. More precisely, we defined two indicator variables for hashtag occurrences in tweets:

1. Whether the current hashtag is equal to the hashtag of interest.
2. Whether the tweet has the target and the stance of interest.

The mutual information between two random variables is computed as:

$$I(X, Y) = \sum_{x \in X, y \in Y} p(x, y) \log \frac{p(x, y)}{p(x)p(y)} \quad (5)$$

We estimate mutual information between our indicator variables using a Bayesian approach. We find the expected value of mutual information, assuming an uninformed Dirichlet prior on the joint distribution of the two variables. It can be approximately computed using the formula provided in (Hutter, 2002):

$$E[I] \approx \sum_{i,j \in \{0,1\}} \frac{n_{ij}}{n} \log \frac{n_{ij}n}{n_{i+}n_{+j}} + \frac{0.5}{n} \quad (6)$$

Where  $n_{ij}$  is the count of samples with indicator variables assuming values  $i$  and  $j$  respectively, corrected by a pseudo-count of 0.5;  $n_{i+} = \sum_j n_{ij}$  and  $n_{+j} = \sum_i n_{ij}$ .

To get a more reliable estimation of hashtag frequencies for tweets unrelated to the targets, we collected a “background” sample of 1.2 million English-language tweets. We treated these tweets as having no stance in relation to any of the targets and used them in computation of the counts above.

For each target-stance pair, we selected 40 hashtags with highest mutual information for further manual filtering. Samples of selected hashtags can

be seen in Table 1. The manual filtering step was necessary, since the statistical association with a target-stance pair could only serve as a proxy for the fact that the tag explicitly expresses the target and the stance. For example, #tcot (standing for “top conservatives on Twitter”) was highly associated with the stance “AGAINST” for the target “Climate Change is a Real Concern”, but not explicitly expressing this stance. Although we did not make the identification of representative hashtags completely automatic, we found that hashtag filtering is a very manageable task for the annotator, taking only an hour of time for all five targets, making it an ideal place to introduce minimal human input.

| Target  | FAVOR (F)      | AGAINST (A)    |
|---------|----------------|----------------|
| Abn.    | #antichoice    | #prolifeyouth  |
| Ath.    | #fuckreligion  | #teamjesus     |
| Cl. Ch. | #cfcc15        | #carbontaxscam |
| Fem.    | #yesallwomen   | #gamergate     |
| H. Cl.  | #hillary4women | #nohillary2016 |

**Table 1:** Samples of representative hashtags

## 4.2 Collecting and Preprocessing Tweets

| Target          | FAVOR (F) | AGAINST (A) |
|-----------------|-----------|-------------|
| Abortion        | 23,228    | 274,769     |
| Atheism         | 3,041     | 551,193     |
| Climate Change  | 355,763   | 60,238      |
| Feminism        | 124,760   | 178,834     |
| Hillary Clinton | 40,060    | 82,294      |

**Table 2:** Number of collected tweets per target and stance

As can be seen in Table 2, the collected tweets are very unevenly distributed between target-stance pairs. There are two causes for this: the uneven distribution of different stances on Twitter in general, and uneven number of representative hashtags that we were able to associate with each target-stance pair. For instance, the pair “Climate Change is a Global Concern: AGAINST” was represented by only 15 tweets in the training data that was provided, limiting us to only two representative hashtags. Since our deep learning models require balanced amount of samples, we used the balancing technique described in the previous section.

To eliminate the possibility that resulting classifiers would only learn the hashtags in the query,

we removed these hashtags from the majority of the collected tweets, keeping them only in 25% of the tweets.

### 4.3 Augmenting Data Using Word2Vec

Data augmentation techniques are widely used to enhance generalization of models with respect to input transformations that are known to not affect the output significantly. An example application of data augmentation in NLP can be found in (Zhang and LeCun, 2015), where they used thesaurus-based synonym replacement (WordNet (Fellbaum, 1998)) to generate additional training samples. We applied the technique used by Zhang et al (Zhang and Le-Cun, 2015) to our task, with the difference that we used Word2Vec (Mikolov et al., 2013) instead of a thesaurus to find similar words. The underlying intuition was that Word2Vec can provide better coverage for phrases related to our targets.

The algorithm of the data augmentation is as follows. At every step, we randomly selected a tweet from the non-augmented training set. We sampled a number  $r$  of words/phrases we would like to replace from a geometric distribution with parameter  $p$ . We then randomly sampled  $r$  words/phrases, that are part of the Word2Vec vocabulary from the current tweet. (if  $r$  was larger than number of available words/phrases  $n$ , we used  $r \bmod n$ .) For each of these words/phrases, we retrieved a list of most similar ones in terms of cosine similarity of Word2Vec vectors. We ordered the list in decreasing order of similarity and truncated it to not include items with similarity less than threshold  $t$ . We then sampled index  $s$  of selected replacement from another geometric distribution with parameter  $q$  (again, we used modulo if  $s$  was too big). The original words/phrases were then replaced, and the tweet was added to the augmented dataset. The particular values of  $p$ ,  $q$  and  $t$  were 0.5, 0.5 and 0.25 respectively. Using this method, we generated 500,000 extra tweets for each target-stance pair.

## 5 Evaluation

### 5.1 Baseline

To have a better sense of our approach’s performance, we compared results against a simple baseline. We built a set of Naive Bayes classifiers using bag-of-word features and optimized their pa-

rameters using 20-fold cross validation on original training data. We experimented with different thresholds on word count for a word to be included into vocabulary. We also set up separate thresholds for hashtags and at-mentions. After selecting the most promising values of thresholds, priors and the smoothing parameter, we ran the Naive Bayes classifiers on the test data to obtain results shown in Table 3.

### 5.2 Validation Results

We trained the models using the collected dataset and validated them on the training set provided for the task. The validation results informed the choice between the word-level and the character-level classifiers for each target. Without Word2Vec augmentation, character-level classifier achieved the best performance only for the target “Feminist Movement”. When Word2Vec augmentation was introduced, the character-level model achieved the best performance for the target “Climate Change” and the stance ”FAVOR” of the target ”Hillary Clinton”. The word-level model performed better for the targets: “Legalization of Abortion”, “Atheism” and the stance ”AGAINST” of the target “Hillary Clinton”. We were able to achieve better average performance for the target ”Hillary Clinton” by combining character-level and word-level classifiers with a simple heuristic: whenever character-level model

| <i>Target</i>    | <i>St.</i> | <i>Precision</i> | <i>Recall</i> | <i>F1</i> |
|------------------|------------|------------------|---------------|-----------|
| Abortion         | F          | 0.44             | 0.35          | 0.39      |
| Abortion         | A          | 0.73             | 0.85          | 0.79      |
| Atheism          | F          | 0.34             | 0.28          | 0.31      |
| Atheism          | A          | 0.79             | 0.86          | 0.82      |
| Clinton          | F          | 0.42             | 0.22          | 0.29      |

**Table 4:** Performance of Word-Level Classifiers for Climate Change, Hillary Clinton and Feminist Movement.

predicts “AGAINST”, use that decision, otherwise resort to the decision of word-level model.

Table 4 compares the performance of the character-level and word-level classifiers for the targets where character-level classifiers yielded an advantage. The macro-average F1 validation score was 0.65.

### 5.3 SemEval Competition Results

Our model was able to achieve a Macro F-score of 0.6354 (placing us eighth out of 19 teams), while the best performing model had a Macro F-score of 0.6782. Table 5 details results on the test data for each target and stance.

| <i>Target (rank)</i> | <i>St.</i> | <i>P</i> | <i>R</i> | <i>F1</i> |
|----------------------|------------|----------|----------|-----------|
| Abn. (1)             | F          | 0.54     | 0.67     | 0.60      |
|                      | A          | 0.86     | 0.54     | 0.66      |
| Ath. (12)            | F          | 0.33     | 0.25     | 0.29      |
|                      | A          | 0.82     | 0.73     | 0.77      |
| H. Cl (9)            | F          | 0.37     | 0.53     | 0.43      |
|                      | A          | 0.68     | 0.66     | 0.67      |

|                      | A          | N/A      | 0        | N/A       |
| Fem. (8)             | F          | 0.37     | 0.40     | 0.38      |
|                      | A          | 0.79     | 0.58     | 0.67      |
| All (8)              | F          | 0.56     | 0.61     | 0.58      |
|                      | A          | 0.78     | 0.61     | 0.68      |
| <i>Macro-Avg</i>     | -          | 0.67     | 0.61     | 0.635     |

**Table 5:** Results on test data, with rank out of the 19 teams.

## 6 Discussion and Future Work

An interesting result of our work was that given enough data, character-level models outperformed word-level models for tweet classification (with a

dramatic improvement in case of ”Hillary Clinton: FAVOR”). Due to the lack of data, it was necessary to resort to a data augmentation technique to generate sufficient amount and diversity of data for character-level model to show its advantage. Another interesting finding from our work is the suitability of word2vec-based substitution as a data augmentation technique. As far as we know, word2vec has not previously been used for data augmentation in this manner.

As can be seen in Table 5, our system did not perform too well for certain target-stance pairs (e.g., Atheism-Against). We hypothesize that the reason for this is the noise and the limited size of the collected training data. Thus, we believe that the performance of the system can be improved through better data expansion and cleaning techniques.

We see several avenues for future improvements. First, it might be beneficial to use unsupervised pre-training for our models (e.g., using autoencoders for Twitter (Vosoughi et al., 2016)). Second, data cleaning can potentially be improved using bootstrapping. This would entail using our current models (optimized for high precision) to gather cleaner data for the second tier of models. It could be repeated while validation performance improves. Finally, because of the constraints of this SemEval task, we did not manually select hashtags or terms commonly associated with target-stance pairs. Inclusion of such hashtags can potentially boost the quality of the dataset, leading to better performance of our models.

## Abstract

Stance classification aims to identify, for a particular issue under discussion, whether the speaker or author of a conversational turn has Pro (Favor) or Con (Against) stance on the issue. Detecting stance in tweets is a new task proposed for SemEval-2016 Task6, involving predicting stance for a dataset of tweets on the topics of abortion, atheism, climate change, feminism and Hillary Clinton. Given the small size of the dataset, our team created our own topic-specific training corpus by developing a set of high precision hashtags for each topic that were used to query the twitter API, with the aim of developing a large training corpus without additional human labeling of tweets for stance. The hashtags selected for each topic were predicted to be stance-bearing on their own. Experimental results demonstrate good performance for our features for opinion-target pairs based on generalizing dependency features using sentiment lexicons.

## 1 Introduction

Social media websites such as microblogs, weblogs, and discussion forums are used by millions of users to express their opinions on almost everything from brands, celebrities, and events to important social and political issues. In recent years, the microblogging service Twitter has emerged as one of the most popular and useful sources of user content, and recent research has begun to develop tools and computational models for tweet-level opinion and sentiment analysis. Stance classification aims to identify, for a particular issue under discussion, whether the

speaker or author of a conversational turn has a Pro (Favor) or Con (Against) stance on the issue (Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010; Walker et al., 2012c; Sridhar et al., 2015; Hasan and Ng, 2013).

| <b>Id</b> | <b>Tweet</b>  | <b>Stance</b> |
|-----------|---|---------------|
| <b>T1</b> | We are causing the ice masses of Earth to melt at an alarming rate. | FAVOR         |
| <b>T2</b> | ONE Volcano emits more pollution than man has in our HISTORY!       | AGAINST       |
| <b>T3</b> | It's most exciting to witness a major development!                  | NONE          |
| <b>T4</b> | The Weather app keeps taunting us with rain. #PNW #drought          | NONE          |

Table 1: Example tweets with stance labels for the issue *Climate Change is a Real Concern*.

Detecting stance in tweets is a new task proposed for SemEval-2016 (Mohammad et al., 2016). The aim of the task is to determine user stance (FAVOR, AGAINST, or NONE) in a dataset of tweets on the five selected topics of abortion, atheism, climate change, feminism and Hillary Clinton. Consider the tweets in Table 1, which express stance toward the target issue *Climate Change is a Real Concern*. It can be inferred that the author of tweet **T1** is in favor of the target while the author of tweet **T2** is clearly against the target. However due to the brevity of tweets, there is not always sufficient information about the target to determine stance: in the case of tweet **T3**, we are unsure what *major development* the user is talking about. In the case of tweet **T4**, we know the user acknowledges the existence of a drought, but we do not know their stance on the issue of climate change solely based on this information. In such cases the stance of the tweets is labelled NONE for

this issue.

The task is nontrivial due to the challenges of the tweet genre. Tweets are often highly informal with language that is colorful and ungrammatical. They may also involve sarcasm, making opinion-mining tasks more challenging (Riloff et al., 2013; Reyes et al., 2012). Users may assert their stance using factual or emotional content, and due to their restricted length, tweets may not be well structured or coherent. As a result, NLP tools trained on well-structured text do not work well in Twitter (Dey and Haque, 2008), and new tools are constantly being developed (Qadir and Riloff, 2014; Kong et al., 2014; Han and Baldwin, 2011; Zhu et al., 2014).

Our approach to stance classification in tweets is primarily based on developing a suite of tools for processing Twitter that mirrors our previous work on stance classification in online forums (Walker et al., 2012c; Sridhar et al., 2015; Anand et al., 2011; Walker et al., 2012b; Misra and Walker, 2015). We develop generalized dependency features that capture expressed sentiment or attitude towards particular targets, using the Tweebo dependency parser (Kong et al., 2014). Given the small size of the official task dataset, we created our own topic-specific training corpus in a semi-supervised manner. We developed a set of high precision hashtags for each topic that were used to query the Twitter API in order to create a large training corpus without additional human labeling of tweets for stance. The hashtags and boolean combinations of hashtags selected for each topic were predicted to be stance-bearing on their own. See Table 2.

There has been considerable previous work on stance classification in online forums and in congressional debates (Thomas et al., 2006; Burfoot et al., 2011; Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010; Walker et al., 2012c; Sridhar et al., 2015; Hasan and Ng, 2013; Boltuzic and Šnajder, 2014; Hasan and Ng, 2014). A number of these studies show that collective classification approaches perform well, and that the context (Walker et al., 2012c; Abbott et al., 2011), and meta information such as author constraints are useful for stance classification (Hassan et al., 2012; Hasan and Ng, 2014). Collective classification is not possible in the current task because the only information provided is the text of each individual

tweet. Inspired by earlier work (Joshi and Penstein-Rosé, 2009; Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010; Walker et al., 2012b), we apply a framework for developing features for opinion-target pairs based on generalized structural dependency features, using the LIWC dictionary as the basis for generalization (Pennebaker et al., 2001). We also develop features to capture domain knowledge using PMI values for topic n-grams in order to improve the recognition of tweets with the NONE stance. We describe our system and data in Sec. 2, our experimental set-up in Sec. 3, and our results and error analysis in Sec. 4. We conclude and discuss future directions in Sec. 5.

## 2 Data

The relatively small, unbalanced training set provided for the task introduced an interesting subtask for precise topic-oriented tweet collection without direct human annotation. Twitter hashtags provide a method for users to tag their own content by topic, and we exploit this self-annotation to collect a larger dataset for training by hand-selecting seed hashtags for both the FAVOR and AGAINST stances for each topic. We then query Twitter for tweets containing these hashtags using the API, and produce a training set from the results without further supervision. We treat the original SemEval dataset as development data, assuming it is similar to the SemEval test set.

When collecting data in this fashion, there are multiple factors that must be accounted for. These include the accuracy of labels, data uniformity and representativeness, and dataset size. The accuracy of our labels is directly related to the specificity of our hashtags. We perform a small evaluation of each hashtag added to our seed pool by checking its accuracy on a subset of queried data by hand. With regard to data uniformity and representativeness, we want to ensure that our collected data is not too uniform as a large collection of very similar tweets provides little additional information, and we want to ensure that our data is representative of the actual SemEval data that may be produced from different preprocessing and collection techniques. We evaluate the uniformity and representativeness of our data in Sec. 4.

After we finish collecting data, we create bal-

| Topic           | Seed Hashtags   |   | Tweets |
|-----------------|---|---|--------|
|                 | FAVOR   | AGAINST   | #N     |
| Abortion        | #ProChoice, #StandWithPP, #IStandWithPP, #RightTo-Choose                  | #ProLife, #UnbornLivesMatter, #DefundPP, #PrayToEndAbortion                     | 22194  |
| Atheism         | #Awesome\atheism, #AtheistVoter, #AntiReligion, #NotAfraidOfBurningInHell | #AntiAtheism, #HolyBible, #God, #Prayer-Works, #PraiseTheLord                   | 11616  |
| Climate Change  | #DemandClimateAction, #SaveThePlanet, #ActOnClimate, #GlobalWarmingIsReal | #Lies\climate, #Hoax\climate, #Global-WarmingIsALie, #Fraud\climate             | 321    |

| Hillary Clinton | #ImWithHer, #HillYes, #ITrustHillary, #TeamHillary                        | #StopHillary, #OhHillNo, #HillNo, #HillaryFor-Prison, #WhyImNotVotingForHillary | 8529   |

Table 2: Example hashtags and hashtag boolean combinations used to produce training data, and size of the resulting final balanced training dataset.

anced FAVOR, AGAINST, and NONE training sets for each topic. Tweets in the NONE class are collected from other topics or from a corpus of random tweets. A summary of the final seed hashtags and dataset sizes is shown in Table 2.

## 2.1 Data preprocessing

Since tweets can be noisy, uninformative, or ambiguously labeled, we apply the three filters below to get better quality tweets.

- *Duplicate removal:* Remove all tweets that have an 80% or greater overlap with another already included tweet.
- *Dictionary words:* Tweets with less than 4 dictionary words are excluded. Although this filter may not be appropriate for all tasks as Tweets may incorporate large amounts of non-dictionary slang, we observe that the SemEval training data has few instances that do not pass this test.
- *Favor and Against:* Remove tweets that have both FAVOR and AGAINST hashtags.

## 2.2 Data Normalization

Tweets can be noisy due to irregular words and other genre specific language. We preprocess all tweets as follows:

- *Repeated characters:* Replace a sequence of repeated characters by two characters. For example, convert “shoooooooooot” to “shoot”.

- *Lexical variation:* We used the Python Enchant dictionary to determine if a token is a dictionary word. If a token is not present in the dictionary then it is replaced by finding a possible lexical variant using the English Social Media Normalisation Lexicon (Han et al., 2012), for example, “tmrrw” is changed to “tomorrow”.

We use a part-of-speech tagger for tweets to perform tokenization and POS labelling (Gimpel et al., 2011). We also use TweeboParser, a dependency parser specifically designed for tweets, to parse each tweet (Kong et al., 2014).

Our data representation for the corpus keeps track of the original tweet, the normalization replacements, the POS tags, and the parses. Sec. 3 describes the features derived from these pre-processing steps that we also store in our corpus database, modelled after IAC 2.0. (Abbott et al., 2016).

## 3 Experimental Setup

We explored a large number of machine learning algorithms and feature combinations, using the automatically harvested tweets as training and the training set provided for the task as our development data to fit the parameters for the final submitted NLDS-UCSC system. Sec. 3.1 describes the feature sets created using the development set. To evaluate the effects of hashtags on the test set we explored two different ways to train the system. Table 4 presents the results on the test set with hashtags present in the dataset while Table 5 is the performance without hashtags.

| Topic           | Features   | Feature Selection | F-score (evaluation metric) |         |         |
|-----------------|--|-------------------|-----------------------------|---------|---------|
|                 |  |                   | favor                       | against | average |
| Abortion        | unigram, bigram, dep, liwc_dep, opinion_dep  | none              | 0.71                        | 0.64    | 0.67    |
| Atheism         | unigram, bigram, dep, liwc_dep, opinion_dep  | correlation       | 0.73                        | 0.66    | 0.69    |

Table 4: Feature ablation w/ hashtags for each topic on Test Set, along with F-measure for favor, against, and their average.

### 3.1 Features

**Unigrams and Bigrams:** We extracted unigrams and bigrams from the preprocessed tweets. The useful unigrams are mainly hashtags. We used both stemmed and unstemmed ngrams.

**POS bigrams and trigrams:** The tweet part-of-speech tagger is used to perform tokenization and POS identification (Gimpel et al., 2011). We then extracted POS bigrams and trigrams as features.

**LIWC:** We derived features using the Linguistics Inquiry Word Count tool and use the count of words in each category as the feature value (Pennebaker et al., 2001).

**Dependency:** We used TweeboParser to extract dependency features. For a given tweet, TweeboParser predicts its syntactic structure, represented by unlabeled dependencies (Kong et al., 2014).

**Generalized LIWC and Opinion Dependency:** We created two kinds of generalized dependency features. Building on the idea that partially generalized dependencies are better than ungeneralized or completely generalized dependencies (Joshi and Penstein-Rosé, 2009), we leave one dependency element lexicalized and generalize the other to its LIWC category for LIWC dependency features. We follow a similar process to produce generalized opinion dependencies using AFINN lexicon and opinion-lexicon-English by (Hu and Liu) replacing one element of the dependency with its sentiment score and leaving the other element lexicalized (Hu and Liu, 2004; Nielsen, 2011). <sup>1</sup> <sup>2</sup>

Inspired by previous work on combining sentiment lexicons we used a combined sentiment score to denote the accuracy of a sentiment word rather than its strength. If dictionaries contradict one another on the sentiment polarity for a word, then the score is neutralized to zero. If a single dictionary lists the polarity word, but it is unlisted or neutral in the other dictionary, then the score is 1 in the direction of the polarity. If both dictionaries list a word with the same polarity, then the score is 2 in the direction of the polarity. After calculating the combined sentiment score, we check if either of the previous two words is listed as a negation by LIWC,

<sup>1</sup><https://www.cs.uic.edu/ liub/FBS/sentiment-analysis.html>

<sup>2</sup><http://neuro.imm.dtu.dk/wiki/AFINN>

and invert the polarity if a negation is found(Cho et al., 2013; Hasan and Ng, 2012).

**Pointwise Mutual Information (PMI):** For each topic, we calculate normalized pointwise mutual information over a combination of an extended version of IAC 2.0, a topic annotated database of posts from debate forums (Abbott et al., 2016; Walker et al., 2012a), and our own collected tweets for each topic. IAC 2.0 includes several topics that are in overlap with the topics in the current task.

We then create a pool of top-N percent PMI unigrams, bigrams, and trigrams for each topic and use the count of words in each tweet that are also in this pool as a feature. We also use the highest PMI value of an n-gram in each tweet as a feature.

## 4 Results

We ran experiments using the SemEval training as our development data with NaiveBayesMultinomial, SVM, and J48 from WEKA. We tried a large number of feature combinations w/ and w/out stemmed n-grams.

The best performing system ended up being different for each topic. Overall, NBM worked the best for all topics. Table 3 describes the system model submitted for each topic based on the results. The model that performed best on the dev set was used to report accuracies on the test set. We present the results on the test set in Table 4. The best performing model from the dev set for the topic of climate control shows a marginal but not significant improvement, and none of the features on their own could beat a unigram baseline for any topic. Since most of the hashtags are unigrams, we hypothesize this may be due to presence of strong stance-bearing hashtags in the data. In order to assess the issue of strong stance-bearing hashtags still existing in the training data, we remove all hashtags from both the training data and test data and retrain classifiers. See Table 5. For the topic of abortion we see that the combined unigram, bigram, and dependency model now outperforms the unigram model, and the dependencies alone start to edge out an advantage as well, suggesting that it may be the case that strong stance-bearing hashtags distract from and disguise true performance of each feature and potentially the model as a whole.

Feature ablation results reveal that for the majority of the topics part-of-speech n-grams perform better than LIWC. This was surprising because LIWC was designed to capture emotional and psychological behavior in conversations, and because previous research on stance classification using debate forums shows LIWC categories can improve an n-gram baseline (Anand et al., 2011). This may be due to *sarcasm and irony*, a frequent phenomena in twitter not captured by LIWC, but which may to some extent be captured by part-of-speech n-grams that reflect the use of adjectives and adverbs in sarcastic posts (Lukin and Walker, 2013; Reyes et al., 2012). Generalizing Twitter-specific dependency structures using LIWC and sentiment lexicons does however prove useful.

### 4.1 Learning Curves

To asses the usefulness of increasing our training set size we plot learning curves for each topic (abortion shown in Figure 1 and all others in appendix A). For each topic we plot the average f-measure (FAVOR, AGAINST) for a unigram baseline, dependency baseline, and best performing model on the dev set.

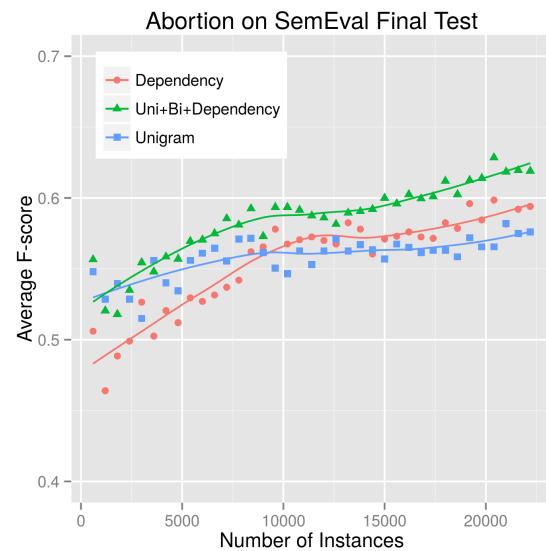

Figure 1: Training set size vs average Fscore for abortion.

Figure 1 shows that the classifier for the abortion topic gains around 0.6 f-measure when increasing the number of instances from 5,000 to 20,000, and it continues to show promise for growth, especially

| Features                | Abortion |         |      | Atheism |         |      | Climate Change |         |      | Feminism |         |      | Hillary Clinton |         |      |
|-------------------------|----------|---------|------|---------|---------|------|----------------|---------|------|----------|---------|------|-----------------|---------|------|
|                         | favor    | against | avg  | favor   | against | avg  | favor          | against | avg  | favor    | against | avg  | favor           | against | avg  |
| <b>unigram</b>          | 0.50     | 0.70    | 0.60 | 0.49    | 0.77    | 0.63 | 0.62           | 0.20    | 0.41 | 0.32     | 0.63    | 0.47 | 0.35            | 0.67    | 0.51 |
| <b>All dependencies</b> | 0.50     | 0.71    | 0.61 | 0.41    | 0.77    | 0.59 | 0.63           | 0.12    | 0.38 | 0.36     | 0.62    | 0.49 | 0.40            | 0.68    | 0.54 |
| <b>POS</b>              | 0.39     | 0.44    | 0.42 | 0.29    | 0.70    | 0.50 | 0.62           | 0.09    | 0.35 | 0.30     | 0.48    | 0.39 | 0.32            | 0.5     | 0.41 |
| <b>POS+Dep</b>          | .51      | 0.73    | 0.62 | 0.47    | 0.81    | 0.64 | 0.66           | .09     | 0.38 | 0.32     | 0.61    | 0.46 | 0.42            | 0.69    | 0.56 |

Table 5: Tweets without hashtags on the Test set, along with F-measure for favor, against and their average.

in terms of the dependency and best model curves. We see a similar promise for growth in the model for Hillary Clinton in which dependencies have just passed unigrams. The differences in learning rate for each topic suggest that the precision of our stance-sided seed hashtags varies largely by topic because similar amounts of data provide less information gain, signaling the data may be of lower quality. In addition to extracting more data for each topic, it would also be helpful to refine our hashtag selection for topics such as atheism, where increase in training set size do not yield performance improvement.

## 5 Conclusion and Future work

We explore a semi-supervised approach to stance classification using stance-bearing hashtags and achieve reasonable accuracies on a hand-annotated test set. This suggests that our approach of querying using seed hashtags and using some heuristic filters to improve tweet quality may be promising for generating a large corpus of training data. It may also be useful in other domains where hand-annotated data does not exist and getting annotations is time consuming and costly effort. To determine the feasibility of using this semi-supervised data in other domains, we removed all the hashtags from the tweets and again compared the performance of our dependency and unigram features. Table 5 shows that these results look promising. In future work, we hope to use more intelligent features that may capture irony and sarcasm, and we plan to expand and refine our data collection process to account for the varying precision of stance-sided hashtags across topics.

## 6 Acknowledgments

We are thankful to Yanfei Tu for her help on the project. This work was supported by the Robust

Intelligence Program of NSF under Award #IIS-1302668.

## A Appendix: Learning Curves

Below we show the learning curves for each topic on the SemEval test data after removing hashtags from both the train and test sets. Climate change is excluded due to the small number of training instances. Each graph includes a line for unigrams, dependencies, and the best model on the dev set (unigrams are the best model for the Hillary Clinton topic).

## Abstract

In this paper, we describe our participation in the first shared task on automated stance detection (*SemEval 2016 Task 6*). We consider the task as a multidimensional classification problem and thus use a sequence of stacked classifiers. For subtask A, we utilize a rich feature set that does not rely on external information such as additional tweets or knowledge bases. For subtask B, we rely on the similarity of tweets in this task with tweets from subtask A in order to transfer the models learnt in subtask A.

## 1 Introduction

Stance-taking is an essential and frequently observed part of online debates and other related forms of social media interaction (Somasundaran and Wiebe, 2009; Anand et al., 2011). In the *SemEval 2016 Task 6: Detecting Stance in Tweets* (Mohammad et al., 2016), stance is defined relative to a given target like a politician or a controversial topic. A text can then either be in favor of the given target (FAVOR), or against it (AGAINST). As the dataset also contains texts without a stance, we additionally have to deal with the class NONE.

Being able to automatically detect and classify stance in social media is important for a deeper understanding of debates and would thus be a great tool for information seekers such as researchers, journalists, customers, users, companies, or governments. In addition, such analysis could help to create summaries, develop a deeper understanding of online debating behavior, identify social or political

groups, or even adjust recommendations to users' standpoints (Anand et al., 2011; Sridhar et al., 2014; Boltuzic and Šnajder, 2014).

In the following, we describe our system for stance detection. We did not make use of any sources of external information such as additional tweets or stance knowledge bases, as our goal was to rely only on the provided training data. Since the task allowed just for one submission, we include some further analysis that will shed light on the usefulness and impact of the used features and parameters.

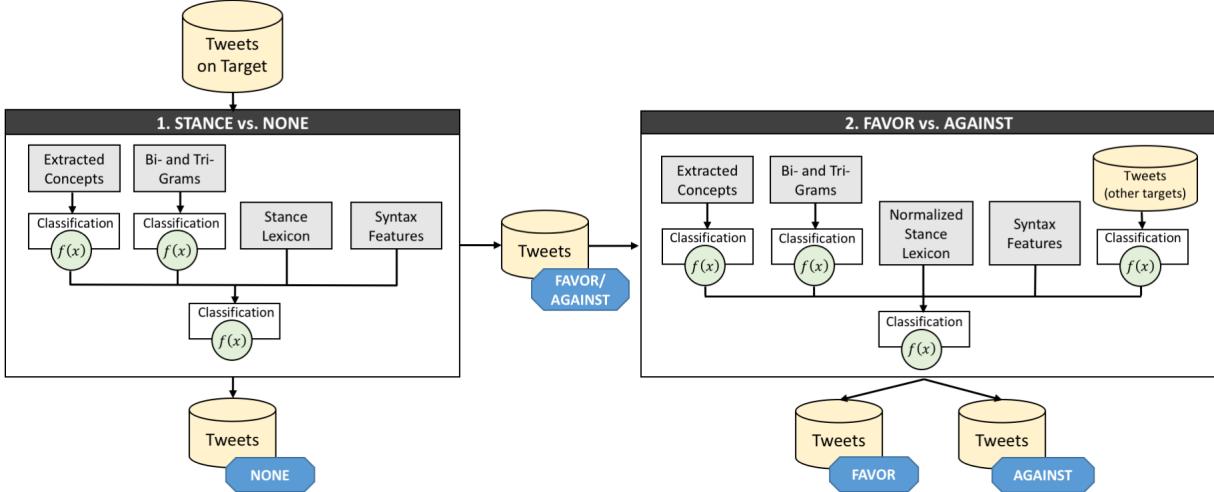

## 2 Subtask A – Supervised Framework

The goal of this subtask is to classify tweets about five targets: *Atheism*, *Climate Change is a Real Concern*, *Feminist Movement*, *Hillary Clinton*, and *Legalization of Abortion*. For each target, there are about 400-600 manually labeled tweets that can be used for training.

As the targets are quite different, we train a separate classifier for each of them. Additionally, we split the three-way classification into a stacked classification, in which we first classify whether the tweet contains any stance (classes FAVOR and AGAINST) or no stance at all (class NONE). In a second step, we classify the tweets labeled as containing a stance as FAVOR or AGAINST. This sequence of classifications is visualized in Figure 1.

All shown classifications are implemented using the DKPro TC framework<sup>1</sup> (Daxenberger et al., 2014) and utilize the integrated Weka SVM classifier.

<sup>1</sup>version 0.8.0-SNAPSHOT

**Figure 1:** Overview on the sequence of stacked classifications that is used for the supervised setting (subtask A)

## 2.1 Preprocessing

We use the DKPro Core framework<sup>2</sup> (Eckart de Castilho and Gurevych, 2014) for preprocessing. We apply the twitter-specific tokenizer Twokenizer<sup>3</sup> (Gimpel et al., 2011), the DKPro default sentence splitter, and the Arktweet Pos tagger<sup>4</sup> (Gimpel et al., 2011).

As the Arktweet PoS tagger has a special tag for hashtags, even syntactically integrated hashtags like in *I like #Hillary !* would be assigned the tag *hashtag*. Since our feature set relies on the syntactic role of the used words (e.g. nouns as the subject or object of an proposition), we only keep hashtag labels that occur at the end of a tweet. For all other hashtags, we additionally apply the OpenNlp PoS tagger<sup>5</sup> and overwrite the hashtag label with the syntactic category.

Afterwards, we annotate a fixed set of negations (*not*, *no*, *none*, *nor*, *never*, *nobody*, *neither*, *nowhere*) including contractions such as *can't*, *aren't*. Finally, we annotate modal verbs (*can*, *could*, *may*, *might*, *must*, *shall*, *should*, *will*, *would*).

## 2.2 Features

Figure 1 shows that both classifications use roughly the same feature set. However, the FAVOR vs.

AGAINST classification additionally uses a feature that transfers models learnt from other targets. In the following, we describe all features in detail, explain how they may relate to stance taking language, and outline differences in both classifications.

**N-Gram Features** We use the 500 most frequent *bi*-and *trigrams* as binary features to capture expressions that are longer than single words. Thereby we want to approximate multi word expressions such as *climate change*. As the resulting 500 features would outnumber the other features, we use stacking to classify according to the n-gram features only and use the outcome as a single feature in the overall model. Note that we handle *unigrams* by using an automatically created stance lexicon.

**Syntactic Features** According to Faulkner (2014), the usage of conditional sentences and modal verbs may indicate stance taking behavior. Hence, we use the number of sentences starting with *if* and the occurrence of modal verbs as a feature. As stance-taking behavior may be indicated by the usage of exclamation- and question marks (Anand et al., 2011), we use as a feature the overall counts as well as the count of over-use like ??? or !?!. Finally, we use as a feature the number of negation markers in a tweet.

**Stance-lexicon Features** For each target, we create a unigram stance lexicon by computing their statistical association with one of the outcome val-

<sup>2</sup>version 1.7.0

<sup>3</sup>version 0.3.2

<sup>4</sup>version 0.3.2

<sup>5</sup>maxent model in version 3.0.3

ues. This feature is inspired by the work of Soma-sundaran and Wiebe (2010) who use a subjectivity lexicon that was created by using the statistical association with negative and positive argumentation. We compute the association measure *gmean* (Evert, 2004) of every unigram towards the two poles (FAVOR/AGAINST or STANCE/NONE) and then use the difference between both values as the stance score  $s$ . The *gmean* association of a word  $x$  with a polarity class + is computed as:

$$gmean_+(x) = \frac{c_+(x)}{\sqrt{c_+(x) \cdot c_-(x)}} \quad (1)$$

where  $c_+(x)$  is the count of  $x$  in + and  $c_-(x)$  is the count of  $x$  in -. Based on the computed stance lexicon, we calculate the final polarity of as the normalized sum over the stance score  $s$  for each token in a tweet. In contrast to the mere use of *unigram* features the resulting lexicon has the advantage that it can distinguish between words that indicate stance with varying strengths.

As a defining feature of social media is the frequent usage of nonstandard spelling, we use text normalization in order to make this feature more robust. We first lowercase all tokens, remove @- and #-prefixes, and lemmatize plurals. For tokens that still do not appear in our stance lexicon, we compute the normalized *Levenshtein* edit distance (implemented using the DKPro Similarity (Bär et al., 2013)) and use the largest score if the value is smaller than .15. However, the normalization is only applied for the STANCE vs. NONE classification, since we observed that even capitalization can be a signal for being in favor or against a certain target.

In addition to unigram stance lexicons, we create a hashtag stance lexicon by using the same methodology, but just considering the tokens with the hashtag PoS tag (see Section 2.1).

**Concept Features** When analyzing the data, we observed that each target is associated with a few concepts that are subject of a controversial debate. Whereas the stance lexicon models words that are highly associated with one class, these words are associated with both classes. Since they are used by authors of different stances, they can be considered as being central for the debate. In order to retrieve the most central concepts, we select the top

12 nouns from each target. These candidates are then normalized (in the same fashion as described above) and cleaned for concepts that are not controversial (i.e. they are only used by authors with the same stance). For reasons of automation, no manual revision of concepts (e.g. handling words that are parts of multiword expressions such as *climate* and *change* or terms that are semantically related such as *feminist* and *feminism*) had been done. The remaining concepts are shown in Table 1.

For these concepts we learn, whether they express being in favor or against (respectively a stance at all) depending on their context. In order to model the context, the classifiers are equipped with n-gram features (*top 200 uni-, bi-, trigrams*). Finally, the prediction of these concept-classifiers is used as a feature.

**Target Transfer Features** Some targets appear to have a certain thematic overlap (e.g. there seems to be an overlap between *Legalization of Abortion* and *Feminist Movement* because both concern the rights of women). For example, consider a tweet about the target *Feminist Movement* that contains a stance towards abortion. If we want to classify the stance towards *Feminist Movement* it seems naturally to incorporate the stance towards abortion. This idea is modeled by applying models to a target that have been trained on a different target. The resulting classification is then used as a feature.

We only apply this feature if the tweet has a minimal topical overlap with one of the other targets domains. We found that on the training data, it works best if a tweet is related to a target if it contains one of the top 60 frequent nouns or named entities for some target domain (see also Section 3).

As shown in figure 1, this feature is only used for the AGAINST vs. FAVOR classification. On the training data, this feature only had an impact for the targets *Climate Change is a Real Concern*, *Hillary Clinton* and *Legalization of Abortion*. Thus, we only apply it for these targets on the test data, too.

## 2.3 Results

We report gained results on the provided test data using the official metric that is the macro-average of  $F_1(\text{FAVOR})$  and  $F_1(\text{AGAINST})$ . As shown in the first row of Table 2, our system achieved a score of

| Atheism  | Climate Change | Feminist Movement | Hillary Clinton | Abortion |
|----------|----------------|-------------------|-----------------|----------|
| day      | change         | equality          | campaign        | abortion |
| death    | climate        | feminism          | candidate       | baby     |
| faith    | summer         | feminist          | country         | body     |
| god      |                | gamergate         | hillary         | child    |
| life     |                | gender            | hillaryclinton  | choice   |
| religion |                | male              | president       | life     |
|          |                | man               | support         | time     |
|          |                | rape              | time            | woman    |
|          |                | time              | vote            |          |
|          |                | woman             | woman           |          |

**Table 1:** Extracted concepts for which a separate classifier is trained

.62. This corresponds to rank 12 in the official ranking (Mohammad et al., 2016). The performance of our system varies significantly between the different targets. For instance, the difference between the classification of the target *Legalization of Abortion* and *Climate Change is a Real Concern* is about 20 percent points.

In order to analyze the impact of the used features, we conducted an ablation test. The results in Table 2 show that the stance lexicon is the only feature that has a significant impact on all targets. The concept features seem to be helpful for some targets. When training a model with only those two features, we reach a score of .65 (whole test data) compared to .62 when using all features.

### 3 Subtask B – Weakly Supervised Framework

There is no training data for subtask B, so this has to be tackled in an unsupervised or weakly supervised fashion. The target is *Donald Trump* and participants are provided with large corpus (about 78 000 tweets) of un-annotated tweets.

Our approach for task B works in two stages (in analogy to task A): First, in order to determine whether a tweet has any stance at all, we compare each tweet with the whole collection. We found on subtask A, that if one filters all tweets that do not contain one of the  $n$  most frequent nouns or named entities of the target, the majority of the remaining tweets have a stance. Of course, larger values for  $n$  will improve recall on the cost of precision. As the second classification (FAVOR vs. AGAINST)

depends on a high precision, we decided to use a threshold that assigns a higher weight to precision. We empirically found that  $n = 60$  works well on subtask A. Tweets that are not similar are treated as NONE from here on.

Second, we select all targets (from Subtask A) that are most similar to a tweet. If a tweet is not similar to any target, we considered its stance as UNKNOWN from here on. If a target is selected, we use the model that has been trained on it to classify the tweet. This is the weakly-supervised part, as we apply a model that is trained on a different target.

There is one additional complication: One may argue that there is an inverse relationship between the stances of subtask A and the target *Donald Trump*. For instance, if a tweet is in favor of *Hillary Clinton*, there is a high likelihood that the tweet is implicitly against *Donald Trump*. A similar relation may be assumed for the other targets or at least for the majority of his supporters. Consequently, all classifications are inverted (AGAINST becomes FAVOR and FAVOR becomes AGAINST) and summed up. The final decision is then made on the majority vote. In case there are as much votes for FAVOR as for AGAINST we assume that the stance is UNKNOWN.

**Results** Our approach yields a score of .26 which corresponds to the 11<sup>th</sup> rank. However, this is inferior to the the performance of the base-rate (AGAINST) which is about .3. This suggests that the made assumptions (e.g. inverse relationship between stances of subtask A and B, majority vote of classifiers) are not optimal.

|                                   | All | Atheism | Climate Change | Feminist Movement | Hillary Clinton | Abortion |
|-----------------------------------|-----|---------|----------------|-------------------|-----------------|----------|
| all features (SemEval Submission) | .62 | .53     | .36            | .55               | .44             | .57      |
| - stance lexicon                  | .54 | .48     | .29            | .50               | .41             | .46      |
| - concepts                        | .62 | .52     | .35            | .54               | .46             | .58      |
| - negation                        | .62 | .55     | .36            | .55               | .44             | .57      |
| - target transfer                 | .62 | .53     | .35            | .55               | .46             | .58      |
| - punctuation                     | .62 | .56     | .35            | .55               | .47             | .57      |
| - conditional sentences           | .63 | .58     | .36            | .55               | .44             | .60      |
| - modal verbs                     | .63 | .58     | .36            | .55               | .44             | .60      |
| - n-grams                         | .64 | .59     | .38            | .56               | .51             | .58      |

**Table 2:** Ablation test of the feature set on the test data

## 4 Conclusion

In this paper, we presented our approach on automated stance detection based on stacked classifications. We split the three-way classification into a first classifier deciding whether there is any stance at all, and a second classifier that only makes a decision about the polarity of a tweet with a stance. Overall, we found a significant variation in performance across the targets and even between train and test data. An ablation test shows that from our rich feature set, only the automatically derived *stance lexicon* feature has a significant impact.

In general, our system (as well as all other participating systems) leaves much room for improvement. Stance detection could probably benefit from more semantically oriented features that go beyond the surface form of words.

## Acknowledgments

We would like to thank the the organizers of the SemEval task 6 for this interesting task and the three anonymous reviewers for their helpful comments. This work was supported by the Deutsche Forschungsgemeinschaft (DFG) under grant No. GRK 2167, Research Training Group "User-Centred Social Media".

## Abstract

We present a supervised system that uses lexical, sentiment, semantic dictionaries and latent and frame semantic features to identify the stance of a tweeter towards an ideological target. We evaluate the performance of the proposed system on subtask A in SemEval-2016 Task 6: “Detecting Stance in Tweets”. The system yields an average  $F_{\beta=1}$  score of 63.6% on the task’s test set and has been ranked the 6<sup>th</sup> by the task organizers out of 19 judged systems.

## 1 Introduction & Background

Automatically identifying a person’s ideological stance (or perspective) from written text is quite a challenging research problem that finds applications spanning from enhancing advertisements targeting to planning political campaigns. From a computational viewpoint, perspective detection is closely related to subjectivity and sentiment analysis. A person’s perspective normally influences his/her sentiment towards different topics or targets. Conversely identifying the sentiment of a person towards multiple targets can serve as a cue for identifying his/her perspective. While from a social-science viewpoint, the notion of “perspective” is related to the concept of “framing”. Framing involves making some topics (or some aspects of the discussed topics) more prominent in order to promote the views and interpretations of the writer (communicator). The communicator can either make these framing decisions consciously or unconsciously (Entman, 1993).

In this paper, we present a system that employs lexical and semantic features to identify the stance of

a person – “Favor”, “Against” or “None” – on topics that are often backed up by one’s ideology or belief system such as abortion, climate change and feminism. We evaluate the performance of the proposed system through the participation in Sub-Task A “Supervised Framework” of SemEval Task 6 “Detecting Stance in Tweets”. (Mohammad et al., 2016)

We build on our previous work on automatic perspective detection (Elfardy et al., 2015) by exploring the use of sentiment, Linguistic Inquiry and Word Count (LIWC) dictionaries, frame and latent semantics in addition to standard lexical features to automatically classify a given tweet according to its stance on the topic of interest.

Most current computational linguistics research on supervised stance detection perform document (or post) level stance classification, whether binary or multiway and use a variety of lexical, syntactic and semantic features to identify the stance of a post towards a specific contentious topic/target such as the Israeli-Palestinian conflict, abortion, creationism, gun-rights, gay-rights, healthcare, legalization of marijuana and death penalty (Lin et al., 2006; Klebanov et al., 2010; Hasan and NG, 2012; Hasan and Ng, 2013; Somasundaran and Wiebe, 2010; Elfardy et al., 2015). For a detailed literature review, we direct the reader to our \*Sem paper. (Elfardy et al., 2015)

## 2 Shared Task Description

SemEval Task 6 “Detecting Stance in Tweets” (Mohammad et al., 2016) aims at evaluating how well an automated system can identify the stance of a

**Table 1:** Number of tweets per class in the training and test data.

tweeter on several contentious targets. Sub-Task A “Supervised Framework” of the task –in which we participate– focuses on five targets: “Atheism”, “Climate Change is a Real Concern”, “Feminist Movement”, “Hillary Clinton”, and “Legalization of Abortion”. The training data has a total of 2,814 tweets and the test data has 1,249 tweets. While each tweet can have one of three class labels “Favor”, “Against” or “None”, the official metric calculates the performance of each system as the average  $F_{\beta=1}$  score of the first two class labels only. Table 1 shows the distribution of the training and test data for each one of the five targets.

### 3 Approach

Our goal is to see how well lexical and semantic features can help in identifying the stance of a tweeter. We split the data into five subsets according to the target –“Atheism”, “Climate Change is a Real Concern”, “Feminist Movement”, “Hillary Clinton”, and “Legalization of Abortion”– and train a separate classifier for each one of these targets.

#### 3.1 Lexical Features

For lexical features, we use standard n-grams. We apply basic preprocessing to the text by removing all punctuation and numbers and converting all words to lower case. Converting the text to lower case is intended to reduce the sparseness of the data while excluding the punctuation and number is meant to avoid overfitting the training data. We use n-grams having a length between 1 and 3 and exclude the ones that occur in only one training instance.

#### 3.2 Latent Semantics

Latent Semantics map text from a high-dimensional space such as n-grams to a low-dimensional one

such as topics. Most of these models assign a semantic profile to each given sentence (or document) by considering the observed words and assuming that each given document has a distribution over K topics. We apply Weighted Textual Matrix Factorization (WTMF) (Guo and Diab, 2012) to each tweet. The advantage WTMF offers –over standard topic models– is that in addition to modeling observed words, it models missing ones. WTMF defines missing words as the whole vocabulary of the training data minus the ones observed in the given tweet/post. Modeling missing words is particularly useful when the input is very short in length because in such case, only a limited context of observed words is present.

We use the distributable version of WTMF which is trained on WordNet (Fellbaum, 2010), Wiktionary definitions<sup>1</sup> and the Brown Corpus<sup>2</sup> and sets the number of topics (K) to 100.

#### 3.3 Sentiment

As mentioned earlier, sentiment analysis is closely related to stance detection. The ideological stance of a person normally influences his/her sentiment towards different ideological topics. Accordingly we decide to identify the overall sentiment of each sentence in the given tweet and use this sentiment as a possible indicator of a tweeter’s stance. Our assumption is that since tweets are inherently short in length, we can assume that the expressed sentiment targets the ideological topic the tweet is discussing. We use Stanford’s sentiment analysis system (Socher et al., 2013) to identify the number of positive, negative and neutral sentences in a given tweet and use these three counts as features for our

| Achievement    | 20.66    | 33.98   | 29.47   | 27.77   | 19.97    | 20.57         | 27.93   | 17.54   | 28.62   | 19.86    |
| Leisure        | 6.61     | 11.65   | 9.82    | 10.76   | 21.92    | 10.28         | 13.51   | 8.77    | 9.76    | 17.77    |
| Home           | 3.14     | 2.72    | 6.55    | 3.28    | 5.41     | 2.48          | 2.7     | 9.94    | 4.04    | 5.57     |
| Money          | 7.27     | 6.41    | 8.82    | 11.08   | 7.81     | 6.38          | 4.95    | 14.62   | 10.44   | 8.01     |
| Religion       | 15.7     | 64.27   | 7.05    | 3.28    | 6.46     | 14.18         | 68.02   | 1.75    | 6.4     | 4.18     |
| Death          | 17.36    | 4.08    | 3.27    | 3.28    | 3.6      | 16.31         | 4.95    | 4.68    | 4.38    | 4.53     |
| Assent         | 3.97     | 3.11    | 3.02    | 9.2     | 5.71     | 4.96          | 3.15    | 4.09    | 3.37    | 4.88     |

**Table 2:** Coverage of the used LIWC categories on the training and test sets of each target/domain

classifier.

### 3.4 Linguistic Inquiry & Word Count (LIWC)

LIWC (Tausczik and Pennebaker, 2010) uses a set of dictionaries to assign words in a given text to a set of psychologically meaningful categories such as death, science, emotion, space, family, swear words and many others. We apply LIWC to each given tweet in order to estimate the percentage of words belonging to each of the following categories:

*Feeling, Biological Processes, Body, Health, Sexual, Ingestion, Relativity, Motion, Space, Time, Work, Achievement, Leisure, Home, Money, Religion, Death and Assent.*

These categories convey the discussed topics in the given tweet. Table 2 shows the coverage of each of these categories. The coverage for each category corresponds to the percentage of tweets –out of all tweets– that have at least one word in this LIWC category. We calculate the coverage of the used LIWC categories on both the training and test sets for all five targets. By analyzing the numbers in Table 2, we find that “Atheism” dataset has the highest coverage for “Religion” category, “Abortion” has the highest coverage for “Death” category while “Cli-

mate Change” has the highest coverage for “Motion”. Moreover for “Abortion”, 25.8% of the tweets opposing it use words in the “death” category as opposed to only 8.6% for the tweets favoring the topic. For “Atheism”, the use of “religion” category is high among both opposing and favoring tweets where 78.26% of the tweets that favor atheism use words in the “religion” category and 80.26% of the ones that oppose it use this category. While LIWC will potentially help in identifying the stance from which a given tweet or text in general is written, a main drawback to it is that it only performs a dictionary look-up on each word hence judging words in isolation of their context.

### 3.5 Frame Semantics

Frame semantics assemble the meanings of different elements in a given piece of text to model the meaning of the whole text (Baker et al., 1998). The basic semantic unit in frame semantics theory is the “frame”. A frame is a conceptual structure that refers to a group of related concepts (or elements) where understanding one of these concepts requires an understanding of its whole structure. When any of these structures is present, it automatically triggers all of the other ones in the reader’s mind (Fillmore, 2006). The word (or phrase) that triggers the

**Table 3:** Development Set Results (measured in average  $F_{\beta=1}$  score of “Favor” and “Against” classes)

|             | Abortion     | Atheism      | Climate      | Clinton      | Feminism     | All-Targets |
|-------------|--------------|--------------|--------------|--------------|--------------|-------------|
| Majority-BL | 40.3         | 42.11        | 6.11         | 36.83        | 39.1         | 36.41       |
| n-grams     | 57.43        | 54.98        | 36.71        | 51.59        | 48.37        | 60.41       |
| WTMF        | 48.08        | <b>57.73</b> | <b>39.83</b> | 45.81        | 52.25        | 62.27       |
| Semantic    | 57.25        | 48.77        | 39.48        | 39.89        | <b>54.29</b> | 63.1        |
| All         | <b>60.52</b> | 56.39        | 38.89        | <b>55.82</b> | 51.93        | <b>63.6</b> |

**Table 4:** Held-Out Test Set Results (measured in average  $F_{\beta=1}$  score of “Favor” and “Against” classes)

frame is called the “frame-target”. For example, the target for the frame “Killing” can be any kill verb and the frame elements will include the killer and the victim.

We use SEMAFOR (Das et al., 2010; Chen et al., 2010), a publicly available frame-semantic parser, to identify all the semantic frames in each given tweet. For example, in the tweet “*Because I want young American women to be able to be proud of the 1st woman president.*”, SEMAFOR identifies the following frames, “*Leadership Target:president*”, “*Capability Target:able*”, “*Origin Target:American*”, “*Desiring Target:want*”, “*People Target:women*” and “*Age Target:young*” . We create a list of all the frames that occur in the training data and use binary features to indicate the presence/absence of each of them in each given tweet. This set of features provides yet another abstraction in order to infer the topics discussed in the given text.

### 3.6 Classifier Training

Using WEKA toolkit (Hall et al., 2009) and the derived lexical and semantic features, we train an SVM classifier for each one of the five targets. We use a

radial basis kernel and set the cost parameter C to 1.

## 4 Experiments & Results

For tuning, we split the training data for each target into two subsets: 90% training and 10% development. We evaluate different configurations of the proposed features on the development set and apply the ones that yield best tuning results to the held-out test set. Specifically we experiment with the following configurations: (1) Lexical Features (n-grams), (2) WTMF, (3) Sentiment, (4) Frames, (5) LIWC, (6) All Semantic features, (7) All features. We compare the proposed approach against a majority baseline which assigns all tweets to the most frequent class in the data (“Against”). Table 3 shows the results on the development set. N-grams outperform using any of the semantic features separately which is quite expected given how well n-grams generally perform on text classification tasks. Moreover WTMF outperforms all other semantic features except on “Climate Change” dataset. Overall we find “Climate Change” to show different trends and a much lower performance than those of the other four targets. We believe that this is at-

tributed to the small size of this set and to its very skewed distribution. Only 3.8% of its tweets belong to “against” class which is the most frequent class in the whole dataset. Combining all semantic features yields better results than using any of them separately for three out of the five targets “Abortion”, “Climate Change” and “Feminist Movement” while for the other two targets using WTMF only outperforms using the full set of semantic features. For the same two targets –“Atheism” and “Hillary Clinton”– using only n-grams outperforms combining n-grams with all-semantic features. Overall, combining lexical and semantic features yields the best results on the majority of tweets. Accordingly we used this setup in our official task submission.

We apply the top four development-set configurations –“n-grams”, “WTMF”, “all semantic” and “all features”– to the test set. Table 4 shows the held-out test results. While using the combination of lexical and all-semantic features yields best overall performance, using only the semantics features achieves close to best results. Additionally, using only WTMF yields best performance on two targets – “Atheism” and “Climate Change”. We also find that while the best configuration for each target varies across the development and test sets, the best overall configuration for the majority of tweets remains the same.

## 5 Conclusion

In this paper, we explore the use of lexical and several semantic feature sets within a supervised framework to identify the stance of a tweet towards an ideological topic. We evaluate the performance of the proposed approach by participating in SemEval-2016 Task 6: “Detecting Stance in Tweets” which aims at identifying the stance of a given tweet towards five targets; “Abortion”, “Climate Change”, “Hillary Clinton” and “Feminist Movement”. We find that WTMF, a latent semantics model that incorporates both observed and missing words, yields the best results among semantic features. Moreover, combining lexical and all semantic features results in the best performance.

## Abstract

We describe the system submitted to the SemEval-2016 for detecting stance in tweets (Task 6, Subtask A). One of the main goals of stance detection is to automatically determine the stance of a tweet towards a specific target as ‘FAVOR’, ‘AGAINST’, or ‘NONE’. We developed a supervised system using Support Vector Machines to identify the stance by analyzing various lexical and semantic features. The average F1 score achieved by our system is 60.60.

## 1 Introduction

Recent research in the areas of opinion mining and/or sentiment analysis on natural language texts is gaining importance due to various academic and commercial perspectives. One of the main reasons is that a vital amount of information can be obtained from text data that are available in the internet in forms of news, reviews, blogs, chats, and tweets.

Several experiments have been attempted in the field of sentiment analysis or opinion mining on user generated content or social media data till date (Patra et al., 2015). One of the main goals in such tasks is to assign polarities (positive or negative) to a piece of text. Identification of the writer’s attitude towards a specific target, known as stance detection, is a relevant and challenging topic which has unduly been averted by most researchers (Mohammad et al., 2016). Lately it has become conventional that people express stance explicitly or implicitly in various microblogging sites.

Stance detection is the task of automatically determining from text whether the author is in favor of

the given target, against the given target, or whether neither inference is likely.<sup>1</sup> The stance detection can often bring complementary information to sentiment analysis, because we often care about the author’s evaluative outlook towards specific targets and propositions rather than simply considering whether the speaker is angry or happy (Mohammad et al., 2016). Stance detection even becomes more difficult when it is performed on the short texts like tweets. The latter being an important sub-field of sentiment analysis/opinion mining. Automatic stance detection can be used in several applications such as information retrieval, text summarization, and textual entailment.

More recent approaches to stance detection have been performed using linguistic rules on *online debate dataset* (Somasundaran and Wiebe, 2009; Hasan and Ng, 2013; Sridhar et al., 2014) and *NPOV Corpus* from Wikipedia (Recasens et al., 2013). To the best of our knowledge, not much computational attempts have been performed on tweets for stance detection. It is also observed that both the supervised and unsupervised machine learning algorithms have been implemented for identifying the stance and several features like n-gram, frame semantic features, and dependency were used in stance detection tasks (Somasundaran and Wiebe, 2009; Anand et al., 2011; Sridhar et al., 2014).

We participated in the SemEval 2016-Task 6: Detecting Stance in Tweets.<sup>1</sup> The main goal of this task is to identify stance present in a tweet towards a specific target. For example, **Target** = ‘Hillary Clinton’, **Tweet** = ‘A Black President, Healthcare 4

<sup>1</sup><http://alt.qcri.org/semeval2016/task6/>

*all, Marriage Equality...what's next?..a Woman President?! Damn RIGHT! #SCOTUS #MarriageEquality, Stance* = ‘FAVOR’. In the above example, the tweet is in favor of the target “*Hillary Clinton*”. In the test dataset, the targets of the corresponding tweets are given and we have to find out whether the stance towards the target is in ‘FAVOR’ or ‘AGAINST’ or ‘NONE’.

There are two subtasks, in subtask A, we have to identify the stance towards a specific target whereas in subtask B, we have to identify the stance towards only one target “*Donald Trump*” using a large set of unlabeled tweets associated with the target. We have only participated in subtask A. Several lexical and semantic features are used to identify the stance towards a target. Support Vector Machines (SVM) is used for the classification purpose.

## 2 Dataset and Evaluation

The organizers provided the trial, training, and test dataset of 100, 2814, and 1249 tweets, respectively for detecting stance towards five targets namely “*Atheism*”, “*Climate Change is a Real Concern*”, “*Feminist Movement*”, “*Hillary Clinton*”, and “*Legalization of Abortion*”. All tweets in the dataset are annotated with stance (‘FAVOR’ or ‘AGAINST’ or ‘NONE’) towards the above mentioned targets. The stance ‘NONE’ means the tweet is not in ‘FAVOR’ or ‘AGAINST’ of the target.

Systems were evaluated using the official metric calculated macro-average of two labels only, i.e. **F1 score** = (F-Score<sub>FAVOR</sub> + F-Score<sub>AGAINST</sub>)/2.

## 3 System Framework

### 3.1 Features

In order to achieve good accuracy using machine learning algorithms, we need to have a good set of features. Based on the genre of tweet, we identified the following features as listed below.

#### 3.1.1 Target Specific Words

Initially, an n-gram model was created to identify the target’s presence in the tweet. But, we observed that the dimension as well as the sparsity of feature vectors were increased enormously. Thus, we created individual topic bags related to

| Topic Bags | Word Bags |         |
|------------|-----------|---------|
|            | Favor     | Against |
| <b>A</b>   | 311       | 69      |
| <b>C</b>   | 129       | 63      |
| <b>F</b>   | 95        | 72      |
| <b>H</b>   | 73        | 40      |
| <b>L</b>   | 101       | 44      |
|            |           | 59      |

**Table 1:** Statistics of the topic, favor, and against bags for five targets (A: Atheism, C: Climate Change is a Real Concern, F: Feminist Movement, H: Hillary Clinton, L: Legalization of Abortion)

each of the targets. Seed words related to the targets were populated using RitaWordNet.<sup>2</sup> Some handcrafted rules were implemented to find names in words and hashtags. For example, “Hillary” is present in “#HillaryClinton”, then we considered “#HillaryClinton” in the topic bag “Hillary”. Further, we checked the topic bags manually and removed some unrelated words collected using the WordNet. The detailed word level statistics of the topic bags are given in Table 1.

At first, we checked that whether a tweet contains any word from the corresponding target related topic bag or not. If no word is present, then we tagged that tweet as ‘NONE’ and no further processing is performed on that tweet. Further, this topic bags are used along with the dependency information.

#### 3.1.2 Sentiment Words

We have used three lexicons namely SentiWordNet (Baccianella et al., 2010), NRC Emotion Lexicon (Mohammad and Turney, 2013), and NRC Hashtag Emotion Lexicon (Mohammad, 2012) for our experiments along with manually created lexicons for each of the targets. Moreover, two bags were created for each of the targets namely ‘favor’ and ‘against’ bags. Hashtags are also included in the above lexicons. The word level statistics of the ‘favor’ and ‘against’ bags are given in Table 1. We used the frequency of the sentiment words matched with the above sentiment or emotion lexicons as features. Again, we used these lexicons in the later experiments also.

Figure 1: Dependency relations from Stanford Parser

#### 3.1.3 Dependency Information

It is found in the literature that the dependency relations act as useful feature in sentiment analysis (Patra et al., 2014a; Patra et al., 2014b). Thus, we used the Stanford Parser<sup>3</sup> to get the dependency relations. We searched for the word pairs in dependency relations that consist of two component words, one of which is present in either ‘favor’ or ‘against’ bag, whereas the other one is present in SentiWordNet.

In the above Figure 1, we found a relation “dobj(support-7, campaign-9)”. The word ‘campaign’ is present in the ‘favor’ bag for the target “Hillary Clinton” and the word ‘support’ is present in SentiWordNet as positive. This relation is considered as favor\_positive type. Similarly, three other types namely favor\_negative, against\_positive, and against\_negative were considered. The counts of each type are used as features.

Again, we identified the simple sentences based on the symbol “(S” or “(ROOT” in Figure 1. For

each of the simple sentences, we removed the stop-words (except the negation words) and identified the sentiment words using SentiWordNet. We applied some handcrafted rules given below. 1. Not + NEG = POS, 2. Not + POS = NEG, 3. POS + POS = POS, 4. NEG + NEG = NEG. If there are multiple positive words present in a simple sentence, we tagged it as positive. If there are only two sentiment words, one with positive and other as negative, we tagged the sentence as negative. It is observed that the frequency of the negative instances is much higher than the positive instances in the training data. Finally, we counted the number of positive and negative instances in a tweet and used as features.

### 3.2 Classification Framework

We used LibSVM, an variant of SVMs implemented in the Weka.<sup>4</sup> We performed the 10-fold cross validation on the training and trial dataset for all the targets using the above features. But, the system performance was observed as poor and the system achieves the average F1 score of 0.43. Again, we performed the 10-fold cross validation on the training and trial dataset for all the targets, separately. We calculated the average F1 score for each of the five targets and these are 0.46, 0.40, 0.48, 0.52, and 0.49 for “Atheism”, “Climate Change is a Real Concern”, “Feminist Movement”, “Hillary Clinton”, and “Legalization of Abortion”, respectively. This yields an average F1 score of 0.47 for all the targets, which is higher than the F1 score achieved by the previous system. This motivates us to develop our final systems separately for each of the targets.

#### 3.2.1 Results

The LibSVM based system achieved the maximum F-Score of 0.4668 and 0.7452 for the ‘FAVOR’ and ‘AGAINST’ classes, respectively as shown in Table 2. The system achieved the maximum average F1 score of 0.6060. Whereas, the team **MITRE** has achieved the first position with the maximum average F1 score of 0.6782.

The confusion matrix for our system is shown in Table 3. From the matrix, we observed that the system is biased towards the ‘AGAINST’ stance (except “Climate Change is a Real Concern” target). The main reason may be the biasness in the

|  | F | 35        | 2  | 9  |
|  | N | 12        | 1  | 32 |

Table 3: Confusion Matrix of our System (A: Against, F: Favor, N: None)

training dataset as the number of instances for the ‘AGAINST’ stance is maximum for all the targets (except “Climate Change is a Real Concern” target). Another reason may be the less number of training instances as we developed our system for each of the targets, separately.

## 4 Conclusion and Future Work

We presented a system for identifying the stance in tweets using dependency and semantic features. The maximum average F1 score of 0.6060 is achieved by the system using SVM classifier. The task stance detection on social media data is helpful for real life applications like political campaign and opinion poll.

In near future, we plan to use the TweeboParser,<sup>5</sup> as it works well for tweets as compared to the Stanford Parser. Another immediate goal is to increase the size of topic bags and sentiment lexicons related to each of the targets. We are also planning to use unsupervised approach and several machine learning

<sup>5</sup><http://www.cs.cmu.edu/ark/TweetNLP/>

algorithms for classifying the stance in near future.

## Abstract

This paper describes an approach to automatically detect stance in tweets by building a supervised system combining shallow features and pre-trained word vectors as word representation. The word vectors were obtained from several collections of large corpora using GloVe, an unsupervised learning algorithm. We created feature vectors by selecting the word vectors relevant to the data and summing them for each unique word. Combining multiple classifiers into a voting classifier, representing the best of both approaches, shows a significant improvement over the baseline system.

## 1 Introduction

This paper describes our submission to the SemEval 2016 competition Task 6A - *Detecting Stance in Tweets*. The goal of the task is to classify a tweet into one of the three classes – *against*, *favor* or *none* in regard to a certain topic. These classes represents the tweet’s stance towards the given target.

Twitter, and other microblogging platforms, have in recent years become popular arenas to apply natural language processing tasks. One of the most popular tasks has been sentiment analysis. Stance detection differs from sentiment analysis because the sentiment of a text – generally positive or negative – does not necessarily agree with its stance regarding a certain topic of debate. For example, a tweet like “all those climate-deniers are morons” is negative in its overall sentiment, but positive with regard to the

stance that climate change is a real concern. We refer the reader to the official SemEval 2016<sup>1</sup> website for a detailed task description.

Our approach to detect stance is based on shallow features (Kohlschütter et al., 2010; Hagen et al., 2015; Walker et al., 2012) and the use of GloVe word vectors (Pennington et al., 2014). During the development phase we explored several approaches by implementing features such as sentiment detection (Hutto and Gilbert, 2014), number of tokens and number of capital words. The experiments later in this paper show that not all features enhanced the performance of the implemented system.

The feature that turned out to boost performance the most, in combination with basic shallow features, was the use of pre-trained GloVe vectors (Pennington et al., 2014). The vector representations of tweets were created by summing the pre-trained word vectors for each unique word. No additional data was added to the training set used for our final submission, although we explored the possibility of gathering and automatically labelling additional tweets by using label propagation (Zhu and Ghahramani, 2002; Zhou et al., 2004). This did enhance our baseline system performance slightly, but not in combination with other features.

## 2 System description

To predict the stance in tweets we built a supervised machine learning system using the scikit-learn machine learning library (Pedregosa et al., 2011). Our system consists of a soft voting classifier that predicts the class label on the basis of the best re-

<sup>1</sup><http://alt.qcri.org/semeval2016/task6/>

sults out of the three classifiers described in subsection 2.3.

## 2.1 Resources

Our system used a limited number of resources. It relies on the annotated training data consisting of 2814 tweets divided into five different topics: *Atheism*, *Climate Change is a Real Concern*, *Feminist Movement*, *Hillary Clinton*, and *Legalization of Abortion*. In addition, it uses pre-trained word vectors<sup>2</sup> created by Pennington et al. (2014).

### 2.1.1 Bootstrapping attempts

The labels for the climate change target showed a highly skewed distribution where only 3.8% were labelled *against*. Skewed data distributions in machine learning are a common problem. Monard and Batista (2002), Provost (2000) and Tang et al. (2009) discuss this problem and suggests several solutions, such as data under- and over-sampling. We did not have time to investigate the effects of these methods, but Elkan (2001) suggest that changing the balance of negative and positive training samples has little effect on learned classifiers.

In an attempt to even out the distribution of the climate change data, we searched for ways to add additional tweets. The most promising approach explored was label propagation (Zhu and Ghahramani, 2002; Zhou et al., 2004), a semi-supervised learning algorithm. Thousands of tweets were fetched based on the most common hashtags found in the climate topic data. We hand-picked a small portion of tweets that seemed relevant to the climate topic (e.g. same language and containing a statement). These tweets were then automatically labelled using label propagation. The label propagation was performed with a (small) representative sample of the labelled training data together with the collected, hand picked, unlabelled tweets. We found that adding more data to our system did not result in substantial improvement. An explanation could be that the gathered tweets were not meaningful enough to be effective. The additional data was therefore not used in subsequent experiments.

---

<sup>2</sup><http://nlp.stanford.edu/projects/glove/>

## 2.2 Features

The submitted system used the following features, generated from the raw data supplied in the training set.

1. **Word bigrams:** All pairs of consecutive words
  - Punctuation ignored
2. **Character trigram:** All triples of consecutive characters
  - Punctuation ignored
  - Converted to lowercase
  - Ignored terms that had a document frequency strictly lower than 5 (cut-off)
3. **GloVe vectors:** Word embeddings for all words in a tweet
  - Punctuation ignored
  - Converted to lowercase
  - Removed stop words

In addition, we experimented with the following features, which were not included in the final system. They were left out as they did not improve the systems performance (section 3 will provide more details on this).

- **Negation:** Presence of negation in the sentence
- **Length of tweets:** Number of characters divided by the maximum length (140 characters)
- **Capital words:** Number of capital words in the tweet
- **Repeated punctuation:** Number of occurrences of non-single punctuation (e.g. !?)
- **Exclamation mark last:** Exclamation mark found last in non-single punctuation (e.g. ?!)
- **Lengthening of words:** Number of lengthened words (e.g. smooooth)
- **Sentiment:** Detecting sentiment in tweet using the Vader system (Hutto and Gilbert, 2014)
- **Number of tokens:** Count of total number of tokens in the tweet

### 2.2.1 GloVe

GloVe (Pennington et al., 2014) is an unsupervised learning algorithm for obtaining vector representations of words. It creates word vectors based on the distributional statistics of words, in particular how frequently words co-occur within a certain window in a large text corpus such as the Gigaword corpus (Parker et al., 2011). The resulting word vectors can be used to measure semantic similarity between word pairs, following the hypothesis that similar words tend to have similar distributions. The Euclidean or Cosine distance between two word vectors can thus be used as a measure of their semantic similarity. For the word *frog*, for example, we can find related words such as *frogs, toad, litoria, leptodactylidae, rana, lizard, eleutherodactylu*.

In order to measure the semantic similarity between tweets, rather than isolated words, we needed a way to obtain vector representations of documents. Mitchell and Lapata (2010) looked at the possibility to use word vectors to represent the meaning of word combinations in a vector space. They suggest, among other things, to use vector composition, operationalized in terms of additive (or multiplicative) functions. Accordingly we created vector representations of tweets by combining the vectors of their words. We used pre-trained word vectors created by Pennington et al. (2014) trained on Wikipedia 2014 + Gigaword 5<sup>3</sup> and Twitter data<sup>4</sup>. The word vectors come in several versions with a different number of dimensions (25, 50, 100, 200, 300) that supposedly capture different granularities of meaning. The resulting features (from here on called GloVe features) were obtained by summing the GloVe vectors, per dimension, for all unique terms in a tweet.

## 2.3 Models

To detect stance we constructed separate models for each of the five topics, each in the form of a soft voting classifier from scikit-learn (Pedregosa et al., 2011). The voting classifiers took input from the following three classifiers:

1. **Multinomial Naive Bayes** trained on word bigrams

<sup>3</sup><http://nlp.stanford.edu/data/glove.6B.zip>

<sup>4</sup><http://nlp.stanford.edu/data/glove.twitter.27B.zip>

2. **Multinomial Naive Bayes** trained on character trigrams

3. **Logistic Regression** trained on GloVe features

The soft voting classifier is – in contrast to a hard voting classifier – able to exploit prediction probabilities from the separate classifiers. For each sample, the soft voting classifier predicts the class based on the argmax of the sums of the predicted probabilities from the input classifiers.

In the task description it was stated that it was not necessary to predict stance for every tweet in the test set, leaving the uncertain ones with an *unknown* label. We decided to use a threshold value, using the extracted probabilities, to prevent predictions with low confidence. Labels predicted with a probability below the threshold were thus changed into *unknown*. Details of the selection of the threshold value are presented at the end of section 4.

Due to the imbalanced distribution of labels in climate change data, our system had a low prediction rate of *against* stances on this target. For that reason we included a second slightly different model for the climate change target. The difference between the first and second model was that the second used a hard (majority rule) voting classifier, which performed slightly better on the against labels in the climate data. The combination of the two models was implemented in a way such that for each of the *against* predictions in the hard voting model, we overwrote the soft model’s prediction, labelling the tweet *against*. Our submitted system thus consisted of two models for predicting the climate class, giving a total of six models.

To summarize, the system contains six models, where five of them consist of a soft voting classifier with input from the three different classifiers introduced above. The sixth is a hard voting model that supplements the soft voting model for the climate change target.

## 3 Results on Development Data

To measure the system performance we conducted multiple experiments using the training data to examine the effects of various shallow features and the use of GloVe features with a varying number of dimensions. All experiments in this paper were conducted using stratified five-fold cross-validation and

the results were measured with macro F-score based on precision and recall on the class labels *favor* and *against*. Our system used supervised machine learning algorithms supplied by the scikit-learn library (Pedregosa et al., 2011).

### 3.1 Baseline

The first experiment was set up to gain insight in the performance of different classifiers and their parameters. We chose a basic approach using only word unigrams (bag of words approach). The best of the resulting models was chosen as the baseline, serving as an indication of the performance of a simplistic system. The models were trained on the entire data set, not divided by individual targets. We chose to perform the experiment with two different Support Vector Machines (SVM) and one Naive Bayes (MNB) classifier with different parameters<sup>5</sup>.

One of the hyperparameters we optimized was  $C$ , which is a regularization term for misclassifications of each sample. Higher values will do a better job correctly labelling the training data during training (smaller hyperplane margin), but are more likely to overfit. Conversely, lower values may have more misclassifications because it will ignore more outliers (larger hyperplane margin), but are less likely to overfit. We also used the *decision function shape* parameter to decide whether to use one-vs-one (*ovo*) or one-vs-rest (*ovr*) as decision function. *Ovo* constructs one classifier per pair of classes. At prediction time, a vote is performed and the class which receives the most votes is selected. The *ovr* strategy consists of fitting one classifier for each class. The table below displays the results from the experiments.

| Classifiers    | Parameter specification    | Macro F       |
|----------------|----------------------------|---------------|
| Multinomial NB | [alpha=0.01]               | 0.5513        |
| SVM            | [kernel='linear', C=0.37 ] | 0.5701        |
| LinearSVM      | [kernel='linear', C=0.28 ] | <b>0.5819</b> |

**Table 1:** Average macro F-scores from five-fold CV experiments with different classifiers on the entire training set.

LinearSVM scored highest and established the base-

<sup>5</sup>SVM with  $\text{kernel}=[\text{linear}, \text{rbf}, \text{poly}], \text{C}=\text{numpy.logspace}(-3, 3, 50)$ ,  $\text{decision.function\_shape}=[\text{ovo}, \text{ovr}]$  and LinearSVM with  $\text{C}=\text{numpy.logspace}(-3, 3, 50)$ . MultinomialNB with  $\text{alpha}=\text{numpy.logspace}(-1, 1, 10)$ .

line with the macro F-score of 0.5819. However, the LinearSVM classifier was not beneficial in later experiments when trained individually per target<sup>6</sup> and therefore only used as a performance baseline.

### 3.2 Improved system

In the development phase, the data set was divided by the individual targets creating five respective data sets. The development experiments began by including more and more shallow features. We started off by applying various forms of n-grams (uni-, bi- and trigram of words and characters). The classifier that achieved the highest cross-validated macro F-score from these experiments was MNB using character trigram. The achieved score was 0.6290. The experiments continued by adding features (listed in section 2.2) to the MNB in addition to the character trigram feature. Results of these experiments can be seen in table 2.

| Shallow Features         | Macro F       | Change     |
|--------------------------|---------------|------------|
| Trigram characters       | 0.6290        |            |
| .+negation               | 0.6308        | (+ 0.0018) |
| .+length of tweets       | 0.6311        | (+ 0.0003) |
| .+capital words          | 0.6313        | (+ 0.0002) |
| .+non-single punctuation | 0.6356        | (+ 0.0043) |
| .+exclamation mark last  | 0.6358        | (+ 0.0002) |
| .+lengthening words      | <b>0.6360</b> | (+ 0.0002) |
| .+sentiment              | 0.6352        | (- 0.0008) |
| .+number of tokens       | 0.6264        | (- 0.0088) |

**Table 2:** Average macro F-scores for different sets of shallow features from five-fold CV experiments with MNB classifier on the entire training set.

Table 2 shows that adding shallow features yielded only a slight increase in macro F-score from 0.6290 to 0.6360. Based on this, relatively small, improvement it is difficult to imply that the addition of features gave any substantial performance boost of the system.

### 3.3 Final system

Subsequent experiments tested the use of a Logistic Regression classifiers with GloVe feature vectors. We used pre-trained word vectors from

<sup>6</sup>Average macro F-score over all targets:  
LinearSVM with word bigram: 0.4955.  
LinearSVM with character trigram: 0.5970.  
LinearSVM with shallow features: 0.5974

| Features              | Overall       | std ( $\sigma$ ) | Atheism | Climate       | Feminism | Hillary | Abortion |
|-----------------------|---------------|------------------|---------|---------------|----------|---------|----------|
| Baseline              | 0.5819        | 0.0494           | -       | -             | -        | -       | -        |
| Best shallow features | 0.6360        | 0.0891           | 0.6601  | 0.5923        | 0.6246   | 0.6022  | 0.7006   |
| Glove features        | 0.6067        | 0.0722           | 0.6516  | 0.6256        | 0.5553   | 0.5898  | 0.6102   |
| Glove + best shallow  | 0.6048        | 0.0659           | 0.5775  | 0.5604/0.6754 | 0.6291   | 0.5479  | 0.7088   |
| Glove + n-gram        | <b>0.6751</b> | 0.0704           | 0.7055  | 0.6540/0.6404 | 0.6537   | 0.6427  | 0.7204   |

**Table 3:** Average macro F-scores, both overall and per target, for different combinations of feature sets from five-fold CV experiments on the entire training set. Baseline model was not trained per target, therefore no individual scores are available. Where two scores are listed, there were two models used (soft/hard voting).

different corpora with a various number of dimensions (*corpus sizes* = [(6Btokens, 400Kvocab), (27Btokens, 1.2Mvocab)] and *dimensions* = [25, 50, 100, 200, 300]). The various dimensions supposedly capture different granularities of meaning obtained from the corpora they were extracted from<sup>7</sup>.

From table 3 we can observe that from the baseline score of 0.5819 the result increased to 0.6360 when applying the best shallow features. It also shows that using only the Logistic Regression classifier with GloVe vectors did not perform well. For this reason we decided to combine multiple classifiers. Initially we tried wrapping the Logistic Regression classifier and the MNB classifier from table 2 in a voting classifier. However, this new voting classifier did not improve the performance, instead a further drop in performance occurred. We later inspected the outcome of the combined classifiers when we reduced the feature set of the MNB classifier down to only applying versions of n-grams. This was more successful and our best result was achieved using the Logistic Regression classifier using GloVe features, MNB classifier using bigram words, and a MNB classifier with trigram characters wrapped inside a soft voting classifier. The final submission therefore included only n-gram features and the rest of the features were discarded. As seen in table 3 this scored 0.6751, which was a substantial improvement over the performance baseline.

<sup>7</sup>The final submission used the following word vectors: Atheism (*size*=6B, *dimension*=200), Climate Change (*size*=27B, *dimension*=200), Feminist Movement (*size*=27B, *dimension*=100), Hillary Clinton (*size*=27B, *dimension*=200), Legalization of Abortion (*size*=27B, *dimension*=100).

## 4 Results on Test Data

Our submitted approach achieved a macro F-score of **0.6247** on the test data, while the best system on task 6A achieved a score of 0.6782. After the gold labels were released, we ran the test ourselves in order to see how well we did on precision, recall, and F-score. Table 4 shows our final results. The high precision on the class *against* shows that predictions for this label were mostly correct, albeit with a relatively low recall.

| Stance                | Precision | Recall | F-score |
|-----------------------|-----------|--------|---------|
| Favor                 | 0.5750    | 0.6053 | 0.5897  |
| Against               | 0.8770    | 0.5287 | 0.6597  |
| Overall macro F-score |           |        | 0.6247  |

**Table 4:** Precision, recall and F-score of the official submission per class as well as overall macro F-score.

At the end of section 2.3, we mentioned that we established a threshold in our system. The threshold value was set at the last minute using a rule of thumb as we did not have time to perform experiments to determine the optimal setting, or even whether it was beneficial at all. Our intention was to use this approach only for the category *Climate Change is a Real Concern*, as this was the most skewed topic. However, by accident, it was applied to *all* topics. Comparing our best result in the development phase with the test result, we can observe a substantial drop in performance. This is a result of the threshold that was – by mistake – applied in all predictions. To measure how much this affected our system, we performed an overall test run where the threshold as used in the original submission was disregarded. This resulted in a macro F-score of 0.6660 - an increase of 0.0413 relative to our submission

score. The threshold proved to have lowered the recall for both *favor* and *against* and explains the low recall in the submitted system predictions.

| Stance                | Precision | Recall | F-score |
|-----------------------|-----------|--------|---------|
| Favor                 | 0.5432    | 0.7237 | 0.6206  |
| Against               | 0.8042    | 0.6378 | 0.7114  |
| Overall macro F-score |           | 0.6660 |         |

**Table 5:** Precision, recall and F-score of the submission without the applied threshold per class as well as overall macro F-score.

It is worth mentioning that even though the addition of all shallow features gave poor results during development phase, it performed a lot better on the test data, scoring 0.6939.

## 5 Conclusion

This paper summarizes our system created for SemEval 2016 task 6A - *Detecting Stance in Tweets*. Using shallow features alone performed well, but combining shallow features and word embeddings created from GloVe word vectors increased the score substantially.

With this system we finished 10th as we were able to detect stance in tweets with a macro F-score of 0.6247 on the test data, whereas the best system in task 6A scored 0.6782. Post-analysis revealed that the application of an ad-hoc threshold to prevent low-confidence predictions was a mistake, resulting in a 0.0413 loss in overall macro F-score. The threshold should have been set using cross-validation, or even better, not at all.

## Abstract

This paper describes our submissions to Task 6, i.e., Detecting Stance in Tweets, in SemEval 2016, which aims at detecting the stance of tweets towards given target. There are three stance labels: *Favor* (directly or indirectly by supporting given target), *Against* (directly or indirectly by opposing or criticizing given target), and *None* (none of the above). To address this task, we present a two-step learning system, which performs two steps, i.e., relevance detection and orientation detection, in a pipeline-based processing procedure. Our system ranked the 5th among 19 teams.

## 1 Introduction

Social platforms, such as *Twitter*, *Facebook*, etc., have attracted hundreds of millions of people to share and express their opinions or standpoints in the past few years. Promoted by that growth, researchers have been enthusiastic about mining useful information in these abundant free texts from social platform, such as stance detection. Determining the stance expressed in a post written for certain target is a relatively new task in sentiment analysis. Classifying stance involves identifying the target of the post and determining its sentiment orientation. The general researches just focus on detecting the stance of posts where the provided posts are relevant to the given target (Somasundaran et al., 2007; Somasundaran and Wiebe, 2010). Besides, the previous work usually aims at the posts collected from forums which have co-posts as reference (Murakami et al., 2007; Agrawal et al., 2003). Some approach-

es were adopted to settle stance detection, for example, Murakami and Agrawal detected the stance in the posts collected from forums and adopted co-posts as reference (Murakami et al., 2007; Agrawal et al., 2003).

The task of Detecting Stance in Tweets (DST) in SemEval 2016 aims at classifying the provided tweets into three stance classes, i.e., *Favor* (directly or indirectly by supporting given target), *Against* (directly or indirectly by opposing or criticizing given target) and *None* (none of the above) refer to a given target. The DST task consists of two subtasks which could be summarized as *supervised* subtask (i.e., subtask A) and *weakly supervised* subtask (i.e., subtask B). The supervised subtask is to test the stances of certain tweets towards five predefined targets with labeled training data, while the weak supervised subtask is to detect the stances of tweets towards one target with the aid of a mass of unlabeled training data.

Somasundaran showed that the stance classifier trained on unigram is a relatively strong baseline (Somasundaran and Wiebe, 2010). Based on Somasundaran and Wiebe's work, Anand augmented the *n*-gram features with several linguistic features (Anand et al., 2011). Except for feature engineering, many researchers focused on other methods to improve performance. For example, Murakami and Sridhar took the forward posts of current post into consideration (Murakami and Raymond, 2010; Sridhar et al., 2014). The previous works usually processed the posts with co-posts or some additional information, such as its author, writing timeline (Faulkner, 2014; Rajadesigan and Liu, 2014;

Hasan and Ng, 2013). Differ from these works, the DST focuses on classifying the stance of tweets into three classes, i.e., *Favor*, *Against* and *None*, rather than two classes. Moreover, the organizers did not provide the related information of tweet, such as author information. Thus, to address this task, we decomposed the stance detecting model into two parts, i.e., relevance detection and orientation detection, which aim at determining whether the tweet is relevant or irrelevant to the given target and whether the tweet is in favor of or against the given target. Since the given 6 targets belong to different types, e.g., *Hillary Clinton* and *Donald Trump* are about people, *Climate Change is a Real Concern* is a environmental topic, etc., considering the diversity of different targets, we built unique model for each target with different features. To achieve high performance, we proposed various features, e.g., *Linguistic Features*, *Topic Features*, *Word Vector Features*, *Similarity Features*, etc., to perform stance detection.

This paper is organized as follows. Section 2 reports our systems including preprocessing, feature engineering, evaluation metrics, etc. The data sets and experiments descriptions are shown in Section 3. Finally, we conclude this paper in Section 4.

## 2 System Description

To address these two subtasks, i.e., supervised framework and weakly supervised framework, we used the two-step model to classify certain tweets into 3 stance labels (i.e., *Favor*, *Against*, *None*). The first step (i.e., relevance detection) is to determine whether the tweet is relevant to the given target. The second step (i.e., orientation detection) aims at classifying whether the tweet is support for the given target. To improve the classification performance, we extract various types of features, such as linguistic features (e.g., *N-grams*, *N-chars*), similarity features (e.g., *cosine similarity*, *JSD similarity*), topic features (e.g., *sent2topic*, *top topic word*), sentiment lexicon features, etc. The difference of the methods to settle two subtasks is located in the different training data they used. For subtask A, we segmented the training data into 5 subsets according to the 5 predefined targets and trained two classifiers for each subset. Thus, for subtask A, our system consists of 10

classifiers and we conducted feature selection procedure for each classifier. As for subtask B, we combined all labeled data in subtask A as training data and constructed two classifiers to perform relevance detection and orientation detection.

### 2.1 Data Preprocessing

Due to the irregular writing form of tweets, we first convert the slangs or abbreviations to their formal forms with the aid of a pre-defined dictionary downloaded from Internet<sup>1</sup>. For example, we convert “*goooooooooood*” into “*good*”, “*gr8*” to “*great*”. The processed data is fed into *CMU TweetNLP tool* (Owoputi et al., 2013) to perform tokenization, POS tagging. Meanwhile, we employ *Stanford Parser tool* (Klein and Manning, 2003) and *LDA-C* (Blei et al., 2003) to implement dependency parsing and topic parsing respectively. Finally, the *NLTK tool* (Bird et al., 2009) is used to conduct lemmatization and stemming.

### 2.2 Feature Engineering

Since we decompose the stance detecting task into two steps, i.e., relevance detection and orientation detection, this task is related to similarity evaluation and stance orientation classification. Thus, we extract five types of features, i.e., *Traditional Linguistic Features*, *Similarity Features*, *Topic Features*, *Sentiment Lexicon Features*, *Tweet Specific Features* and *Word Vector Features*.

#### 2.2.1 Traditional Linguistic Feature

*N-grams*: *N-grams* features are widely used in many NLP tasks. In this task, we extract *unigram*, *bigram*, *trigram* and *4-gram*.

*N-chars*: We record presence or absence of contiguous sequences of 3, 4, and 5 characters as *N-chars* features, i.e., *3-char*, *4-char* and *5-char*.

*Pos*: There are total 23 types of pos tags collected in training data processed by *CMU TweetNLP tool*. We record the number of each pos tags as *Pos* features.

*Cluster*: The *CMU TweetParser tool* provides the token clusters produced with the Brown clustering algorithm on 56 million English language tweets. The 1,000 clusters are served as *Cluster* features.

---

<sup>1</sup>This dictionary and the following Internet resources are available at <https://github.com/haierlord/resource.git>

*Dependency*: The dependency tree is generated by *Stanford Parser tool* and each tweet is represented as several triple (i.e., *relation(government, dependent)*). We extract three types of *Dependency* features: *relation-government* (*Rel-Gov*), *government-dependent* (*Gov-Dep*), *relation-government-dependent* (*Rel-Gov-Dep*). The feature value is set as 1 or 0 if corresponding tuple is present or absent in tweet.

*Top Tfidf Word (TopTfidf)*: We divide the labeled tweet datasets with *Favor* or *Against* stances into 5 subsets towards given targets and calculate the *tfidf* score for each word in 5 subsets separately. We collect the 20 words with top *tfidf* scores in each subset and set binary feature value to indicate whether the corresponding word exists in current tweet as *TopTfidf* feature.

*Punctuation*: The numbers of exclamations (!) and questions (?) are also noted.

*Negation*: We collect 29 negations from Internet and designed binary feature to record if there is negation in tweet.

## 2.2.2 Topic Feature

We feed all training data into *LDA-C tool* to produce some topic-related information.

*Sent2Topic*: The *LDA* could generate the document distribution among predefined topics. We extract this distribution as *sent2topic* feature.

*Word2Topic*: Each word in input tweets could be expressed as the probabilities among topics. The *word2topic* feature is represented as the accumulation of the probability of corresponding topic of all word in single tweet.

*Top Topic Word (TopTopic)*: Since the topic probability of each word indicates the significance for corresponding topic, thus we collect the top 20 words in each topic to build *TopTopic* feature.

## 2.2.3 Similarity Feature

Since we first determine whether the tweet is relevant to the given target, some similarity features are extracted to model the relevance detect classifier.

*JSD Similarity (JSD)*: For each target, we collect the *Favor* and *Against* tweets to construct word distribution for different targets. Specifically, for subtask B, the tweets with “*#DonaldTrump*” are regarded as relevant record. For each tweet, we calcu-

late *Jensen-Shannon Divergence (JSD)* similarity of word distributions between current tweet and corresponding target, which denotes as follows:

$$\begin{aligned} JSD(S, T) &= \frac{1}{2}KL(P_S || Q) + \frac{1}{2}KL(P_T || Q) \\ Q(w) &= \frac{1}{2}(P_S(w) + P_T(w)) \\ KL(P || Q) &= \sum_{x \in X} P(x) \log \frac{P(x)}{Q(x)} \end{aligned} \quad (1)$$

where  $KL(P || Q)$  means the Kullback-Leibler divergence between distribution  $P$  and  $Q$ . Furthermore, we also take the distributions under lemmatization and stemming forms into consideration.

*Cosine Similarity (Cosine)*: Similar with *JSD*, we obtain the word distributions among targets current tweet respectively. The cosine distance among two distributions is calculated as *Cosine Similarity* feature. For *Cosine Similarity*, we take lemmatization and stemming forms into account as well.

*Overlap Similarity (Overlap)*: *Overlap Similarity* is a simple and effective similarity measure and calculated as follows:

$$Overlap\ Similarity = \frac{|A \cap B|}{|A|} \quad (2)$$

where where  $|A \cap B|$  denotes the size of intersection of set  $A$  and set  $B$  and  $|A|$  means the size of set  $A$ . Here, we treat the top 5/10/20 most relevant words of corresponding target produced by the *LDA tool* as  $|A|$  and the current tweet as  $|B|$ . Similar with *JSD* and *Cosine Similarity*, we also consider the lemmatization and stemming forms. Thus, final dimension of *Overlap Similarity* is 9.

*ContainTopic*: It indicates whether there is any intersection between target words and tweet.

## 2.2.4 Sentiment Lexicon Feature

We employ the following seven sentiment lexicons to extract sentimental lexicon (*SentiLexi*) features: *Bing Liu lexicon*<sup>2</sup>, *General Inquirer lexicon*<sup>3</sup>, *IMDB*<sup>4</sup>, *MPQA*<sup>5</sup>, *AFINN*<sup>6</sup>, *NRC Hashtag Sentiment*

<sup>2</sup><http://www.cs.uic.edu/liub/FBS/sentiment-analysis.html#lexicon>

<sup>3</sup><http://www.wjh.harvard.edu/inquirer/homecat.htm>

<sup>4</sup><http://anthology.aclweb.org//S/S13/S13-2.pdf#page=444>

<sup>5</sup><http://mpqa.cs.pitt.edu/>

<sup>6</sup>[http://www2.imm.dtu.dk/pubdb/views/publication\\_details.php?id=6010](http://www2.imm.dtu.dk/pubdb/views/publication_details.php?id=6010)

*Lexicon*<sup>7</sup>, and *NRC Sentiment140 Lexicon*<sup>8</sup>. Generally, we transform the scores of all words in all sentiment lexicons to the range of  $-1$  to  $1$ , where the minus sign denotes negative sentiment and the positive number indicates positive sentiment.

Given a tweet, we first convert it to lowercase. Then for each sentiment lexicon, we calculate the following five sentimental scores: (1) the ratio of positive words to all words, (2) the ratio of negative words to all words, (3) the maximum sentiment score, (4) the minimum sentiment score, (5) the sum of sentiment scores. If one word does not exist in one sentiment lexicon, its corresponding score is set to zero.

### 2.2.5 Tweet Specific Feature

*AllCaps*: It represents the number of words with uppercase letters.

*Hashtag-Ngrams*: The hashtag always carries significant information. Thus, we segment the hashtag to normal phrase and construct *Hash-unigram* and *Hash-bigram*.

*Elongated*: It indicates the number of words with one character repeated more than two times in raw tweet, e.g., “*gooooood*”.

*Emoticon*: We collect 69 emoticons from Internet and this binary feature records whether the corresponding emoticon is present in tweet.

### 2.2.6 Word Vector Feature

Word vector is a continuous-values representation of the word which usually carries important information. In this part, we utilize two types of word vector, i.e., general word vector, sentiment word vector.

*General Word Vector (GoogleW2V)*: We used the publicly available *word2vec* tool<sup>9</sup> to get word vectors with dimensionality of 300, which is trained on 100 billion words from Google News as *general word vector*.

*Sentiment Word Vector (SWV)*: Zhang proposed the *Combined-Sentiment Word Embedding Model* to settle sentiment analysis task (Zhang and Lan, 2015). In this work, we continue to use this mod-

el to train the *sentiment word vector* with the aid of *NRC140 tweet corpus*(Go et al., 2009).

Since one tweet contains more than one word, we adopted simple *min*, *max*, *average* pooling strategies to obtain the text vector. Thus the final text vector  $V(t)$  is concatenated by  $V_{max}(t)$ ,  $V_{min}(t)$  and  $V_{average}(t)$ .

## 2.3 Evaluation Metrics

For both subtask, we adopt the macro-averaged  $F$  score of *Favor* and *Against* stances (i.e.,  $F_{macro} = \frac{F_{Favor} + F_{Against}}{2}$ ) to evaluate the performance, which considers a sense of effectiveness on small classes. To estimate the system performance on training data, we employ  $F_{macro} = \frac{F_{Relevant} + F_{Irrelevant}}{2}$  for step1 (i.e., relevance detection) and  $F_{macro} = \frac{F_{Favor} + F_{Against}}{2}$  for step2 (i.e., orientation detection).

## 3 Experiments

### 3.1 Datasets

| Target     | Favor    | Against    | None     | Total  |
|------------|----------|------------|----------|--------|
| subtask A: |          |            |          |        |
| train:     |          |            |          |        |
| Hillary    | 118(17%) | 393(57%)   | 178(26%) | 689    |
| Abortion   | 121(19%) | 355(54%)   | 177(27%) | 653    |
| Atheism    | 92(18%)  | 304(59%)   | 117(23%) | 513    |
| Climate    | 212(54%) | 15(4%)     | 168(42%) | 395    |
| Feminist   | 210(32%) | 328(49%)   | 126(19%) | 664    |
| all        | 753(26%) | 1,395(48%) | 766(26%) | 2,914  |
| test:      |          |            |          |        |
| Atheism    | 32(14%)  | 160(73%)   | 28(13%)  | 220    |
| Abortion   | 46(16%)  | 189(68%)   | 45(16%)  | 280    |
| Hillary    | 45(15%)  | 172(58%)   | 78(27%)  | 295    |
| Climate    | 123(73%) | 11(6%)     | 35(21%)  | 169    |
| Feminist   | 58(20%)  | 183(64%)   | 44(16%)  | 285    |
| all        | 304(24%) | 230(57%)   | 230(19%) | 1,249  |
| subtask B: |          |            |          |        |
| train:     |          |            |          |        |
| Donald     |          |            | -        | 68,984 |
| test:      |          |            |          |        |
| Donald     | 148(21%) | 299(42%)   | 260(37%) | 707    |

**Table 1:** Statistics of data sets in training data for subtask A and B. (*Hillary*, *Abortion*, *Climate*, *Feminist* and *Donald* refer to “*Hillary Clinton*”, “*Legalization of Abortion*”, “*Climate Change is a Real Concern*” “*Feminist Movement*” and “*Donald Trump*” respectively.)

For subtask A, the organizer supplied all training data, which consists of 5 targets, i.e., “*Hillary*

<sup>7</sup><http://www.umiacs.umd.edu/saif/WebDocs/NRC-Hashtag-Sentiment-Lexicon-v0.1.zip>

<sup>8</sup><http://help.sentiment140.com/for-students/>

<sup>9</sup><https://code.google.com/archive/p/word2vec>

*Clinton*", "*Legalization of Abortion*", "*Atheism*", "*Climate Change is a Real Concern*" and "*Feminist Movement*". The statistics of datasets are listed in Table 1. For subtask B, the participants just received tweet ids and a script to collect data and the provided tweets have no labels. The distribution of test data of both subtasks is established in Table 1 as well.

### 3.2 Experiments on Training Data

#### 3.2.1 Subtask A

To address this subtask A, we adopted a two-step method, which aims at determining whether the tweet is relevant to the given target and whether the tweet is support for the given target, respectively. Furthermore, considering the diversity of different targets, we separated the training data into 5 subsets according their targets and trained 5 models to settle subtask A. For each target, we built two classifiers to perform stance detection. Thus, there are altogether 10 classifiers constructed for subtask A. In order to improve the performance of stance detection, we conducted feature selection procedure for every classifier. The 5-fold cross validation was performed for system development.

Since the majority of features are high dimensional and sparse, e.g., the dimensions of *4-char* and *5-char* in *Feminist* are 15,536 and 26,658 respectively, in our preliminary experiments for all five targets, we employed the *Logistic Regression* algorithm implemented in *liblinear tools*<sup>10</sup>, which has good generalization for sparse data.

Table 2 shows the results of feature selection experiments for subtask A. For each target, the two columns, i.e., *Rel* and *Ori*, list the optimal feature sets for relevance detection step and orientation detection step, respectively. As for feature selection strategy, we adopted *hill climbing*: keeping adding one type feature at a time until no further improvement can be achieved. Due to page limitation, we only listed optimal feature types for each corresponding target.

From Table 2, it is interesting to find:

(1) The *Similarity Features* are effective to detect the stance regardless of the targets. Since almost half of training tweets are labeled as *None* records which

are not relevant to the given target, the *Similarity Features* are more adept at determining whether the tweet is related to the given target.

(2) The *Sentiment Lexicon* and *SWV* features are not quite effective as expected. Based on the observation on training data, we found that the *Favor* stance tweets not always directly express positive emotion and so are the *Against* tweets. For example, many tweeters usually support or against the target by commenting statements opposed to the given target rather than explicitly express their own opinions to the given target. Thus, it is hard to classify the tweet stance according to its sentiment polarity expressed in tweets alone. Furthermore, we also compared the output of feature selection procedure and the results using all features is much poorer than using optimal feature subsets (e.g., 57.81% vs 65.09% in *Hillary Clinton*), which shows that not all features are suitable for stance detection.

(3) The *Tweet Specific* features are beneficial to this task. It may be that the tweeters often use the emoticons (i.e., *Emoticon*), emphatic words (i.e., *Elongated*, *AllCaps*) to express their attitudes. Besides, the *hashtag* usually carries the main stance of the corresponding tweet.

We also performed preliminary experiments to tune parameters of classifier , e.g., the *penalty coefficient C*. Finally, the optimized configurations listed in Table 3 are adopted for subtask A test data.

#### 3.2.2 Subtask B

As for subtask B, we did not construct extra system and just continued to use the method as subtask A. All labeled data of 5 targets in subtask A were used as training data for *Donald Trump* and two classifiers were built. The last two column in Table 2 shows the experiment results on training data for subtask B. The submitted system configuration is shown in Table 3.

| Subtask | Target   | Configuration |           |
|---------|----------|---------------|-----------|
|         |          | Step1         | Step2     |
| A       | Hillary  | LR, c=1       | LR, c=2   |
|         | Abortion | LR, c=1       | LR, c=2   |
|         | Atheism  | LR, c=1       | LR, c=0.5 |
|         | Climate  | LR, c=1       | LR, c=1   |
|         | Feminist | LR, c=5       | LR, c=0.5 |
| B       | Donald   | LR, c=1       | LR, c=1   |

**Table 3:** System configurations for subtask A and B.

**Table 2:** Results of feature selection experiments for subtask A and subtask B. *Rel* and *Ori* stand for *relevance detection step* and *orientation detection step* respectively.

### 3.3 Results and Discussion

Using the optimum feature sets shown in Table 2 and configurations shown in Table 3, we constructed 10 classifiers for subtask A and 2 classifiers for subtask B and assessed them against the SemEval 2016 Task 6 test data. Table 4 lists the results of our systems and the top-ranked systems on test data provided by organizer for subtask A and B. In subtask A, our system ranked 5th out of 19 teams and in subtask B, the ranking is 5th/9.

| Subtask | TeamID       | Target   | $F_{macro}(\%)$ |
|---------|--------------|----------|-----------------|
| A       | ECNU(5)      | Hillary  | 57.84           |
|         |              | Abortion | 61.25           |
|         |              | Atheism  | 61.96           |
|         |              | Climate  | 41.32           |
|         |              | Feminist | 56.20           |
|         |              | All      | 65.55           |
| B       | MITRE(1)     | All      | 67.82           |
|         | pkudblab(2)  | All      | 67.33           |
|         | ECNU(5)      | Donald   | 34.08           |
|         | pkudblab(1)  | Donald   | 56.28           |
|         | LitisMind(2) | Donald   | 44.66           |

**Table 4:** Performances of our systems and the top-ranked system for subtask A and B. *All* stands for the overall result for subtask A.

First, the results in Table 4 showed that our two-step system performed comparable to the best result in supervised framework (subtask A). It indicates that the proposed system and features are adept in detecting stance in tweet. However, compared with the results on training data, the results on test data are much poorer. The possible reason may be the difference between training data and test data. A further deep analysis will be done later.

Second, in subtask B, our system performed worse than the top results. The major reason lies in that we only adopted the same configuration tuned on training data and did not expanded the training data by adding unlabeled data.

### 4 Conclusion

In this paper, we decomposed the stance detection task into two steps, i.e., relevance detection and orientation detection, which aim at determining whether the tweet is relevant to the given target and whether the tweet is support for the given target. Considering the diversity of different targets, we built unique model for each target. Several types of features are proposed, for example, *Similarity Features*, *Linguistic Features*, *Topic Features*,

etc. The experimental results on training and test data show that the proposed systems is suitable for stance detection. In future work, we consider to optimize the feature engineering to avoid overfitting.

## Abstract

We describe MITRE’s submission to the SemEval-2016 Task 6, Detecting Stance in Tweets. This effort achieved the top score in Task A on supervised stance detection, producing an average F1 score of 67.8 when assessing whether a tweet author was in favor or against a topic. We employed a recurrent neural network initialized with features learned via distant supervision on two large unlabeled datasets. We trained embeddings of words and phrases with the word2vec skip-gram method, then used those features to learn sentence representations via a hashtag prediction auxiliary task. These sentence vectors were then fine-tuned for stance detection on several hundred labeled examples. The result was a high performing system that used transfer learning to maximize the value of the available training data.

## 1 Introduction

This paper describes a system for performing automatic stance detection in social media messages. Our approach employs a recurrent neural network which was initialized from pre-trained features learned in successive attempts to encode world knowledge via weak external supervision.

Stance detection is the task of determining whether the author of a text is in favor or against a given topic, while rejecting texts in which neither inference is likely. This task is distinct from sentiment analysis in that an *in favor* or *against* stance can be measured independently of an author’s emotional state. In stance detection we attempt to mea-

sure how an author’s opinion is expressed in spontaneous, unstructured messages rather than the explicit prompts of formal opinion polls.

Declarations of stance are often couched in figurative language that can be difficult for machines to unravel. Consider the texts *We don’t inherit the earth from our parents we borrow it from our children* and *Last time I checked, Al Gore is a politician, not a scientist*. To the human observer messages like these contain an interpretable stance relevant to the topic of climate change. But to understand rhetorical devices like sarcasm, irony, analogy, and metaphor, a reader often uses personal experience to infer broader context. For machines, matters are additionally complicated by use of informal vocabulary, grammar, and spelling. Furthermore, training data is often expensive or difficult to collect in bulk. These challenges motivated our efforts to seek transfer learning of broad world knowledge through feature pre-training using large unlabeled datasets.

## 2 Related Work

It is common for machine learning approaches to begin learning of any new task from scratch, for example by randomly initializing the parameters of a neural network. This disregards any knowledge gained by similar algorithms when solving previous tasks. Transfer learning approaches, on the other hand, store the knowledge gained in one context and apply it to different, related problems. This type of approach is particularly appealing when one lacks sufficient quantity of in-domain labeled training data, such as when there are only a few hundred known examples of a target.

One strategy for performing transfer learning is to train the parameters of a neural network on multiple tasks: first on an auxiliary task with plentiful data that allows the network to identify meaningful features present in the corpus, then a second time using actual task data to tune and exploit those features learned in the first pass.

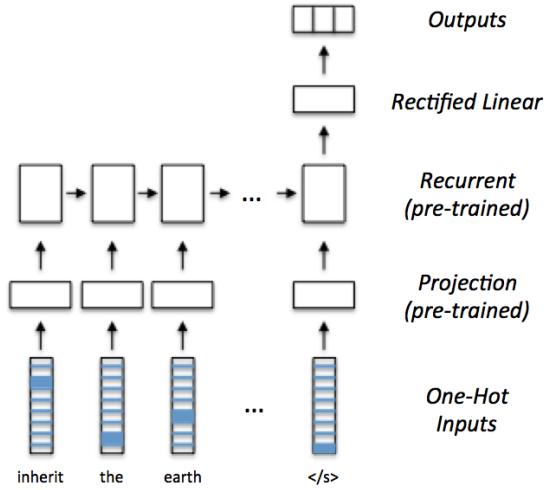

Deep neural networks trained for image classification can be improved when initialized with features learned from distant tasks, for example Yosinski et al. (2014). In natural language processing domains, sentence representations learned on unlabeled data have been shown to be useful across a variety of classification and semantic similarity tasks (Kiros et al., 2015; Dai and Le, 2015; Hill et al., 2016). Weston et al. (2014) used a hashtag prediction task to learn sentence representations that improve a downstream content-based recommendation system.

Previous work in stance detection is significant (Mohammad, 2016), often with a focus on analysis of congressional debates or online forums (Thomas et al., 2006; Somasundaran and Wiebe, 2009; Murakami and Raymond, 2010; Walker et al., 2012) in which discourse and dialogue features offer clues for identifying oppositional speakers. Rajadesingan and Liu (2014) study stance detection in Twitter conversations and use a retweet-based label propagation approach. This objective of this work differs in that we attempt to detect an author’s stance purely from analysis of the text of a single message.

### 3 Task and Evaluation

*Detecting Stance in Tweets, Subtask A: Supervised Frameworks* (Mohammad et al., 2016) was a shared task organized within SemEval-2016.

The task organizers provided training data in the form of 2,814 tweets covering five topics, with 395 to 664 tweets per topic. The organizers used crowdsourcing to manually annotate these tweets for stance. Class balance varied between topics, with some topics showing significant skew (e.g. *Climate Change is a Real Concern* with 4% AGAINST and 54% FAVOR) while others were more balanced (e.g. *Feminist Movement* with 49% AGAINST and 32% FAVOR). Approximately 74% of the provided tweets were judged to be either in favor or against,

**Figure 1:** A recurrent neural network for stance detection.

while the remainder contained neither inference. An additional 1249 tweets with held-out labels were used as evaluation data. Systems were evaluated using the macro-average of F1-score(FAVOR) and F1-score(AGAINST) across all topics.

### 4 System Overview

We now describe an approach to stance detection that employs a recurrent neural network organized into four layers of weights (shown in Figure 1). Input tokens are encoded in a one-hot fashion, such that each token is represented by a sparse binary vector containing a single one-value at the index corresponding to the token’s position in the vocabulary. A sequence of these inputs are projected through a 256-dimensional embedding layer, which feeds into a recurrent layer containing 128 Long Short-Term Memory (LSTM) units. The terminal output of this recurrent layer is densely connected to a 128-dimensional layer of Rectified Linear units trained with 90% dropout (Srivastava et al., 2014). Finally, this layer is fully connected to a three dimensional softmax layer in which each unit represents one of the output classes: *FAVOR*, *AGAINST*, or *NONE*.

This approach did not incorporate any manually engineered task-specific features or inputs relevant to the surface structure of the text. The only inputs to the network were the sequence of indices representing the identity of lowercased tokens (words

or phrases) in the text. All feature pre-training was done using weak supervision from larger unlabeled text datasets, with a goal of automatically learning useful representations of words and input sequences.

#### 4.1 Pre-Training the Projection Layer

The weights for the projection layer of the network were initialized from 256-dimensional word embeddings learned using the `word2vec` skip-gram (Mikolov et al., 2013a) algorithm. We sampled 218,179,858 tweets from Twitter’s public streaming API during 2015, and used this unlabeled data as our training corpus. Retweets, duplicates, and non-English messages were not included in this sample. Text was lowercased and tokenized to mimic the style of the task data. We then applied `word2phrase` (Mikolov et al., 2013b) twice consecutively to identify phrases comprised of up to four words, for example making a single token of the phrase *global climate change*.

We then trained 256-dimensional skip-gram embeddings for the 537,366 vocabulary items that appeared at least 100 times in our corpus, with a context window of 10 words and 15 negative samples per positive example. These hyperparameters were chosen in advance based on our prior experience in training embeddings for identifying word analogies and estimating semantic similarity of sentences. Out of vocabulary items were represented by the average of all in-vocabulary vectors.

Note that these projection layer weights were later tuned by backpropagation during training of the recurrent networks. Thus these initializations served to provide the RNNs with initial feature representations intended to capture the nuances of informal word usage observed in a large sample of text.

#### 4.2 Pre-Training the Recurrent Layer

The second layer of our network was composed of 128 Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997). This recurrent layer received as input a sequence of up to 30 embeddings, folding each into its hidden state in turn. It was initialized with weights that were pre-trained using the distant supervision of a hashtag prediction auxiliary task. In this manner the network learned distributed sentence representations from a dataset containing a broad array of stance declara-

tions, rather than relying exclusively on the 2,814 explicitly labeled in-domain tweets.

We began by automatically identifying 197 hashtags with relevance to the topics under consideration, for example `#climatechange`, `#climatescam`, and `#gamerGate`. These hashtags were selected on the basis of a nearest-neighbor search of the word embedding space. We queried the vector space using the embeddings of the topic titles, and selected the unique hashtags with high (top-50) cosine similarity. These selections varied greatly in frequency and task specificity, including a number of tags which were related to multiple topics and others which appeared ambiguously related. Half of the 40 most frequent tags in this list were related to the 2016 United States presidential elections. The final list of 197 relevant hashtags was held constant across all experiments.

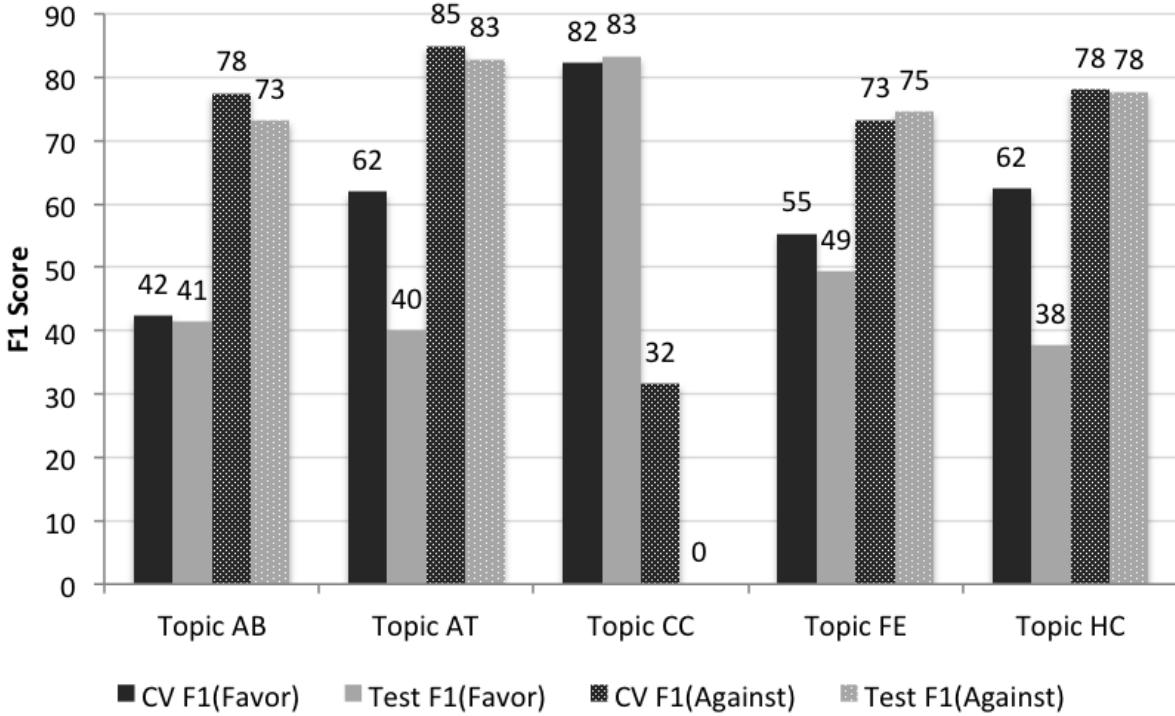

We extracted 298,973 tweets containing at least one of these 197 hashtags from the 2015 corpus of 218 million English tweets. Text was lowercased, tokenized, and phrase chunked according with the preprocessing choices made during the training of word embeddings. If a tweet contained more than one hashtag, the most frequent tag was used as the prediction target. Tweets were then stripped of all hashtags, including both the correct hashtag and any additional hashtags appearing in the tweet.

This corpus was divided into a training set and development set using a 90/10 split. Each word in the tweet was converted into a vector using the word embeddings. The sequence of vector representations of the words in the tweet served as the input to a neural network with a 128-dimensional LSTM layer, followed by a dense softmax layer over the 197 possible candidate hashtags.

We trained the neural network with gradient descent using AdaDelta and categorical cross entropy minimization. Both the word embeddings and the recurrent layer were tuned during this process. Training continued until the accuracy on the development set reached its maximum, which took seven epochs. The final model correctly predicted development set hashtags with 42.6% accuracy.

### 5 Experiments

The system described in section 4 was designed to detect stances pertaining to a single topic. As such

**Figure 2:** F1 scores for each topic and class on both cross-validation and test conditions.

we trained five distinct classifiers, one for each of the five topics under consideration in the evaluation. The embedding and recurrent layers of each classifier were initialized with the weights obtained from the pre-training process described above. The remainder of the weights were randomly initialized and the network was trained with stochastic gradient descent using a learning rate of 0.015 and momentum of 0.9. These networks were trained using a categorical cross-entropy loss function, with costs for each example weighted according to the prevalence of the class in the training data. This placed higher weight on rare classes. The recurrent networks were implemented using the Keras framework (Chollet, 2015).

The training data for each topic was shuffled and split into five chunks for cross-validation. The training process for a single topic's classifier therefore resulted in five distinct neural networks, each learning from 80% of the training data. These training set sizes ranged from 316 to 532 tweets. Each network was trained for 50 epochs, with early stopping to select the model with the best validation loss. Predictions from these five trained networks were used

to select a single class via majority vote at decode time.

Variants of this approach were considered as well. One variant used an identical framework with a recurrent layer initialized instead from a RNN trained on 6.5 million tweets containing the top 10,000 most frequent hashtags (as opposed to 197 topic-relevant hashtags). We also omitted the RNN pre-training altogether and randomly initialized the recurrent layer. These variants were not found to improve performance.

## 6 Results

Our submission achieved an average F1 score of 67.8 on the *FAVOR* and *AGAINST* classes of the held out test set, which contained tweets from all five topics. This was the top scoring system among the 19 entries submitted to the supervised stance detection shared task.

This same system had an average F1 of 71.1 in testing of the component systems using cross-validation on the training set, indicating a small amount of overfitting. Scores also varied moderately

across topics and classes (Figure 2).

One consistent observation across all topics was that the majority class, whether it was *FAVOR* or *AGAINST*, significantly outperformed the corresponding minority class. There was positive correlation ( $R^2 = 0.67$ ) between the F1 score for a given class and the raw number of training examples representing that class.

The weight pre-training and initialization regimes that we applied improved performance relative to the tested alternatives. Entirely omitting pre-training of the recurrent layer (while keeping the projection layer pre-training) resulted in a drop of average F1 from 71.1 to 70.0 in 5-fold cross-validation. Meanwhile the RNN trained to select from among 10,000 popular hashtags led to an average F1 of 66.0, a relative reduction of 7.2% compared to the submission initialized from the RNN trained on 197 highly relevant hashtags.

## 7 Conclusion

We described a state-of-the-art system for automatically determining the stance of an author based on the content of a single tweet. This approach was able to maximize the value of limited training data by transferring features from other systems trained on large, unlabeled datasets.

Our results demonstrated that hashtag prediction and skip-gram tasks can result in pre-trained features that are useful for stance detection. The selection of domain-relevant hashtags appears to be a crucial aspect of this architecture, as experiments employing a larger collection of frequent hashtags resulted in significantly worse performance on the stance detection task.

Transfer learning does not completely eliminate the need for labeled in-domain training data. The most frequent stance classes uniformly outperformed the minority classes by all metrics. It is likely that stances which are rare in this training set are also proportionally absent from the larger unlabeled auxiliary hashtag task. Future experiments could investigate other techniques for identifying relevant hashtags, with a goal of maximizing the diversity of opinions represented in the auxiliary datasets.

## Abstract

This paper describes our system for the detection of stances in tweets submitted to SemEval 2016 Task 6A. The system uses an ensemble of learning algorithms, fine-tuned using a genetic algorithm. We experiment with various off-the-shelf classifiers and build our model using standard lexical and a number of task-specific features. Our system ranked 3rd among the 19 systems submitted to this task.

## 1 Introduction

Stance is the overall position held by a person towards an object, idea, or proposition (Somasundaran and Wiebe, 2009). The task of stance detection – the automatic classification of stance expressed in text – has been attracting increasing interest, as it is of practical interest to many stakeholders, ranging from political bodies to companies. Most recent work focused on stance detection in online debates (Somasundaran and Wiebe, 2009; Somasundaran and Wiebe, 2010; Anand et al., 2011; Hasan and Ng, 2014; Sridhar et al., 2015).

Twitter is an outstanding platform for large-scale stance analysis. However, unlike in the case of dedicated online debate platforms, Twitter data is much less structured and dialogical. Furthermore, as pointed out by Rajadesingan and Liu (2014), processing of tweets poses specific challenges stemming from the high volume of data, brevity of messages, and the use of non-standard language.

In this paper, we describe a system for stance classification in tweets, with which we participated in the SemEval-2016 Task 6A. Given a tweet and the topic

of the tweet (the *target*), the task was to predict the stance of the tweet author as either in FAVOR of the target, AGAINST it, or NONE. Our system relies on a supervised three-way classifier, using features standardly employed for stance classification and similar tasks, but also a number of task- and target-specific features. The gist of our approach was to start out with the entire “kitchen sink” of features, as well as a number of off-the-shelf classification algorithms, and then perform a comprehensive model optimization on a per-target basis. However, instead of relying on a single model for each target, we trained four different models and combined them into one classifier ensemble for each target using a genetic algorithm. Our system (TakeLab) ranked 3rd among the 19 systems submitted to the SemEval-2016 Task 6A.

## 2 Related Work

To the best of our knowledge, the only work to have addressed the stance classification in tweets is that of Rajadesingan and Liu (2014), who specifically tackle the data sparseness problem using a semi-supervised approach based on label propagation. Somasundaran and Wiebe (2009) and (2010) address stance detection in two-sided debates using supervised models with opinion-target pairs, as well as sentiment and argumentation trigger words as features. Anand et al. (2011) address the same domain, but also consider the dialogical properties of debates by identifying the rebuttals between posts, while Sridhar et al. (2015) consider the joint stance classification of posts and relations among them. Hasan and Ng (2014) combine stance classification with reason classification in a joint learning framework.

### 3 Model

We approach this task as a three-way multiclass supervised classification problem. We start off with a number of learning algorithms and also design a number of lexical and task-specific features. Subsequently, we reduce the algorithm and feature space by employing a series of optimization rounds. Finally, we train and fine-tune an ensemble of the chosen classifiers using a genetic algorithm. Following sections describe these steps in more detail.

#### 3.1 Features

We first preprocess the data: we tokenize the tweets,<sup>1</sup> stem the resulting tokens, and finally eliminate the stop words using the NLTK toolkit (Bird et al., 2009). In some configurations, we use a sentiment lexicon compiled by Han and Baldwin (2011) to replace all positive and negative sentiment-bearing words with dummy labels \$POS\$ and \$NEG\$, respectively.

We compute two types of features: lexical features and task-specific features. We compute the former after preprocessing and the latter before preprocessing the data. The lexical features are as follows:

- **Word features** – Word unigrams, bigrams, and trigrams, computed as (1) binary vectors, (2) count-based vectors, and (3) tf-idf-weighted vectors. We use a frequency cut-off of 2 and additionally filter based on class entropy with a cut-off set at 1.1;
- **Character features** – Character bigrams and trigrams, computed in the same manner as the word features;
- **Word embeddings** – A 300-dimensional distributional representation of the tweet obtained as a weighted addition of the distributional vectors of the individual words. We use the freely available<sup>2</sup> skip-gram embeddings of Mikolov et al. (2013) and weight each vector based on the information content of the corresponding word, following Šarić et al. (2012).

We also used the following task-specific features:

- **Counting features** – The average word length, number of retweet symbols, number of hashes, number of emoticons, number of capitalized words,

and the number of exclamation marks;

- **Repeated vowels** – Whether the tweet contains at least one sequence of the same vowel longer than two characters. This feature is often employed in Twitter sentiment analysis, e.g., in (Xu et al., 2015);
- **Number of misspelled words** – The number of misspelled words, determined using the freely-available PyEnchant spellchecking library;<sup>3</sup>
- **Scripture citation** – Our analysis of the dataset revealed that, for two out of five targets, namely *Atheism* and *Legalization of Abortion*, the users who quote the scriptures are by and large AGAINST the targets. To capture this regularity, we include a feature that checks whether the tweet matches some of the common scripture citation patterns, such as “Rom. 14:17” in “RT @prayerbullets: Let the righteousness, peace, and joy of the kingdom be established in my life -Rom. 14:17”;
- **Hashtag splitting** – Our analysis also revealed that for some targets the hashtags are highly indicative of the stance. In some cases, however, a hashtag – although highly indicative – occurs quite rarely in the dataset. For example, in the tweet “Rethink your beach clothes. Bc it may oppress some people!! #thisoppresseswomen” the hashtag is fully indicative of the stance, but overall it occurs rarely. On the other hand, the unigram “oppress” and the bigram “oppress women” are rather frequent in the dataset and also indicative of the stance. To account for this, we split up each hashtag into its constituent words by employing a simple greedy procedure: we start from the end of the hashtag and work our way towards its start, always taking the longest possible word contained in the dictionary.

#### 3.2 Model Optimization

**Algorithm selection.** We started off considering a number of different classification algorithms, implemented in the scikit-learn package (Pedregosa et al., 2011): Support Vector Machine (SVM), Random Forest (RF), Logistic Regression (LR), Gradient Boosting (GB), Multinomial Bayes (MB), Extra Trees (ET), and general stochastic gradient descent classifier (SGDC). We then fixed a baseline set of fea-

<sup>1</sup><http://sentiment.christopherpotts.net/code-data/happyfuntokenizing.py>

<sup>2</sup><https://code.google.com/archive/p/word2vec/>

<sup>3</sup><http://pythonhosted.org/pyenchant/>

tures consisting of word unigrams and bigrams, and evaluated all the combinations of classifiers and text representations using a 3-fold cross-validation. We discarded the classifiers that performed considerably worse than the others, leaving us with four classifiers: RF, GB, LR, and SVM.

**Ensemble learning.** We decided to opt for an ensemble classifier using the four remaining algorithms, motivated by the fact that ensembles generally work better than their base learners as well as the fact that all of our algorithms performed comparably.

With this in mind, our next step was to optimize the hyperparameters of each of the four classifiers to have a fixed ensemble model. Since an exhaustive search would be too time-consuming, we arbitrarily fixed multiple feature sets and hyperparameter ranges.

We define the ensemble model as a linear combination of the output probabilities of the classifiers, and optimize its weights with respect to the F-score. A common way of building the ensemble is stacking, in which one uses the classifiers' predictions as inputs to a meta-level classifier. However, we decided not to use this approach as it would not allow us to optimize for the F-score. Instead, we used a genetic algorithm, which works with arbitrary objectives as fitness functions. As we optimize only four values, running time was not an issue.

We modeled the operators of the genetic algorithm as follows. We initialized the population of size 100 uniformly across the interval  $[0, 1]$ , and constrained the weights to the same interval by clipping. For crossover, we used tournament selection, randomly selecting three individuals from the population, replacing the worst of the three with the child of the remaining two. The crossover created a child by randomly selecting weights from either of the parents. We used mutation with random uniform noise from the interval  $[-0.3, 0.3]$ .

**Feature selection.** Lastly, we needed to find the best feature set for each target. We manually compiled a list of feature sets based on our experience with the task as well as intuition about which features work well in practice. We treated the ensemble as a single classifier, and all the constituents received the same feature sets as the input. However, instead of optimizing the score of the individual classifiers, we cross-validated the whole ensemble with respect to

the input features and the F-score, treating the genetic algorithm as a trainable classifier, with the stochastic search as an optimization algorithm.

## 4 Evaluation

### 4.1 Task Description

The dataset consisted of 2814 tweets in the train set and 1249 in the test set divided into five targets – *Atheism (ATH)*, *Climate Change is a Real Concern (CC)*, *Feminist Movement (FM)*, *Hillary Clinton (HC)*, and *Legalization of Abortion (LA)*. Possible stances were FAVOR, AGAINST, and NONE, where the latter served both as an indicator of a tweet not being related to the target (e.g., “*Pop may throw in the towel second half..*”), as well as the tweet being neutral towards the target (e.g., “*atheism involves what a person does or does not believe, agnosticism involves what a person does or does not know. #Waterford*”).

The official evaluation measure was the macro-average of F-score for FAVOR and AGAINST across all targets, meaning that weak F-score performance on an unbalanced label distribution for a target could be compensated for by the overall good performance on other targets. Note that the label NONE was ignored during the evaluation. Consequently, misclassifying FAVOR or AGAINST as NONE (or vice versa) was penalized less than misclassifying FAVOR as AGAINST (or vice versa).

Although the task can straightforwardly be approached as a three-way classification problem, it can also be framed as a two-step binary classification problem, first discriminating between NONE and FAVOR+AGAINST, and then between FAVOR and AGAINST. The potential benefit of the two-step approach is that the features may be separated more clearly between classes, while the downside is that the error propagates from the first to the second stage.

The ambiguity of the label NONE posed a problem in approaching the task as a two-step binary classification. The best accuracy on the first step (NONE vs. FAVOR and AGAINST) was around 70%, while the best classifiers reached about 80% accuracy in the second step (FAVOR vs. AGAINST), resulting in an overall much higher error rate than that of the three-way classification model.

## 4.2 Feature Analysis

As described in Section 3, we used an ensemble of classifiers fit by a genetic algorithm. One of the steps was to determine the best features for each target and for each classifier. For brevity, we provide just a part of the results of our feature analysis study in Table 1. We show the F-score for FAVOR and AGAINST for each target as well as the score across all targets. We consider the following ten feature groups (the first three are the groups used in the submitted system):

- **Group 1** – binary-weighted word unigrams, bigrams, and trigrams, as well as character trigrams and stylistic features (the first four task-specific features). This group was used for the ATH and LA targets;
- **Group 2** – \$POSS\$/NEG\$ labels, binary-weighted word unigrams, bigrams, and trigrams, character trigrams. This group was used for the CC and FM targets;
- **Group 3** – binary-weighted word unigrams, bigrams, and trigrams, as well as character trigrams, stylistic features, and word embeddings. This group was used for the HC target;
- **Group 4** – binary-weighted word unigrams;
- **Group 5** – word embeddings;
- **Group 6** – binary-weighted character trigrams, word embeddings;
- **Group 7** – frequency-weighted word unigrams and bigrams, character trigrams, stylistic features;
- **Group 8** – no stemming, binary-weighted word unigrams, bigrams, and trigrams, character trigrams, stylistic features;
- **Group 9** – no stemming, frequency-weighted word unigrams, bigrams, and trigrams, character trigrams, stylistic features;
- **Group 10** – frequency-weighted unigrams and bigrams, character trigrams.

## 4.3 Model Variants

In Table 2, we provide the performances (scored with the official evaluation metric) of the top three systems from the official run, namely MITRE, pkudblab, and TakeLab (our submission), as well as of the number of other model variants we produced. We include our single best performing classifier – the Random Forest classifier (Best single) and an ensemble where the output probabilities are simply averaged (Averag-

| Group | ATH          | CC           | FM           | HC           | LA           | All          |
|-------|--------------|--------------|--------------|--------------|--------------|--------------|
| 1     | <b>0.686</b> | 0.712        | 0.645        | 0.638        | 0.660        | <b>0.698</b> |
| 2     | 0.669        | <b>0.720</b> | <b>0.689</b> | 0.621        | 0.658        | 0.694        |

| pkudblab      | 0.6733   |
| TakeLab*      | 0.6683   |
| Majority vote | 0.6522   |
| Averaging     | 0.6331   |
| Best single   | 0.6161   |

**Table 2:** Model performances (\* marks our submitted model).

ing). Additionally, we include an optimistic variant of our best model (Optimistic), where the features and classifier hyperparameters are the same as in our submitted model, but we used the gold labeled test set as the validation set for the genetic algorithm. The result is a rough estimate of the upper-bound F-score of our submitted model on this dataset.

We also include a majority vote per target baseline model (Majority vote). The baseline yields an F-score of 0.6522, which surprisingly places it in the 6th place on the task leaderboard.

## 5 Conclusion

We described the stance classification system with which we participated in the SemEval-2016 Task 6A. Our system uses an ensemble of supervised classifiers, trained using a number of lexical and task-specific features, and optimized using a genetic algorithm. Our system ranked 3rd in the official evaluation run.

There are many possible directions for future work. One is to use the tweet data of users and their social network to augment the training data. Multi-task learning might also be worth investigating, as

some of the topics are semantically related. Furthermore, using external knowledge, such as searching the Wikipedia for keywords related to a topic, may be useful for identifying the tweets related to a topic.

## Abstract

In this paper, we present our contribution in SemEval2016 task7<sup>1</sup>: Determining Sentiment Intensity of English and Arabic Phrases, where we use web search engines for English and Arabic unsupervised sentiment intensity prediction. Our work is based, first, on a group of classic sentiment lexicons (e.g. Sentiiment140 Lexicon, SentiWordNet). Second, on web search engines' ability to find the co-occurrence of sentences with predefined negative and positive words. The use of web search engines (e.g. Google Search API) enhance the results on phrases built from opposite polarity terms.

## 1 Introduction

A sentiment lexicon is a list of words and phrases, such as "excellent", "awful" and "not bad", each is being assigned with a positive or negative score reflecting its sentiment polarity and strength. Sentiment lexicon is crucial for sentiment analysis (or opining mining) as it provides rich sentiment information and forms the foundation of many sentiment analysis systems (Pang and Lee, 2008; Liu, 2012).

Sentence intensity is essential when we need to compare sentences having the same polarity orientation. It is expressed by words or phrases with different strengths. For example, the word "excellent" is stronger than "good". The sentiment words, like "good" and "bad", are used to express positive and negative sentiments. But also intensifier and diminisher words can change the degree of the expressed sentiment, an intensifier increases the intensity of a

positive or negative word like "very" and a diminisher decrease its intensity like "barely".

However, sentence intensity prediction of short sentences faces several challenges:

1. Due to the nature of the short sentence itself; the limited size of the sentences, the informal language of the content that may contain slang words and non-standard expressions (e.g. LOL instead of laughing out loud, greaaaaat etc.), and the high level of noise due to the absence of spell checker tools.
2. Due to the sentiment lexicons not including all of the vocabulary needed, or may not be totally balanced between positive and negative sentences.

Our proposal is to:

1. Calculate the probability of positivity for the phrase in the sentiment lexicons, using the point-wise mutual information (PMI) (Cover et al., 1994).
2. When the phrase is not included in the sentiment lexicons, we use the web search engine to find probability of positivity for the phrase based on its co-occurrence near the word "excellent" and near the word "poor".

## 2 Related work

The sentiment words are the main factor for sentiment classification, by consequence sentiment words and phrases can be used for sentiment classification in an unsupervised method, a method that

<sup>1</sup><http://alt.qcri.org/semeval2016/task7/>

can solve the problem of domain dependency and reduce the need for annotated training data. The method of Turney (2002) is such a technique. It performs classification based on fixed syntactic patterns that are usually used to express opinions. The syntactic patterns are formed based on part-of-speech (POS) tags, then the sentiment orientation (SO) of the patterns is calculated using the pointwise mutual information (PMI) measure. We renounced the use of syntactic patterns due to the majority of one word phrases in the competition files. Turney and Littman (2003) created two sets of prototypical polar words, one containing positive and another containing negative example words. To compute a new term's polarity, they used the point-wise mutual information (PMI) between that word and each of the prototypical sets (Lin, 1998). The same method was used by Kiritchenko et al. (2014), for the purpose of creating a large scale Twitter sentiment lexicons.

The work of Turney and Littman (2003) is the base of our approach, we use several available sentiment lexicons, and also we use web search engine for each phrase not included in those sentiment lexicons.

### 3 Difficulties Comparison in this task with languages: English and Arabic

Although the same method is applied for both languages: English and Arabic, the level of difficulty is different when treating both of them. On the resources level, for the English language, we can find many "free" and "available on-line" data-sets of sentiment lexicons and labeled tweets (e.g. Sentiment140 with 1600k records). For the Arabic language, the resources are limited and our data-set of sentiment lexicons and labeled tweet is of 16K records only. On the language characters level, the Arabic language needed special treatment for the sentiment lexicons files, and for using the web search engines (e.g. using coding: UTF-8). On the language use and diversity level, there are 22 Arabic-speaking countries but the people of these countries speak their own "mutant-Arabic" languages (dialects), mostly influenced by other languages (e.g. French, English). Also most of the Arabic sentences are pronounced differently (due to accents) in these countries, and then written differently

on the social media.

### 4 Method

Our contribution is an unsupervised method with the use of web search engine as a way to maximize the chances of finding all the slang words, abbreviations, non-standard expressions that a classic corpora will not include.

The method is to calculate the sentiment score for a term  $w$  from the sentiment lexicons as shown in the Equation 1 (Kiritchenko et al., 2014):

$$SentSc(w) = PMI(w, pos) - PMI(w, neg) \quad (1)$$

PMI stands for pointwise mutual information, it measures the degree of statistical dependence between two terms. It is used in our work to calculate the degree of statistical dependence between a term and a class (negative or positive).

$$PMI(w, pos) = \log_2 \frac{freq(w, pos) \cdot N}{freq(w) \cdot freq(pos)} \quad (2)$$

Where  $freq(w, pos)$  is the number of times a term  $w$  occurs as positive or in a positive tweet,  $freq(w)$  is the total frequency of term  $w$  in sentiment lexicons and labeled tweets,  $freq(pos)$  is the total number of positive terms in sentiment lexicons and labeled tweets, and  $N$  is the total number of terms in the data-set (Kiritchenko et al., 2014).  $PMI(w, negative)$  is calculated similarly.

For the English language, we have done our testing using the below manual constructed sentiment lexicons:
