

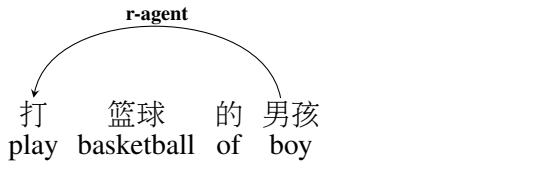

Figure 3: Reverse relations.

could use only the given training data to train their systems and any other additional resource is forbidden. While any knowledge beyond training data is allowed in open track. The closed track encourages participants to focus on building dependency

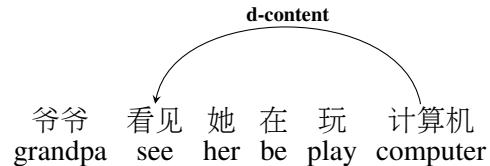

Figure 4: Nested relations.

parsing systems on graphs and the open track stimulates researchers to try how to integrate linguistic resource and world knowledge into semantic dependency parsing. The two tracks will be ranked separately. We provide two training files containing sentences in each domain. There is no rules for the use of these two training data.

### 3.1 Corpus Statistics

Since texts in rich categories have different linguistic properties with different communication purpose. This task provides two distinguished corpora in appreciable quantity respectively in the domain

of NEWS and TEXTBOOKS (from primary school textbooks). Each corpus contains particular linguistic phenomena. We provide 10,068 sentences of NEWS and 14,793 sentence of TEXTBOOKS. The sentences of news keep the same with the data in task 5 at SemEval 2012, which come from the Chinese PropBank 6.01 (Xue and Palmer, 2003) as the raw corpus to create the Chinese semantic dependency corpus. Sentences were selected by index: 1-121, 1001-1078, 1100-1151. TEXTBOOKS refer to shorter sentences with various ways of expressions, i.e., colloquial sentences (3,000), primary school texts (11,793). Detailed statics are described in Table 2.

|      |       | Train   | Dev    | Test   |
|------|-------|---------|--------|--------|
| NEWS | #sent | 8,301   | 534    | 1,233  |
|      | #word | 250,249 | 15,325 | 34,305 |
| TEXT | #sent | 10,817  | 1,546  | 3,096  |
|      | #word | 128,095 | 18,257 | 36,097 |

**Table 2:** Statics of the corpus.

### 3.2 Data Format

All data provided for the task uses a column-based file format, similar to the one of the 2006 CoNLL Shared Task (Table 3). Each training/developing/testing set is a text file, containing sentences separated by a blank line. Each sentence consists of more than one tokens, and each token is represented on one line consisting of 10 fields. Buchholz and Marsi (2006) provide more detailed information on the format. It's worth noting that if one word has more than one heads, it will appear in more than one lines in the training/developing/testing files continuously. Fields are separated from each other by a tab. Only five of the 10 fields are used: token id, form, pos tagger, head, and deprel. Head denotes the semantic dependency of each word, and deprel denotes the corresponding semantic relations of the dependency. In the data, the lemma column is filled with the form and the cpostag column with the postag.

### 3.3 Evaluation

During the phase of evaluation, each system should propose parsing results on the previously unseen testing data. Similar with training phase, testing

files containing sentences in two domains will be released separately. The final rankings will refer to the average results of the two testing files (taking training data size into consideration). We compare predicted dependencies (predicate-role-argument triples, and some of them contain roots of the whole sentences) with our human-annotated ones, which are regarded as gold dependencies.

Our evaluate measures are on two granularity, dependency arc and the complete sentence. Labeled and unlabeled precision and recall with respect to predicted dependencies will be used as evaluation measures. Since non-local dependencies (following Sun et al. (2014), we call these dependency arcs making dependency trees collapsed non-local ones) discovery is extremely difficult, we will evaluate non-local dependencies separately. For sentences level, we will use labeled and unlabeled exact match to measure sentence parsing accuracy. Following Task 8 at SemEval 2014, below and in other task-related contexts, we abbreviate these metrics as:

- Labeled precision (LP), recall (LR), F1 (LR) and recall for non-local dependencies (NLR);
- Unlabeled precision (UP), recall (UR), F1 (UF) and recall for non-local dependencies (NUR);
- Labeled and unlabeled exact match (LM, UM).

When ranking systems participating in this task, we mainly refer to the average F1 (LF) on the two testing sets.

## 4 Participating Systems

Fifteen organizations were registered to participate in this task. Finally, five systems were received from three organizations. These systems are as follows:

1. IHS-RD-Belarus. This system applied transition-based dependency parsing with online reordering, in order to deal with non-projective dependency arcs. The model is trained with both gold training instances and auto-parsed training instances, referred to as *bootstrapping*. Additional semantic features extracted from the IHS Goldfile Question-Answering system are utilized and demonstrated to be effective. It also used graph

| ID | FORM | LEMMA | CPOS | PPOS | FEAT | HEAD | REL   | PHEAD | PREL |
|----|------|-------|------|------|------|------|-------|-------|------|
| 1  | 现在   | 现在    | NT   | NT   | -    | 4    | Time  | -     | -    |
| 2  | 她    | 她     | PN   | PN   | -    | 3    | Poss  | -     | -    |
| 2  | 她    | 她     | PN   | PN   | -    | 7    | Exp   | -     | -    |
| 3  | 脸色   | 脸色    | NN   | NN   | -    | 4    | Exp   | -     | -    |
| 4  | 难看   | 难看    | VA   | VA   | -    | 7    | eCau  | -     | -    |
| 5  | ,    | ,     | PU   | PU   | -    | 4    | mPunc | -     | -    |
| 6  | 好像   | 好像    | AD   | AD   | -    | 7    | mMod  | -     | -    |
| 7  | 病    | 病     | VV   | VV   | -    | 0    | ROOT  | -     | -    |
| 8  | 了    | 了     | SP   | SP   | -    | 7    | mTone | -     | -    |

Table 3: Data format.

pre- and post-processing to handle ambiguities of some specific semantic relations (i.e., *eCoo*).

2. OCLSP (lbpq, lbpqg, lbpq75). This system proposed a bottom-up neural parser using long short-term memory (LSTM) networks. Since the basic neural parser (lbpq) has no guarantee to produce a dependency graph, they applied Chu-Liu-Edmond’s algorithm (Chu and Liu, 1965) to generate the minimal spanning directed graph (lbpqg). To further address the multi-head annotation in this task, a threshold of  $\delta$  is set on the probabilities to decide whether an extra arc exists (lbpq75).
3. OSU\_CHGCG. This system proposed to use parsers trained with Chinese Generalized Categorial Grammar (GCG) (Bach, 1981) annotations to obtain the syntactic structures of a sentence. Then the GCG features, along with traditional features (e.g., word, POS, etc.) are fed into a multinomial classifier for semantic dependency classification.

## 5 Results & Analysis

We use LF, UF and NLF, NUF as the main evaluation metrics here. Table 4 shows the results of all participating systems. Note that all of the submitted systems used additional resource beyond training data provided in the task. IHS-RD-Belarus used semantic features extracted from the output of IHS Goldfire Question-Answering system, and both OCLSP and OSU\_CHGCG used GCG features. Therefore, the results reported in Table 4 are all in the open track.

Overall, the IHS-RD-Belarus system achieves the best results in both NEWS and TEXT domain. However, it didn’t perform well on the prediction of non-local labeled dependencies. OSU\_CHGCG instead behaves more promising in the prediction of non-local dependencies. OCLSP (lbpq75) achieves remarkable results in the non-local labeled dependencies of the TEXT domain (57.51 of NLF).

From the perspective of methodology, IHS-RD-Belarus is a tree-structure prediction system, lacking the ability of revealing multi-head structures; while both OCLSP and OSU\_CHGCG deal with graph structure, with either post-processing or classification-based models. From the perspective of resource, all the systems demonstrated that features extracted from a syntactic or semantic source are helpful for the SDP task, which is expected.

In general, some novel methods and ideas were proposed for this task, providing evidences for future research on both model design and feature selection of semantic dependency parsing.

## 6 Conclusion

We described the Chinese Semantic Dependency Parsing task for SemEval-2016, which is designed to analyze the graph-structured semantic representation of Chinese sentences. Five systems were submitted by three organizations. The systems explored the semantic dependency parsing problem along different directions, which will significantly push forward the research on SDP. We also note that the performance of SDP is still far from promising, especially for labeled dependencies and non-local dependencies. Challenges still remain in designing more effective and efficient parsing algorithms for graph-

## Abstract

This paper describes the second edition of the shared task on Taxonomy Extraction Evaluation organised as part of SemEval 2016. This task aims to extract hypernym-hyponym relations between a given list of domain-specific terms and then to construct a domain taxonomy based on them. TExEval-2 introduced a multilingual setting for this task, covering four different languages including English, Dutch, Italian and French from domains as diverse as environment, food and science. A total of 62 runs submitted by 5 different teams were evaluated using structural measures, by comparison with gold standard taxonomies and by manual quality assessment of novel relations.

## 1 Introduction

Taxonomies are useful tools for content organisation, navigation, and retrieval, providing valuable input for semantically intensive tasks such as question answering (Harabagiu et al., 2003) and textual entailment (Geffet and Dagan, 2005). In general, a hierarchical relation is any asymmetrical relation that indicates subordination between two terms, but in this task we focus on hyponym-hypernym relations. Taxonomy learning from text is a challenging task that can be divided in several subtasks, including term extraction, hypernym identification and taxonomy construction. Existing approaches for hypernym identification from text rely on lexico-syntactic patterns (Hearst, 1992; Lefever et al., 2014), cooccurrence information (Grefenstette, 2015), substring inclusion, or exploit semantic relations provided in textual definitions (Velardi et al., 2013). This stage

usually produces a large number of noisy, inconsistent relations, which assign multiple parents to a node and contain cycles. Hence, the third stage of taxonomy learning, taxonomy construction, focuses on the overall structure of the resulting graph and aims to organise terms in a hierarchical structure, more specifically a directed acyclic graph (Velardi et al., 2013; Kozareva and Hovy, 2010).

More recently, the hypernym identification subtask has attracted an increased interest from the distributional semantics community (Santus et al., 2014; Rei and Briscoe, 2014; Roller et al., 2014; Yu et al., 2015), as part of a wider effort to distinguish between different semantic relations which exist between distributional similar words (Weeds et al., 2014; Levy et al., 2015). Although this is a promising direction of research, that addresses some of the limitations of pattern-based approaches, including low coverage of domain-specific terms, most participants in this shared task opted for traditional approaches for hypernym identification, with the exception of one system (Pocostales, 2016).

TExEval-2 is mainly concerned with automatically extracting hierarchical relations from text and subsequent taxonomy construction, therefore we make the assumption that a list of terms is readily available. This simplifies evaluation by providing a common ground for all the systems, but participants are allowed to add additional nodes, i.e. terms, in the hierarchy as they consider appropriate. To avoid the need for term extraction, terms are extracted from existing taxonomies, providing participants with a domain lexicon that has to be organised in a hierarchical structure.

## 2 Task Description

The first TExEval shared task (Bordea et al., 2015), organised as part of SemEval 2015, introduced a monolingual dataset that covers terms and hierarchical relations from four domains that were not previously considered for this task. Performance was evaluated across domains, considering common sense knowledge as well as technical domains gathered from WordNet and other well known taxonomies. The second TExEval shared task aimed to extend this experimental setting to a multilingual setting, covering English, French, Italian and Dutch. A main challenge faced by the participants in the first TExEval was that no corpus was provided by the task organisers. We address this issue by providing participants with instructions for downloading and preparing a Wikipedia-based corpus. Depending on the selected approach, a system may or may not require large amounts of text to extract relations between terms, therefore participants are allowed to extend this corpus as they consider appropriate. The task is structured in several subtasks, including monolingual subtasks for hypernym identification and taxonomy construction in English, as well as two corresponding multilingual subtasks that cover Dutch, French and Italian.

## 3 Dataset Creation

We selected three target domains (i.e. Environment, Food and Science) with three root concepts (i.e. “environment”, “food” and “science”, respectively). Then, for each domain we considered different sources for gathering gold standard taxonomies, including a multilingual thesaurus, Eurovoc<sup>1</sup>, a large lexical database of English, WordNet, and a general purpose resource, the Wikipedia Bitaxonomy (Flati et al., 2014). We also considered other domain-specific resources including “The Google product taxonomy”<sup>2</sup> for Food, and the “Taxonomy of Fields and their Subfields”<sup>3</sup> for Science.

**English taxonomies** The English gold standard taxonomies are collected from each of the sources

<sup>1</sup>Eurovoc: <http://eurovoc.europa.eu/drupal/>

<sup>2</sup><http://www.google.com/basepages/producttype/taxonomy.en-US.txt>

<sup>3</sup>[http://sites.nationalacademies.org/PGA/Resdoc/PGA\\_044522](http://sites.nationalacademies.org/PGA/Resdoc/PGA_044522)

described above as follows. Gold standards are gathered from WordNet by selecting concepts and relationships in the hypernym-hyponym hierarchy rooted on the corresponding root concept for each domain. Relations extracted from Wikipedia are combined together with relations extracted from domain-specific resources, to obtain high-coverage domain-specific taxonomies. Hierarchical relations from Eurovoc were used integrally without any modification, but currently Eurovoc covers only the Environment and Science domains. It is worth noting that the English gold standard taxonomies gathered from WordNet and from combined resources were also used as test data in the previous edition of this shared task (Bordea et al., 2015).

**Multilingual taxonomies** For the three other languages, the collected English gold standards were manually translated by six linguists (two computational linguists and four master students of the Ghent University Translation, Communication and Interpreting department). In a first step, the English term lists were translated in Excel by one annotator per language. The first annotator was allowed to mark entries that needed to be revised by a second annotator. In addition, the annotators could make remarks in an additional column. Some of the English terms could not be properly translated in the specific domain (e.g. “center” in the food domain) and were left out. In a second step, the translated term lists were used to automatically replace the English terms in the gold standard taxonomies with their corresponding translation.

The translation of English gold standards revealed a number of issues. First of all, some of the translations were near-synonyms in the other language, which eventually lead to cycles in the taxonomy. Examples in Italian are for instance “cibo” (English: food) and “vitto” (English: fare) which are in Italian almost synonymous, whereas their English counterparts have a more distinctive meaning. Another problematic example are the Italian words “condimento” (English: seasoning, sauce, dressing) and “salsa” (English: dressing, sauce), which can be hypernyms of each other, depending on the exact meaning of the word. The translated taxonomies also revealed errors in the original English taxonomy, such as for instance “conserve” is a kind of “confiture”, which is incorrect.

| Language | Domain      | Source   | V    | E    | #i.i. | #c.c.    | Cycles     |
|----------|-------------|----------|------|------|-------|----------|------------|
| English  | Environment | Eurovoc  | 261  | 261  | 60    | 1        | no         |
|          |             | Combined | 1556 | 1587 | 70    | 1        | no         |
|          |             | WordNet  | 1486 | 1576 | 302   | 1        | no         |
|          | Science     | Combined | 453  | 465  | 54    | 1        | no         |
|          |             | Eurovoc  | 125  | 124  | 31    | 1        | no         |
|          |             | WordNet  | 429  | 452  | 117   | 1        | no         |

**Table 1:** Structural measures of gold standard taxonomies, including number of vertices ( $|V|$ ), edges ( $|E|$ ), intermediate nodes (#i.i.), connected components (#c.c.) and cycles.

Table 1 shows the resulting number of vertices  $|V|$  and edges  $|E|$  of the produced gold standard taxonomies for each considered domain, source and language. We also report structural information about the number of intermediate nodes (#i.i.), the number of connected components (#c.c.) and the number of cycles. Test data for this task consists of six lists of domain-specific terms for each language that were provided to participants as a shared basis to construct the taxonomies. The initial English taxonomies provide connections from the root node to all the other nodes, as they form one connected component. As some of the terms did not have a correspondent in all the other languages, some of the translated taxonomies have several components. This is specifically the case for the food domain that is highly dependent on the language and that shows the largest variation in number of nodes. For example, 127 terms from the Combined English taxonomy for Food could not be translated into Dutch

and 279 terms could not be translated into Italian. Additionally, four cycles are erroneously introduced for the WordNet Italian taxonomy for Food, including “cibo”-“vitto”-“cibo” and “piatto principale”-“piatto”-“piatto principale”. Slight differences exist between the Eurovoc taxonomies constructed for different languages as well, and these taxonomies underwent a thorough review process.

#### 4 Evaluation Approach

The construction of taxonomies is a challenging task even for humans but evaluating a taxonomy is not a trivial task either. In this shared task, taxonomies are evaluated through comparison with gold standard relations collected from WordNet and other well known, freely available taxonomies. This is complemented by a manual evaluation of relations that are not covered by the gold standard and through quantitative and qualitative structural analysis of the resulting graph. The evaluation methodology is sim-

| Domain      | Source   | System    | $ V $       | $ E $       | #i.i.      | #c.c.    | cycles    |

**Table 2:** Structural analysis of the submitted taxonomies and the string-based baseline for the monolingual setting

ilar to the approach introduced in the first edition of TExEval, with the main difference that we also report separate overall rankings of the participant systems for each of the subtasks.

Let  $S = (V_S, E_S)$  be an output taxonomy produced by a system for a given domain, where  $V_S$  includes the set of domain concepts initially provided by the task organizers and  $E_S$  is the set of taxonomy edges extracted by the system. To broadly analyze

the quality of the produced set of hypernymy relationships  $E_S$ , these results are benchmarked against the string-based baseline described in Section 4.1, using the following evaluation approaches: i) analyse the graph structure and check if the produced taxonomy is a Directed Acyclic Graph (DAG); ii) compare the edges  $E_S$ , against the set of relations from each type of gold standard; iii) manually validate a sample of novel relationships produced by the

system that are not contained in the gold standard.

The final ranking of the systems takes into consideration these three types of evaluation by aggregating the achieved ranks using a voting scheme. First, the output taxonomies are ranked on the basis of the average performance obtained for each evaluated aspect and for each domain. The resulting ranks are simply summed up, favoring systems at the top of the ranked list and penalizing systems at the lower end.

#### 4.1 Baseline

Simple string-based approaches that exploit term compositionality as a main property to hierarchically relate terms are known to be highly effective (Bordea et al., 2015). In this task, we implement the following baseline approach for hypernym extraction and taxonomy construction that is used to benchmark the evaluated systems. The baseline accounts for relations between compound terms such as (*science, network science*) and is implemented as follows:

$$B = (V_B, E_B) \quad (1)$$

where  $E_B = \{(a, b) | b \text{ starts with } a \text{ or ends with } a \text{ and } |b| > |a|\}$ . In this equation  $a$  is a term and  $b$  is a compound term that includes  $a$  as a substring. This baseline approach takes as input only a list of terms and does not require any external corpora or other structured information. It is worth noting that the same approach was applied in the multilingual setting, without any language-specific modification.

#### 4.2 Structural Analysis

In this task, the structural evaluation quantifies the size of a taxonomy under investigation in terms of nodes and edges, evaluating whether the overall graph generated by hypernym-hyponym relations provides connections between the root of the taxonomy and all the other nodes. This is an important property of taxonomies that are used for search because it ensures that all the nodes are findable when exploring the taxonomy from the root. Another structural property of taxonomies is the absence of cycles, which are inconsistent with the semantics of hierarchical relations. Additionally, we highlight the number of nodes located on higher lev-

els of a taxonomy, called intermediate nodes. Finding these nodes is more important than connecting a large number of leaves, as they generate taxonomies with a deeper and richer structure.

Based on these considerations, structural evaluation is performed by computing the cardinality of  $|V_S|$  and  $|E_S|$ . We use an algorithm that finds all the elementary circuits of a simple directed graph (Johnson, 1975) to establish if the taxonomy  $S$  contains simple directed cycles (self loop excluded). We then use an approach based on the Tarjan algorithm (Tarjan, 1972) to calculate the number of connected components in  $S$ . Finally, we compute the number of intermediate nodes as the number of nodes  $|V_S| - |L_S|$  where  $L_S$  is the set of leaf nodes in  $S$ , where a leaf node is defined as a node with the out-degree zero.

#### 4.3 Gold Standard Comparison

While initial gold standard datasets for evaluating taxonomy extraction were mainly based on relations extracted from WordNet (Kozareva and Hovy, 2010), more recent work (Velardi et al., 2013) focuses on specialized domains such as artificial intelligence. The dataset introduced in this shared task brings together gold standards collected from WordNet together with gold standards extracted from domain-specific taxonomies and from Wikipedia, a collaborative resource.

Given a gold standard taxonomy  $G = (V_G, E_G)$ , the comparison between a target taxonomy and a gold standard taxonomy is quantified using the following measures:

- Edge precision:  $P = |E_S \cap E_G| / |E_S|$
- Edge recall:  $R = |E_S \cap E_G| / |E_G|$
- F-score:  $F = 2(P * R) / (P + R)$

Additionally, we consider the Cumulative Fowlkes&Mallows (Cumulative F&M) measure (Velardi et al., 2013), denoted as  $B_{S,G}$ , and defined as a value between 0.0 and 1.0 which measures level by level how well a target taxonomy  $S$  clusters similar nodes compared to a gold standard taxonomy  $G$ .  $B_{S,G}$  is calculated as follows: let  $k$  be the maximum depth of both  $S$  and  $G$ , and  $H_{ij}$  a cut of the hierarchy, where  $i \in \{0, \dots, k\}$  is the cut level and  $j \in \{G, S\}$  selects the clustering of interest.

Then, for each cut  $i$ , the two hierarchies can be seen as two flat clusterings  $C_{iS}$  and  $C_{iG}$  of the  $n$  concepts. When  $i = 0$  the cut is a single cluster incorporating all the objects, and when  $i = k$  we obtain  $n$  singleton clusters. Now let:  $n_{11}$  be the number of object pairs that are in the same cluster in both  $C_{iS}$  and  $C_{iG}$ ;  $n_{00}$  be the number of object pairs that are in different clusters in both  $C_{iS}$  and  $C_{iG}$ ;  $n_{10}$  be the number of object pairs that are in the same cluster in  $C_{iS}$  but not in  $C_{iG}$ ;  $n_{01}$  be the number of object pairs that are in the same cluster in  $C_{iG}$  but not in  $C_{iS}$ .

The generalized Fowlkes&Mallows measure of cluster similarity for the cut  $i$  ( $i \in \{0, \dots, k\}$ ), as reformulated in (Wagner and Wagner, 2007), is defined as:

$$B_{S,G}^i = \frac{n_{11}^i}{\sqrt{(n_{11}^i + n_{10}^i) \cdot (n_{11}^i + n_{01}^i)}}. \quad (2)$$

And the Cumulative Fowlkes&Mallows Measure:

$$B_{S,G} = \frac{\sum_{i=0}^{k-1} \frac{i+1}{k} B_{S,G}^i}{\sum_{i=0}^{k-1} \frac{i+1}{k}} = \frac{\sum_{i=0}^{k-1} \frac{i+1}{k} B_{S,G}^i}{\frac{k+1}{2}}. \quad (3)$$

#### 4.4 Manual Evaluation

Even the most complete and up to date taxonomy can be extended with additional nodes and relations, therefore it is possible for systems to identify correct relations that are not covered by the gold standard. A problem faced by gold standard evaluation is that these relations are considered incorrect when relying on a direct comparison with the gold standard taxonomy. This is why we additionally evaluate by hand a subset of new relations proposed by each system to estimate the number of relations in  $E_S$  that do not belong to  $E_G$ . Due to limited resources, we extract only a random sample of novel relations from each submission and manually annotate them to compute precision  $P$  as:  $|correctISA|/|sample|$ . At most 100 relations were evaluated by one annotator for each system, domain, and language for a total of 6200 term pairs. Two different annotators were tasked to evaluate submissions for the monolingual subtask (English) and for the multilingual subtask (Dutch, French, Italian).

The annotators were provided with a list of term pairs organized by domain and were asked if the relation was a correct ISA relation, if the relation and

the terms were domain specific, and if the relation was too generic. Overall, a relation is considered correct only if it is considered a correct hypernym-hyponym relation, if it is relevant for the given domain and not over-generic. Take for example the following edges from the food domain: (*linguine*, *pasta*) and (*lemon*, *food*). Both edges are correct ISA relations and are domain specific, but the second edge is over-generic because lemons can be categorized more precisely as fruits.

## 5 Participants and Results

A total of five teams participated in the shared task, but only two systems participated in the multilingual subtasks. Two of the systems that participated in the monolingual subtask alone did not submit runs for the food domain, which has the largest number of nodes. Overall, 62 system runs were submitted by the five teams, 36 for the multilingual subtasks and 26 for the monolingual subtasks. Next, we provide a short description of each approach starting with the two systems that participated in the multilingual subtasks.

**JUNLP** The JUNLP system makes use of an external linguistic resource for hypernym identification (Maitra and Das, 2016). This resource is the BabelNet semantic network that connects concepts and named entities in a very large network of semantic relations, called Babel synsets (Navigli and Ponzetto, 2010). To make sure that no relations that were used to construct the gold standards are considered, only relations that mention Wikipedia as a source were selected, discarding relations from all the other sources. Additionally, the system makes use of two string inclusion heuristics. The first heuristic checks if any of the terms provided by the organisers is included as a substring in another term. The second heuristic considers terms that have a considerable overlap, for instance *Chocolate Pudding* and *Vanilla Pudding* although their hypernym (i.e., *Pudding*) is not mentioned in the list of terms. A limitation of this approach is that stopwords are also considered as hypernyms, but this can be easily avoided by using a stopword list.

**TAXI** The methods for hypernym identification used in the TAXonomy Induction system (TAXI) rely on two sources of evidence: substring matching

**Table 4:** Manual evaluation of 100 (at most) randomly selected novel relations based on precision for English

and Hearst-like patterns (Panchenko et al., 2016). The Hearst patterns for all languages are extracted from Wikipedia and from focused crawls with seed pages that are Wikipedia pages. In addition, for English, several additional corpora are used including GigaWord, ukWaC, a news corpus and the CommonCrawl. For French, Italian and Dutch the method is completely unsupervised and relies on KNN approach. For English, an SVM classifier is trained on the trial data. For all languages the features are the same: substrings and ISA relations extracted with lexico-syntactic patterns. No databases or linguistic resources beyond trial data and raw text corpora mentioned above are used. For the taxonomy construction subtasks, the system makes use of an unsupervised graph pruning approach based on the Tarjan algorithm, connecting the resulting disconnected components to the root of the graph.

**NUIG-UNLP** The system implements a semi-supervised method that finds hypernym candidates for the provided noun phrases by representing them as distributional vectors. Roughly, this method assumes that hypernyms may be induced by adding a

vector offset (Mikolov et al., 2013; Rei and Briscoe, 2014) to the corresponding hyponym representation generated by GloVe over a Wikipedia dump. The vector offset is obtained as the average offset between 200 pairs of hyponym-hypernym in the same vector space selected from trial data.

**USAAR** This system introduces hypernym endocentricity as a useful property for hypernym identification (Tan, 2016). Often multi-word hyponyms are endocentric constructions which contains a word that fulfills the same function as one part of its word. E.g. an "apple pie" is essentially a "pie". The number of multi-words terms that are endocentric in English is investigated and whether this endocentric property can be used to generate entity links to connect terms in the Wikipedia list of list.

**QASSIT** A semi-supervised methodology is used for the acquisition of lexical taxonomies based on genetic algorithms (Cleuziou and Moreno, 2016). It is based on the theory of pretopology that offers a powerful formalism to model semantic relations and transforms a list of terms into a structured term space by combining different discriminant criteria.

In particular, rare but accurate pieces of knowledge are used to parameterize the different criteria defining the pretopological term space. Then, a structuring algorithm is used to transform the pretopological space into a lexical taxonomy.

### 5.1 Monolingual Subtasks (English)

Table 2 presents the results of the structural analysis for English, giving an overview of the structural measures presented in Section 4.2 for each of the submitted runs. The taxonomies constructed by the TAXI and QASSIT systems are the only taxonomies that provide a path from the root to all the other nodes, as the corresponding graphs have a single connected component. All the other submissions have more than ten disconnected components. The string-based baseline is also producing several disconnected components. The TAXI and USAAR systems are the only systems that produce directed acyclic graphs across all the domains. The QASSIT system generates two cycles in the case of the combined taxonomy for Science. Overall, only the TAXI system consistently produces well-structured taxonomies across domains. The systems that output taxonomies with a large number of nodes, edges and intermediate nodes (e.g., JUNLP and NUIG-UNLP) tend to do so at the cost of introducing cycles in the graph.

In Table 3 we summarize the results of the comparison with gold standards in terms of Fscore and the Cumulative F&M measure. The string-based baseline is relatively strong compared to the other systems in terms of Fscore, providing the best results for all the domains with the exception of the food domain. A reason why the baseline is weaker in this domain is that a much larger number of food terms are single-word terms that are not compositional, but in absolute terms the results are still comparative with the results of the best system coming second on the overall ranking. In terms of the Cumulative F&M measure that quantifies structural similarity with the gold standards, the QASSIT system takes the lead for all the domains where a taxonomy was submitted. In the case of the Food domain, it is the TAXI system that achieves the best results for the Combined gold standard and the USAAR system for the WordNet gold standard. The string-based baseline captures only a small part of the structure of the

gold standard, as shown by the poor results for the Cumulative F&M measure.

The results of the manual evaluation of a sample of novel relations is presented in Table 4. It is worth noting that not all the systems had at least one hundred novel relations to analyse, therefore in some cases a smaller number of relations was manually evaluated. The USAAR submissions introduce the largest number of correct novel relations, with precision higher than 70% for Food taxonomies and the Science taxonomy gathered from Combined sources. The TAXI system comes second for all the domains with the exception of the Science taxonomy gathered from Eurovoc, where the QASSIT system achieves the best results.

The final ranking of the systems is produced by using a voting approach based on the averaged scores of selected measures that cover the main properties of a well-formed taxonomy. For this shared task all the properties are considered to be equally important, but a weighted approach could also be considered depending on the intended purpose of a taxonomy. These properties include (1) cyclicity, measured in terms of the number of submissions that have cycles; (2) structural similarity with gold standard taxonomies, measured with Cumulative F&M measure; (3) categorization, measured in number of intermediate nodes #i.i. that can be interpreted as taxonomical categories; (4) connectivity, measured in number of connected components #c.c.; (5) overlap of edges with the gold standard taxonomy, measured by Fscore; (6) number of covered domains; (7) precision of novel relations from manual evaluation of sample relations. Table 5 presents the averaged results for each of these measures across domains.

Take for example the best ranked system TAXI, where none of the submitted taxonomies had any cycles, which resulted in an overall score of 0 for cyclicity and a rank 1 in the overall ranking, as this is a desirable feature for a taxonomy. In the case of the structure property, measured by averaging the Cumulative F&M measure over all the submitted taxonomies, the TAXI system achieved the second highest score. This score is below the score achieved by the QASSIT system for the same feature, which brings the TAXI system on the second position in the final ranking for the structure property. Cyclicity

| Measure                | Baseline    | JUNLP      | TAXI     | NUIG-UNLP | USAAR       | QASSIT     |
|------------------------|-------------|------------|----------|-----------|-------------|------------|
| Cyclicity              | <b>0</b>    | 3          | <b>0</b> | 4         | <b>0</b>    | 1          |
| Structure (F&M)        | 0.01        | 0.15       | 0.29     | 0.04      | 0.00        | <b>0.4</b> |
| Categorisation (#i.i.) | 77.67       | <b>377</b> | 104.5    | 213       | 96.33       | 59.5       |
| Connectivity (#c.c.)   | 36.83       | 53.17      | <b>1</b> | 44.75     | 76.67       | <b>1</b>   |
| GS Fscore              | <b>0.33</b> | 0.20       | 0.32     | 0.19      | 0.26        | 0.22       |
| Domains                | <b>6</b>    | <b>6</b>   | <b>6</b> | 4         | <b>6</b>    | 4          |
| Manual Precision       | n.a.        | 0.09       | 0.20     | 0.07      | <b>0.49</b> | 0.10       |

**Table 5:** Average scores achieved by the systems for the monolingual subtasks.

| Subtask | Measure                | JUNLP    | TAXI     | NUIG-UNLP | USAAR    | QASSIT   |
|---------|------------------------|----------|----------|-----------|----------|----------|
| TC      | Cyclicity              | 3        | <b>1</b> | 4         | <b>1</b> | 2        |
|         | Structure (F&M)        | 3        | 2        | 4         | 5        | <b>1</b> |
|         | Categorisation (#i.i.) | <b>1</b> | 3        | 2         | 4        | 5        |
|         | Connectivity (#c.c.)   | 3        | <b>1</b> | 2         | 4        | <b>1</b> |
| TC & HI | GS Fscore              | 4        | <b>1</b> | 5         | 2        | 3        |
|         | Domains                | <b>1</b> | <b>1</b> | 2         | <b>1</b> | 2        |
|         | Manual Precision       | 4        | 2        | 5         | <b>1</b> | 3        |
| TC      | Ranking                | 4        | <b>1</b> | 5         | 3        | 2        |
| HI      |                        | 3        | <b>1</b> | 4         | <b>1</b> | 2        |

**Table 6:** Overall ranking of the systems for the monolingual subtasks on Taxonomy Construction (TC) and Hypernym Identification (HI).

and connectivity are the only two properties where low scores are preferable, while for the structure, categorisation, gold standard Fscore, domains, and manual precision higher values are preferred.

The averaged scores shown in Table 5 are directly used to obtain the final ranking of the system for the monolingual subtasks presented in Table 6. The scores used to generate the rankings for the Hypernym Identification (HI) subtask are mainly the last three properties, namely the Fscore with the gold standard, the number of domains, and the precision from manual evaluation. All the seven taxonomical properties described above are used for ranking systems for the Taxonomy Construction (TC) subtask. The TAXI system achieves the best results based on most of these measures, coming third only for the categorization property. This brings the system to the first place both for the Hypernym Identification and the Taxonomy Construction subtasks, in the monolingual setting. There is a tie with the USAAR system, but only for the Hypernym Identification subtask. The second placed system is the QASSIT system, that is ranked on the top three positions for most of the properties with the exception

of the categorization property, where it is ranked on the second last place. This is due to the fact that the QASSIT system produces a relatively flat structure, with a smaller number of intermediate nodes.

## 5.2 Multilingual Subtasks (Dutch, French, Italian)

The results for the multilingual subtasks cover a much smaller number of systems, as only two out of the five participants submitted multilingual taxonomies. The same properties are used for the final rankings of the systems as in the previous section, as can be seen in Table 7. This table shows the average scores of the two systems and of the string-based baseline across domains. Both systems submitted runs for all the domains, therefore in the multilingual subtask the number of domains was not used for ranking the systems. Table 8 presents the final ranking of the systems for the multilingual Taxonomy Construction subtask and the multilingual Hypernym Identification subtask. The TAXI system achieves the best results across all the metrics, with the exception of the categorisation property where JUNLP system introduces a larger number of in-

| Measure                | Baseline    | JUNLP         | TAXI        |
|------------------------|-------------|---------------|-------------|
| Cyclicity              | <b>0</b>    | <b>0</b>      | <b>0</b>    |
| Structure (F&M)        | 0.01        | 0.02          | <b>0.19</b> |
| Categorisation (#i.i.) | 64.28       | <b>178.22</b> | 64.94       |
| Connectivity (#c.c.)   | 40.5        | 34.89         | <b>1</b>    |
| GS Fscore              | <b>0.31</b> | 0.19          | 0.28        |
| Manual Precision       | n.a.        | 0.30          | <b>0.63</b> |

**Table 7:** Average scores of the systems for the multilingual subtasks.

| Subtask | Measure                | JUNLP    | TAXI     |
|---------|------------------------|----------|----------|
| TC      | Cyclicity              | <b>1</b> | <b>1</b> |
|         | Structure (F&M)        | 2        | <b>1</b> |
|         | Categorisation (#i.i.) | <b>1</b> | 2        |
|         | Connectivity (#c.c.)   | 2        | <b>1</b> |
| TC & HI | GS Fscore              | 2        | <b>1</b> |
|         | Manual Precision       | 2        | <b>1</b> |
| TC      | Ranking                | 2        | <b>1</b> |
| HI      |                        | 2        | <b>1</b> |

**Table 8:** Overall ranking of the systems for the multilingual subtasks on Taxonomy Construction (TC) and Hyponym Identification (HI).

termediate nodes. Again, the string-based baseline achieves the best Fscore results in comparison with the gold standards. The TAXI system achieves the best results for English, with a 12.5% decrease in Fscore for Dutch and French and a 9.4% decrease for Italian. JUNLP performance is more stable across languages, with only a 5% drop in Fscore for Dutch and Italian compared to English, and the same Fscore for French.

## 6 Conclusion

This paper provides an overview of the SemEval 2016 task on Taxonomy Extraction, that introduced a multilingual dataset for evaluating hyponym extraction and taxonomy construction. The constructed dataset covers three domains including Environment, Food, and Science. The task attracted 62 submissions from five teams that were automatically evaluated against gold standards collected from WordNet, Eurovoc, Wikipedia and other domain-specific resources. We also reported the results of an extensive structural analysis of the submitted taxonomies and a manual evaluation of a sample of edges that are not covered by the gold

standards.

The best results were obtained by an approach based on Hearst patterns that makes use of a large web-based corpus including Wikipedia. All the systems could benefit from addressing the taxonomy construction subtask, by paying attention to the overall structure of the taxonomy not just the task of extracting pairs of terms. Compared to the previous edition of TExEval, there are two systems that submitted proper taxonomies compared to just one system last year. In this edition, it is also worthy of mention the introduction of methods that make use of purely distributional approaches. These approaches leave a lot of place for improvement, achieving a competitive recall but lagging behind pattern-based approaches in terms of precision.

A possible improvement of this shared task is to analyse system performance in relation to word polysemy. This could be measured by example based on Wikipedia disambiguation pages or on the number of WordNet senses. It is reasonable to assume that hypernym/hyponym pairs between polysemous words are more difficult to connect without using disambiguation methods to identify the appropriate sense for a domain.

# SemEval-2016 Task 14: Semantic Taxonomy Enrichment

David Jurgens

Stanford University

jurgens@cs.stanford.edu

Mohammad Taher Pilehvar

University of Cambridge

mp792@cam.ac.uk

## Abstract

Manually constructed taxonomies provide a crucial resource for many NLP technologies, yet these resources are often limited in their lexical coverage due to their construction procedure. While multiple approaches have been proposed to enrich such taxonomies with new concepts, these techniques are typically evaluated by measuring the accuracy at identifying relationships between words, e.g., that a dog is a canine, rather relationships between specific concepts. Task 14 provides an evaluation framework for automatic taxonomy enrichment techniques by measuring the placement of a new concept into an existing taxonomy: Given a new word and its definition, systems were asked to attach or merge the concept into an existing WordNet concept. Five teams submitted 13 systems to the task, all of which were able to improve over the random baseline system. However, only one participating system outperformed the second, more-competitive baseline that attaches a new term to the first word in its gloss with the appropriate part of speech, which indicates that techniques must be adapted to exploit the structure of glosses.

## 1 Introduction

Semantic networks and ontologies are key resources in Natural Language Processing. Of these resources, WordNet (Fellbaum, 1998), the de facto standard lexical database of English, has remained in widespread use over the past two decades, with a broad range of applications such as Word Sense Disambiguation (Navigli, 2009), Query expansion

and Information Retrieval (Varelas et al., 2005; Fang, 2008), sentiment analysis (Esuli and Sebastiani, 2006), and semantic similarity measurement (Budanitsky and Hirst, 2006a; Pilehvar et al., 2013). The performances of these WordNet-based techniques are directly affected by the lexical coverage of WordNet’s vocabulary, especially if applied to specific domains and social media texts. However, the manual maintenance of WordNet is an expensive endeavour which requires significant effort and time. As a result, WordNet is not updated frequently and omits many lemmas and senses, such as those from domain specific lexicons (e.g., DNA replication, regular expression, and long shot), creative slang usages (e.g., homewrecker), or those for technology or entities that came into recent existence (e.g., selfie, mp3).

Hence, a variety of techniques have tried to tackle the coverage limitation of WordNet, often by drawing new word senses from other domain-specific or collaboratively-constructed dictionaries and adding the new word senses to the WordNet hierarchy (Poprat et al., 2008; Snow et al., 2006; Toral et al., 2008; Yamada et al., 2011; Jurgens and Pilehvar, 2015). However, these approaches have usually been tested on relatively small datasets, often testing for word-level relationships without precisely measuring integration accuracy at the concept level. Similarly, other techniques have been proposed for automatically discovering novel senses of words (Lau et al., 2012); however, these senses were not re-integrated into the taxonomy.

Given the availability of large-scale dictionaries such as Wiktionary, Task 14 is designed to inspire

new automated approaches for using the definitions in these resource to expand WordNet with new concepts. Accordingly, the task provides a high-quality dataset of one thousand definitions from a wide range of domains to be added to the WordNet hierarchy, either by adding them as new concepts or integrating them as new lemmas of an existing concept. The task provides a robust evaluation framework for measuring the accuracy of ontology expansion techniques. More broadly, the techniques developed as a part of Task 14 can play an important role in the construction of new automatically-built ontologies.

## 2 Task Description

The goal of Task 14 is to evaluate systems that enrich semantic taxonomies with new word senses drawn from other lexicographic resources. The task provides systems with a set of word senses that are not defined in WordNet.<sup>1</sup> Each word sense comprises three parts: a lemma, part of speech tag, and definition. For example, the noun *geoscience* is a word sense in our dataset which is associated with the definition “Any of several sciences that deal with the Earth”. The word sense is drawn from Wiktionary.<sup>2</sup> For each of these word senses, a system’s task is to identify a point in the WordNet’s subsumption (i.e., is-a) hierarchy which is the most plausible point for placing the new word sense. In other words, a system’s task is to find the most semantically similar WordNet synset to the given new word sense.

**Operations** Once the target synset is identified, a system has to decide how to integrate the new word sense. For a given new word sense  $s$  and a target synset  $\mathcal{S}$  we define two possible operations:

- MERGE: when  $s$  refers to the same concept that is conceptualized by the synset  $\mathcal{S}$ . As a result of this operation  $s$  is added to the set of synonymous word senses in  $\mathcal{S}$ .
- ATTACH: when  $s$  refers to a more specific concept than  $\mathcal{S}$ . In other words,  $\mathcal{S}$  is a generalization of the new word sense  $s$  (i.e., its hypernym). This operation creates a new synset containing the sole word sense  $s$  and attaches

<sup>1</sup>We use WordNet 3.0.

<sup>2</sup><http://www.wiktionary.org>

the new synset as a hyponym of  $\mathcal{S}$  in the WordNet’s subsumption hierarchy.

Table 1 shows example new word senses together with the target synset and the operation. Note that after both these operations, the polysemy of the lemma of  $s$  is increased by one. Also, the total number of synsets in the enriched WordNet increases by one after an ATTACH operation whereas it remains unchanged after MERGE, since in the latter case, a new word sense is added to an existing synset. Our datasets contain instances from noun and verb parts of speech.

### 2.1 Subtasks

For each item in our datasets, we provide the source dictionary from which the corresponding word sense (i.e., a word and its definition) is obtained. The participating systems were allowed to use the source dictionary in order to draw additional information or exploit its structural properties. Based on their usage of the source dictionary, we classify the participating systems into two categories:

- Resource-aware: the participating systems could use the URLs provided in the dataset to gather additional information (e.g., hyperlinks, wiki-markup) for performing the integration and may use additional information from any dictionary, including the one from which the target word sense had been obtained, e.g., Wiktionary.
- Constrained: the system might use any resource other than dictionaries.

We allowed each team to submit up to three runs per system type to let them explore different configurations, features, or parameter settings in the official rankings.

### 2.2 Related Tasks

Task 14 directly relates to three branches of prior tasks in SemEval. First, two recent tasks have evaluated automatic methods for constructing taxonomies (Bordea et al., 2015; Bordea et al., 2016). In these tasks, participants are presented with word pairs –but no glosses– and tasked with organizing the words into hypernym relationships. Task 14 provides the next step in such evaluations by explicitly

| <b>Lemma</b>  | <b>POS</b> | <b>Definition</b>  | <b>Target synset</b>   | <b>Operation</b> |
|---------------|------------|--|--|------------------|
| geoscience    | noun       | Any of several sciences that deal with the Earth   | earth_science – (any of the sciences that deal with the earth or its parts)                            | MERGE            |
| mudslide      | noun       | A mixed drink consisting of vodka, Kahlua and Bailey's.  | cocktail – a short mixed drink   | ATTACH           |
| euthanize     | verb       | To submit (a person or animal) to euthanasia.  | destroy, put down – put (an animal) to death   | MERGE            |
| changing_room | noun       | A room, especially in a gym, designed for people to change their clothes.  | dressing_room – a room in which you can change clothes   | MERGE            |
| Apple         | noun       | An American multinational technology company headquartered in Cupertino, California, that designs, develops, and sells consumer electronics, computer software, online services, and personal computers. | corporation, corp – (a business firm whose articles of incorporation have been approved in some state) | ATTACH           |
| own           | verb       | To illicitly obtain “super-user” or “root” access into a computer system thereby having access to all of the user files on that system.  | crack – gain unauthorized access computers with malicious intentions.                                  | ATTACH           |

**Table 1:** Sample instances from Task 14’s datasets. A system’s task is to identify, for a new word sense, the target synset and the corresponding operation.

incorporating polysemy into the task by requiring systems to specify a concept, rather than a word, as a hypernym. For example, when recognizing the relationships that a dog is a canine, the system would be required to specify that the concept should be attached to the animal sense of canine, not the tooth sense.

Second, the task of comparing a gloss associated with a new concept is closely related to the recent tasks on semantic similarity, i.e., Semantic Textual Similarity (Agirre et al., 2012; Agirre et al., 2013, STS) and Cross-Level Semantic Similarity (Jurgens et al., 2014, CLSS). Indeed, prior STS tasks included gloss pairs from OntoNotes in the datasets (Hovy et al., 2006) and CLSS had, among its four different evaluation types, an evaluation for systems measuring the similarity between word senses and words. However, while textual similarity is likely to be core component of Task 14 systems, the data is often richer than raw text by containing (a) regular linguistic structure where the parent concept is likely to be introduced first and (b) contextual features from where the gloss appears such as hyperlinks or example usages, which may help to disambiguate.

Third, prior tasks on Word Sense Induction (WSI)

have evaluated methods that automatically discover the different meanings of a word (Manandhar et al., 2010; Jurgens and Klaptis, 2013; Navigli and Vannella, 2013). However, the new senses discovered by these methods were never integrated into any taxonomy, making them difficult to use and relate to existing concepts. Task 14 provides a natural next step for WSI pairs, should any novel induced senses be matched with a gloss describing it.

### 3 Task Data

Given that WordNet 3.0 offers wide coverage of common concepts, the majority of novel concepts to be integrated are likely to come from topical domains, informal expressions, and neologisms. Therefore, the dataset for Task 14 was constructed to contain concepts from a wide variety of domains and to include glosses typical of those seen if performing an automated integration from online sources, such as those from heavily-curated sources such as Wiktionary and more idiosyncratic online glossaries with a single author. Table 3 shows the distribution of instances in the Task 14’s training and test datasets across different genres. The dataset consists of a total of 1000 items, split into training and test datasets containing 400 and 600 items, respectively.

|       | Training |     |       | Test |     |       |
|-------|----------|-----|-------|------|-----|-------|
|       | M        | A   | Total | M    | A   | Total |
| Noun  | 27       | 322 | 349   | 26   | 490 | 516   |
| Verb  | 6        | 45  | 51    | 6    | 78  | 84    |
| Total | 33       | 367 | 400   | 32   | 568 | 600   |

**Table 2:** The distribution of items in the task’s datasets according to the part of speech and the target operation, i.e., Merge (M) and Attach (A).

Novel concepts were limited to nouns and verbs, as only these parts of speech have fully-developed taxonomies in WordNet.<sup>3</sup> Table 2 shows the distribution of training and test items according to their parts of speech and the intended operation, highlighting the fact that most new items are novel concepts that require a new synset to be added, rather than new lemmas to be included in an existing synset.

For each item, in addition to the target synset and the operation, we also provide the resource from which the new word sense was obtained. Glosses were provided as purely text data, with the hope was that systems may use the source URL provided with each gloss to identify additional page structure that could prove useful for concept integration (e.g., hyperlinks, wiki-markup, page topics).

### 3.1 Annotation Process

The two authors independently annotated each of the 1000 items, identifying the appropriate synset and operation. In a small number of cases, neither author could determine an appropriate integration for an item; such items were discarded and replaced with more-easily annotated items. Ultimately, all disagreements were discussed and adjudicated to determine the final dataset.

Annotators initially agreed on the annotation for 37.5% of the items. While this rate seems low at first glance, most disagreements were due to one annotator finding a more refined integration of the item, e.g., DNA vs. Mutant Gene, which is expected given the large search space of over 82K noun and 13.7K verb synsets from which to find the appropriate hypernym or synonym synset. Indeed, most disagreements were very close in meaning; in fact, dis-

agreements had an average semantic similarity between their synsets of 0.74 according to the Wu and Palmer (1994) measure. Hence, the moderate exact-match agreement is an underestimate of the true semantic agreement between annotators. Furthermore, several of the remaining dissimilar pairs were instances where similar concepts were distantly located in WordNet’s structure.

The annotation proved difficult for three categories of concepts, not all of which were successfully integrated. First, many technical domains include unique processes and techniques specific to their field, e.g.,

Lautering (noun) – The process of separating the sweet wort (pre-boil) from the spent grains in a lauter tun or with other straining apparatus.

However, some techniques and processes do not have a correspondence to any existing synsets, leaving their closest appropriate hypernym as a sense of process or technique. This difficulty is reflected in the current structure of WordNet, where *process#n#1* already has the dissimilar concepts of “fingerprinting,” “computation,” and “modus operandi” all as direct hyponyms, highlighting the challenge of placing some concepts. Where possible, we opted to avoid attaching new concepts to general senses, either by finding a more specific concept or leaving them out of the dataset entirely.

Second, in rare occasions, WordNet does not contain an intermediate concept necessary for the appropriate integration. For example, integrating the new concept

Root (noun) – The administrative account (UID 0) on a \*nix system that has all privileges; cf. superuser.

requires first having a concept of a computer account, which is not currently present in WordNet. These gaps are particularly evident for action nouns, where most verbs do not have a corresponding noun gerund. While the novel concept may still be attached to a more-distant hypernym of the appropriate location, this situation points to the need for an iterative integration process where intermediary concepts are first inserted.

<sup>3</sup>We do note that Tsvetkov et al. (2014) have proposed a taxonomy for adjectives, for which our methodology could be applied.

Third, concepts that express a negated or partial state often do not have associated concepts in the more-specific depths of the taxonomy. For example, annotators had difficulty finding appropriate synsets that were not too general for the following two concepts:

NaN (noun) – Not a number; applied to numeric values that represent an undefined or unrepresentable value, such as zero divided by itself

Neomort (noun) – A brain-dead human being that could be kept on life support for organ transplantation, medical and nursing education, and drug research.

Without additional synsets for representing partial or negated state, these concepts would need to be attached to very general synsets such as *value#n#1* or *person#n#1*.

The challenge of agreeing upon a specific location for a new concept underscores the need for automated approaches developed as a part of this task. As an ontology grows in size, it becomes less obvious where a new concept could be integrated, despite an annotator’s familiarity with the concepts contained therein. Our annotation process relied on two annotators whose collective experience was necessary to identify the appropriate location. However, for larger ontologies such as BabelNet (Navigli and Ponzetto, 2012), which contains several orders of magnitude more concepts than WordNet, automated integration approaches will be necessary as it is infeasible for a single human annotator to recall the appropriate insertion point among millions of concepts.

### 3.2 Evaluation Metrics

We evaluated the performance of the participating system according to two criteria: (1) the accuracy by which the placements were performed, and (2) the percentage of items for which a decision was made (Recall).

#### 3.2.1 Accuracy (Wu&P)

Our first criteria verifies the ability of a system to correctly identify the attachment or merge point in the WordNet hierarchy. Checking for exact

matches would penalize equally both a placement in the near proximity of the intended synset and a random placement far in the network. A system’s automatically-made attachment to the WordNet hierarchy is expected to be as close as possible to the correct attachment point given by the gold-standard data. We therefore evaluate the systems according to a fuzzy measure of accuracy which is sensitive to the distance between the intended target synset and the one outputted by the system. However, we recognize that links in the taxonomy do not necessarily represent uniform semantic distances, since siblings that are deep in the hierarchy tend to be more related to one another. Hence, a direct edge-counting approach might not provide a reliable basis for the evaluation of the attachment accuracy. Interestingly, the attachment accuracy evaluation can be cast as a WordNet-based semantic similarity measurement in which the goal is to compute the similarity between two concepts based on the structural properties of WordNet (Budanitsky and Hirst, 2006b), most important of which is the distance between the two. Therefore, we measure accuracy using the Wu and Palmer (1994, Wu&P) semantic similarity measure, defined as:

$$\frac{2 \cdot depth_{LCS}}{depth_1 + depth_2} \quad (1)$$

where  $depth_1$  and  $depth_2$  are the depths of the two concepts in WordNet’s subsumption hierarchy (hypernymy/hyponymy relations) and  $Depth_{LCS}$  is the depth of their least common subsumer, i.e., the most specific concept which is an ancestor of both the concepts. For each instance in the test set for which the system made a prediction, we measure the Wu&P similarity of the output attachment and the corresponding correct synset. An accurate system is expected to have a high similarity score when aggregated over all instances in the test set. Please note that picking the correct target synset with an incorrect operation is analogous to increasing the distance by one edge.

#### 3.2.2 Lemma Match

A key challenge in the integration task is identifying the appropriate word in the gloss that denotes the hypernym (if it exists) and then disambiguating which sense of that word is the appropriate concept for attachment or merger. For example, given the

| Genre              | Subgenre            | Training | Testing | Subgenre Total | Genre Total |
|--------------------|---------------------|----------|---------|----------------|-------------|
| Medical            | UMLS                | 7        | -       | 7              | 200         |
|                    | Genomics            | 69       | -       | 69             |             |
|                    | Virology            | 10       | -       | 10             |             |
|                    | Dental              | 8        | -       | 8              |             |
|                    | Healthcare          | 6        | 8       | 14             |             |

| Total              |                     | 400      | 600     | 1000           | 1000        |

**Table 3:** The distribution of instances across different genres in the training and test data sets of Task 14.

item

Grief (verb) – To deliberately harass and annoy or cause grief to other players of a game in order to interfere with their enjoyment of it

a system may correctly identify that the verb *harass* is the hypernym but select the wrong sense to which *grief* should be attached. Such a mistake would be penalized heavily according to the Wu&P measure and mask that the system is accurate at identifying hypernyms in glosses. Therefore, we include a second unofficial metric, lemma match, that measures the percentage of items for which the system has selected a synset with at least one word in common with the correct synset where the item should be integrated; i.e., how often the system picked the right word but wrong sense.

### 3.2.3 Recall

Some word senses may be more difficult to place in the WordNet hierarchy than others due to a variety of reasons, such as an entry with a gloss that contains many out-of-vocabulary words. Therefore, we allow a system to decline to place these senses in order to avoid making placements with low confidence. As an evaluation metric, we report Recall as the percentage of items for which a decision was made by the system.

### 3.3 System ranking

A system’s performance is computed by the F1 score of Wu&P and Recall. The official ranking of the systems was done according to their F1 scores.

## 4 Systems

Five teams submitted 13 systems, where each team’s systems were variations on a common architecture. No system utilized resource-specific features beyond the gloss (e.g., the Wiktionary markup) and so all systems were ultimately submitted in the constrained category. Systems were compared against two baselines.

### 4.1 Participants

The **MSejrKU** systems build definitional representations based on skip-gram vectors trained on Wikipedia data and incorporates syntactic features.

Words in a candidate gloss are disambiguated using the method of Agirre and Soroa (2009) and then a classifier predicts the goodness of fit for a candidate attachment synset related to those in the gloss.

The **Duluth** systems perform string matching to compare a definition with each of the glosses in WordNet. Given a new definition, systems differ in which words are included from the WordNet synset for comparison: Duluth2 uses only the words in the definition after stopword removal, while Duluth1 extends Duluth2 by including words from the hypernyms of the compared synset. Duluth3 extends Duluth1 with words from the hyponyms but also takes the step of breaking each definition into character tri-grams to capture surface-form regularities. The **UMNDuluth** team performs a similar approach but weights gloss similarity by favoring specific kinds of terms, such as those that are longer and those that appear in WordNet.

The **TALN** systems project the definition of the novel term into a vector space using **SENSEMBED** (Iacobacci et al., 2015). Then this vector is compared with the vectors for senses in WordNet to find the closest match. System variations address issues when words have no associated vectors and how to select between candidate attachments.

The **JRC** system uses a form of second-order similarity by representing each definition as a vector over the synsets that contain its words. New terms are attached by finding the WordNet synset whose definition has maximal cosine similarity.

The **VCU** systems adopt multiple approaches based on textual similarity. Run1 uses a second-order expansion by representing a definition using frequency of words related to those in the definition. Run2 compares glosses using Lesk relatedness measure. Run3 performs no pre-processing and compares the words in the glosses directly as first-order vectors.

### 4.2 Baselines

The first baseline, **Random synset** captures the expected performance of a system at chance when attaching the new concept to a randomly picked synset from WordNet with the appropriate part of speech. This baseline provides the lower bound in expected similarity for an attachment.

The second baseline captures our observation that

| Rank                              | Team      | System                | LM    | Wu&P  | Recall | F1    |
|-----------------------------------|-----------|-----------------------|-------|-------|--------|-------|
| 1                                 | MSejrKU   | System2               | 0.428 | 0.523 | 0.973  | 0.680 |

**Table 4:** Evaluation results showing the Lemma Match (LM), Wu&P, and Recall measures.

glosses are reasonably well structured such that the word expressing the hypernym concept appears early in the gloss (if at all). Therefore, given new word sense  $s$  with definition  $d_s$  and part of speech tag  $p$ , the **First word, first sense** (FWFS) baseline picks the first occurring word  $w$  in  $d_s$  with part of speech  $p$  as the hypernym (i.e., the first noun if the word sense to be attached is a noun and the first verb otherwise).

The new word sense is then attached to the synset containing the first sense of  $w$ . For example, given the item

Immunoglobulin (noun) – Any protein that functions as an antibody

the FWFS baseline attaches the item to the first sense of the noun protein in WordNet, i.e., *protein#n#1*. Despite the wide variety of domains seen in the data, 65% of all integrations in the gold standard data connect the first sense of the target word, suggesting that in the absence of specific information to disambiguate a word in the gloss, its first (most frequent) sense is relatively high precision back-off strategy.

For the FWFS baseline, glosses are POS-tagged using CoreNLP (Manning et al., 2014) and we include a minimal heuristic that prevents attaching to “a” or “an,” both of which are nouns in WordNet. In the rare event that no word can be found with the same part of speech, the item is attached to either the

general concepts of *entity#n#1* or *be#v#1*, depending on the part of speech.

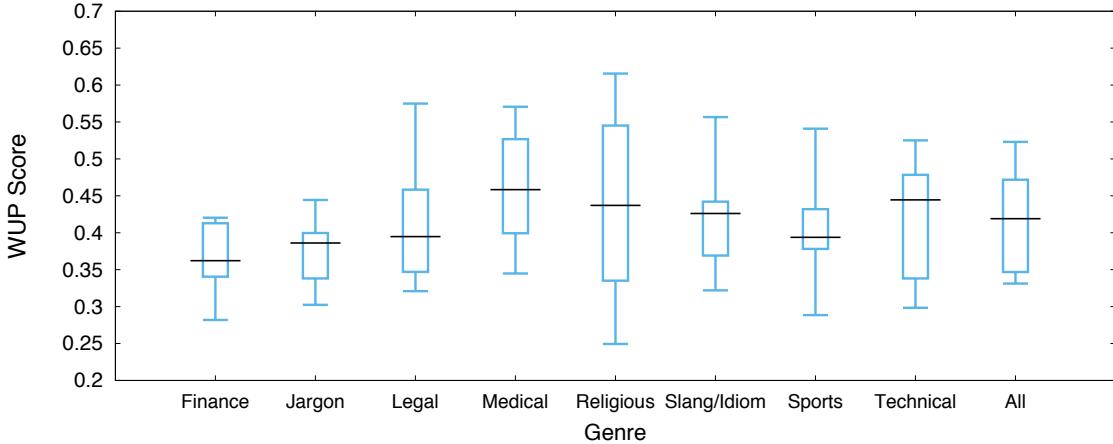

## 5 Results

All of the thirteen participating systems improved over the Random synset baseline. Table 4 shows the evaluation results for Task 14’s participating systems. However, only one of the systems, System2 of MSejrKU, could slightly outperform the FWFS baseline, showing the competitiveness of this simple baseline, which takes advantage of the inherent structure of definitions. Indeed, the lower ranked systems frequently performed holistic comparisons between gloss texts, which frequently include terms from later in the gloss that do not aid in identifying the closest meaning.

While its performance is relatively high among participants, the FWFS baseline should not be mistaken for a satisfactory solution; many of the attachments made by the baseline are overly general and do not take advantage of the remainder of the gloss’s content, which can identify the correct, more-specific concept to which the item should be attached. For example, with the item

Hot reactor (noun) – A person whose blood pressure and heart rate increase abnormally in response to stress

the baseline naively attaches to *person#n#1*, while a

**Figure 1:** The distribution of Wu&P scores of the participating systems per genre. Whiskers show minimum and maximum scores and lines denote the median.

more sophisticated solution could use the additional text in gloss to identify an appropriate hyponym of *person#n#1* to which the item may be attached, e.g., *sick\_person#n#1*. Thus, we speculate that the gloss similarity used by participants may still prove highly useful by first identifying the appropriate general concept in the gloss (e.g., as the baseline does) and then searching its hyponyms for a better match.

Examining the performances of systems in Table 4, we see that no system performed significantly better on the Lemma Match measure than Wu&P, with both measures being highly correlated at  $r=0.96$ . This suggests that when the appropriate hypernym lemma was present in a gloss, systems struggled most with selecting it as the correct candidate lemma in the gloss, rather than identifying which synset of that lemma was the correct attachment.

Given the variety of genres and sources from which new definitions were drawn, we performed a follow-up analysis to examine the impact of the genre on system performance. Figure 1 shows the distribution of scores per genre. Surprisingly, Religious definitions cause the most variance among systems and also saw the highest and lowest system scores per genre. Religious definitions were drawn from more sources beyond just Wiktionary and thus, such variance may reflect systems' robustness to different writing styles. Systems performed worst on the Finance and Jargon domains; however, both genres had little training data relative to testing data, suggesting that systems had difficulty generalizing

from few examples. Nevertheless, systems still performed well for the Legal genre which was held out as a surprise dataset with no training data.

## 6 Conclusion

Semantic taxonomies are core components of many NLP systems and multiple approaches have been proposed for how to extend such taxonomies automatically with new concepts. We have introduced SemEval-2016 Task 14 as a framework and dataset for evaluating the accuracy of systems at integrating new definitions as concepts into an ontology using WordNet 3.0 as a base resource. Five teams submitted 13 systems for participation, with all teams performing better than chance but only one team surpassing a simple baseline that leverages knowledge of the expected word order in a definition to guess the correct hypernym concept. Our results point towards significant opportunity for improving taxonomy enrichment. In future work, we intend to integrate the best insights of this task into the next version of CROWN,<sup>4</sup> an automatically constructed extension of WordNet with concepts from online glossaries and lexicographic resources.

## Abstract

SemEval 2016 Task 12 addresses temporal reasoning in the clinical domain. In this paper, we present our participation for relation extraction based on gold standard entities (subtasks DR and CR). We used a supervised approach comparing plain lexical features to word embeddings for temporal relation identification, and obtained above-median scores.

## 1 Introduction

SemEval 2016 Task 12 offers 6 subtasks addressing temporal reasoning in the clinical domain using the THYME corpus (Styler IV et al., 2014). This corpus provides annotated clinical and pathological notes from colon cancer patients. The first group of subtasks concerns the identification of time and event expressions within raw text. The second group of subtasks deals with the identification of temporal relations. The latter consists of two subtasks. In the *Document Creation Time Relation* subtask (DR), participants are challenged to identify relations between the events and the document creation time. For the *Container Relation* subtask (CR), participants have to identify container relations between entities. Participants may submit either a complete system extracting entities and relations or focus on either the entity extraction or relation extraction (using the gold standard entities provided by the organizers). More details about the task and the definition of each subtask can be found in Bethard et al. (2016).

In this paper, we present our submission for the CR and DR subtasks based on gold-standard entities (phase 2). Our global approach, which is illustrated in Figure 1, tackles the identification of temporal relations as a set of supervised classification tasks. We submitted two runs, one using plain lexical features and one using word embeddings computed on a large clinical corpus. We obtained scores well above the median scores in both subtasks.

The remainder of this paper is organized as follows. Section 2 presents our system for the DR subtask while Section 3 describes our system for the CR subtask. Section 4 gives an overview of the system implementation. Finally, Section 5 presents our results.

## 2 Document Creation Time Relation (DR) Subtask

We treated the subtask as a supervised classification problem where each EVENT entity was classified into four categories (*Before*, *Before-Overlap*, *Overlap*, *After*).

We extracted lexical, contextual and structural features from the texts. Regarding the lexical features of EVENT entities, we took their surface forms, their gold standard attributes (*type*, *modality*, *degree* and *polarity*), their lemma(s)<sup>1</sup>, as well as their Part-Of-Speech (POS) and Coarse Part-Of-Speech (CPOS) tags. We also extracted the semantic types

<sup>1</sup>The span of an EVENT entity can overlap with several tokens.

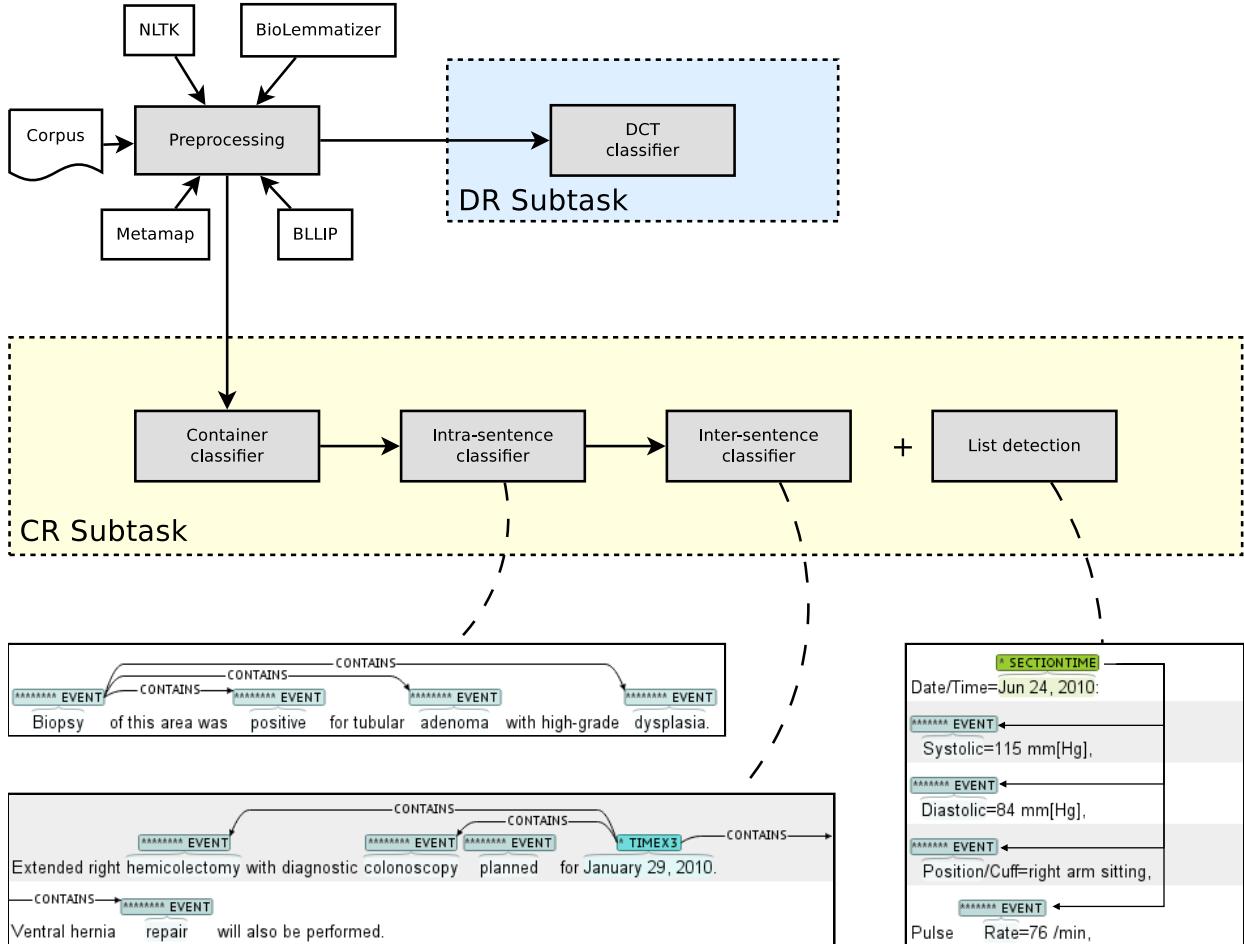

Figure 1: Overview of the processing chain

and semantic groups of the medical entities that have been detected by Metamap (Aronson and Lang, 2010) and that share a span overlap with the EVENT entities.

Concerning the contextual features, we extracted the gold standard entities that were present in the right and left contexts<sup>2</sup> within the sentence. We added the corresponding lemmas, surface forms, types, POS and CPOS tags, as well as the corresponding semantic groups and semantic types. We also added the lemmas of the tokens occurring in both left and right contexts. At the section level, we added entities occurring before and after the EVENT entity within the section. We used the same set of features as the one we used for the intra-sentence context: surface forms, lemmas, types, POS and CPOS tags, semantic types and semantic groups. We

also added the gold standard attributes of these entities.

Regarding the structural features, we used the position of the sentence within the section and the position of the section within the document. We added the number of tokens and entities occurring before and after the EVENT entity within the section, and the number of entities figuring before and after the EVENT entity at the document level.

### 3 Container Relation (CR) Subtask

#### 3.1 Principles

Similarly to the DR subtask, we treated the CR subtask as a supervised classification problem and more particularly, as a binary classification task applied to pairs of EVENT and/or TIME entities in documents. However, considering all possible pairs of such entities for building the training set without any scope

<sup>2</sup>There is no size restriction on the contexts

restriction would lead to unbalanced training examples where the negative examples largely outnumber the positive examples. Hence, some choices have been made to reduce the number of training examples.

The analysis of the training corpus shows that a large majority – around 76% – of the CONTAINS relations are intra-sentence relations, which means that the problem of their scope actually occur for one quarter only. The remaining relations, called inter-sentence relations, spread over at least two sentences. Given this context, we have built two separate classifiers, the first one for the intra-sentence relations, the second one for the inter-sentence relations. This distinction has two main advantages: first, it reduces drastically the number of negative examples, which produces better results as we observed on our development set; second, the intra-sentence classifier can benefit from a larger and richer set of features coming from sentence-level linguistic analyzers.

Concerning the inter-sentence relations, considering all pairs of EVENT and/or TIME entities would still give us a very large amount of negative examples. We first observed that all of them were contained within sections (no relation overlaps section boundaries). Within the scope of a section, we further noticed that inter-sentence relations within a 3-sentence window covered approximately 89% over all existing relations. A wider window would bring too much noise while giving us a very small bump on coverage. Table 1 shows the number of covered relations according to the size of the window, expressed in the number of sentences. The first line corresponds to the intra-sentence level (window=1).

To further reduce the number of candidates for both inter- and intra-sentence classifiers, we transformed the 2-category problem (*contains* vs. *no-relation*) into a 3-category classification problem (*contains*, *is-contained* or *no-relation*). Instead of considering all permutations of events within a sentence or a sentence-window, we considered all pairs of events from left to right, changing when necessary the *contains* relations into *is-contained* relations. This strategy allowed us to divide by a factor of two the number of candidates. We obtained 111,349 pairs for the intra-sentence classifier and 311,284 pairs for the inter-sentence classifier.

| win. <sup>a</sup> | nb. of rel. <sup>b</sup> | total <sup>c</sup> |
|-------------------|--------------------------|--------------------|
| 1                 | 13,304                   | 13,304 (76.30%)    |
| 2                 | 1,463                    | 14,767 (84.69%)    |
| 3                 | 752                      | 15,519 (89.00%)    |
| 4                 | 497                      | 16,016 (91.85%)    |
| 5                 | 364                      | 16,380 (93.94%)    |
| 6                 | 151                      | 16,531 (94.80%)    |

<sup>a</sup> Sentence window

<sup>b</sup> Number of CONTAINS relations

<sup>c</sup> Cumulative count of CONTAINS relations

**Table 1:** CONTAINS relations according to sentence window size. Window of size 1 corresponds to the intra-sentence level.

Some entities are more likely to be containers. By example, SECTIONTIME and TIMEX entities are, by nature, potential containers. This is also the case for some medical events. For instance, a *surgical operation* may contain other events such as *bleeding* or *suturing*. It will not be the same with the two latter in most cases. Following this observation, we have built a model to classify entities as being a potential *container* or *not*. As we will show in Section 5, this classifier obtain a high accuracy. We used its output as feature for our intra- and inter-sentence classifiers.

Finally, we developed a rule-based module to capture specific CONTAINS relations. There are some strong regularities in the handling of laboratory results where the first SECTIONTIME contains all the results, which are expressed with EVENT entities (see an example in Figure 1). The module we have built aims at capturing these inter-sentential regularities with the use of rules.

To summarize, our system is composed of four modules:

1. **Container detection module:** entities are classified according to whether or not they are the source of one or more CONTAINS relations;
2. **Intra-sentence relation module:** combinations of entities within sentences are considered (relations *contains*, *is-contained* or *no-relation*);
3. **Inter-sentence relation module:** combinations of entities within a 3-sentence window are

considered. We use the same relation classes as those used for intra-sentence relations;

4. **List detection module:** specific laboratory results written as lists are handled via manual rules.

### 3.2 Feature Extraction

For the container classifier, we used the form and the type of the considered entity, as well as its gold standard attributes. We extracted the semantic types and semantic groups of the entities that have been detected by Metamap and that share an overlap with the considered entity. We also extracted its lemma(s), POS and CPOS tags. Concerning the contextual features, we extracted the entities that are present in both left and right contexts within the sentence boundaries. Similarly to the DR subtask, we used entity forms, types, semantic groups and semantic types, POS and CPOS tags and lemmas. We also added the tokens from both left and right contexts. We used the corresponding lemmas, POS and CPOS tags. Finally, we added the number of entities within the sentence and the number of entities before and after the considered entity within the sentence.

For the intra-sentence classifier, we extracted the forms, semantic types and semantic groups, and the gold standard attributes of the two considered entities. We added their lemmas and their POS and CPOS tags. We added the number of tokens occurring between the two entities. We also extracted the entities occurring between the two considered entities. We used their entity types, gold standard attributes, semantic groups and semantic types. We added the number of entities that have been classified as containers by our container classification model and the number of entities that appear between the pair of entities. Finally, we added the syntactic paths<sup>3</sup> between the two entities (from left to right). We also added the results of our contain classification model for the two considered entities.

For the inter-sentence classifier, we used similar features. We extracted the forms, types, gold standard attributes and semantic groups and semantic types of the two considered entities. We also extracted features from the results of the intra-sentence

<sup>3</sup>Several paths are considered when the entities spread over more than one token.

classifier. We specified whether the considered entities are intra-sentence containers or are contained by other entities at the intra-sentence level. We also extracted entities that are positioned between the two considered entities. We used entity types, gold-standard attributes, semantic groups and semantic types. We also added a feature specifying if these entities are containers at the intra-sentence level and the number of entities between the considered pair of entities. Finally we added the positions, at the section level, of the sentences in which the considered events are embedded.

## 4 System Implementation

### 4.1 Strategies

We implemented two strategies to represent the lexical features in both the DR and CR subtasks. In the first one, we used the plain forms of the different lexical attributes we mentioned (Strategy 1). In the second strategy, we substituted the lemmas and forms with word embeddings (Strategy 2). These embeddings have been computed on the Mimic 2 corpus (Saeed et al., 2011) using the word2vec tool with a CBOW model<sup>4</sup> (Mikolov et al., 2013). We used the mean of the vectors for multi-word units. Lexical contexts are thus represented by 200-dimensional vectors. When several contexts are considered e.g. right and left, several vectors are used.

### 4.2 Algorithm Selection

A grid search strategy was applied to select the most appropriate machine learning algorithm and its parameters. For Strategy 1, three algorithms were considered in our search: Random Forests, Linear Support Vector Machine (liblinear) and Support Vector Machine with a RBF kernel (libsvm). For Strategy 2, we only considered the Linear Support Vector Machine for the CR task and Random Forests for the DR task.

In both cases, 5-fold cross-validation was used to choose the algorithm and its parameters. We also implemented statistical feature selection as part of the grid search for Strategy 1 reducing progressively the number of attributes, using ANOVA F-test.

<sup>4</sup>Parameters used during computation: min-count: 5; vector size: 200; window: 20; number of word classes: 1000; frequency threshold: 1e-3.

| Run            | Classifier | Algorithm      | Parameters   | % feat. <sup>a</sup> |
|----------------|------------|----------------|--|----------------------|

<sup>b</sup> Tolerance for stopping criteria

<sup>c</sup> Using plain text features

<sup>d</sup> Using word embeddings

**Table 2:** Machine learning algorithms and parameters used for the final submission

The machine learning algorithms used for the final submission are presented in Table 2 together with their parameters and the percentage of the feature space kept after statistical feature selection. We used the Scikit-learn machine learning library (Pedregosa et al., 2011) for both implementing our classification models and performing statistical feature selection.

### 4.3 Corpus Preprocessing

We applied a four-step preprocessing on the 440 texts that were provided for the subtasks. First, we used NLTK (Loper and Bird, 2002) to segment the texts into sentences with the *Punkt Sentence Tokenizer* pre-trained model for English provided within the framework.

The second step consisted of parsing the resulting sentences. For this task, we used the BLLIP Reranking Parser (Charniak and Johnson, 2005) and a pre-trained biomedical parsing model (McClosky, 2010).

In the third step, we lemmatized the corpus using BioLemmatizer (Liu et al., 2012), a tool built for processing the biomedical literature. We used the Part-Of-Speech tags from the previous step as parameters for the lemmatization.

The last step consisted in using Metamap (Aronson and Lang, 2010) to detect biomedical events and linking them, after disambiguation, to their related UMLS® (Unified Medical Language System) concept. We chose to keep biomedical entities that had a

span overlapping with at least one entity of the gold standard.

## 5 Results and Discussion

In Table 3, we present the cross-validation accuracies of our DCT and Container models over the development corpus. For DCT, we obtain high performance with Strategy 1, which is based on plain lexical features. Strategy 2, which exploits words embeddings, gives lower performance. Concerning the Container model, we obtain high performance with both strategies.

| Model     | plain text | word embeddings |
|-----------|------------|-----------------|
| DCT       | 0.873      | 0.778           |
| CONTAINER | 0.917      | 0.924           |

**Table 3:** DCT and CONTAINER model accuracies

We submitted two runs with our system, one for each strategy. The results for both subtasks are presented in Tables 4 and 5.

Concerning the DR subtask, we obtained above-median scores (median score: 0.724) for both runs. The second run, which relies on word embeddings to represent the lexical features of the EVENT entities, achieves better performance. These results are consistent with what was expected during the cross-validation process using the development set. The fact that the second strategy achieves the best performance is however in contradiction with the scores

obtained during cross-validation, where Strategy 1 performed best.

In the CR subtask, we obtained above-median F1 for the first run and median scores for the second run (median score: 0.449). Using plain lexical features gives us a more balanced system than using word embeddings. With a F1 of 0.538, our system achieves performance close to the best system (0.573), thus validating our modeling choices. These results are consistent with those we obtained when testing against the development part of the corpus. The reasons for the decrease in recall when using the second strategy are however unclear and need further investigation.

## Abstract

Two extensions to the AMR smatch scoring script are presented. The first extension combines the smatch scoring script with the C6.0 rule-based classifier to produce a human-readable report on the error patterns frequency observed in the scored AMR graphs. This first extension results in 4% gain over the state-of-art CAMR baseline parser by adding to it a manually crafted wrapper fixing the identified CAMR parser errors. The second extension combines a per-sentence smatch with an ensemble method for selecting the best AMR graph among the set of AMR graphs for the same sentence. This second modification automatically yields further 0.4% gain when applied to outputs of two nondeterministic AMR parsers: a CAMR+wrapper parser and a novel character-level neural translation AMR parser. For AMR parsing task the character-level neural translation attains surprising 7% gain over the carefully optimized word-level neural translation. Overall, we achieve smatch F1=62% on the SemEval-2016 official scoring set and F1=67% on the LDC2015E86 test set.

## 1 Introduction

Abstract Meaning Representation (AMR) (Banarrescu et al., 2013) initially was envisioned as an intermediate representation for semantic machine translation, but has found applications in other NLP fields such as information extraction.

For SemEval-2016 Task 8 on Meaning Representation Parsing we took a dual approach: besides developing our own neural AMR parser, we also extended the AMR smatch scoring tool (Cai and Knight, 2013) with a rule-based C6.0 classifier<sup>1</sup> to guide development of an accuracy-increasing wrapper for the state-of-art AMR parser CAMR (Wang et al., 2015a; 2015b). A minor gain was also achieved by combining these two approaches in an ensemble.

The paper starts with the description of our smatch extensions, followed by the description of our AMR parser and wrapper, and concludes with the results section evaluating the contributions of described techniques to our final SemEval result.

## 2 Smatch Extensions

We describe two extensions<sup>2</sup> to the original AMR smatch scoring script. These extensions do not change the smatch algorithm or scores produced, but they extract additional statistical information helpful for improving results of any AMR parser, as will be illustrated in Section 3.

### 2.1 Visual Smatch with C6.0 Classifier Rules

The original AMR smatch scoring metric produces as output only three numbers: precision, recall and F1. When developing an AMR parser, these three numbers alone do not reveal the actual mistakes in the AMR parser output (we call it *silver* AMR) when compared to the human-annotated *gold* AMR.

<sup>1</sup> Available at <http://c60.ailab.lv>

<sup>2</sup> Available at <https://github.com/didzis/smatchTools>

**Figure 1.** Visual smatch with Rules. Left pane shows the document content and statistics. Right pane shows single sentence gold AMR (left) and silver AMR (right) along with smatch aligned instance, attribute, relation AMR graph edges. The bottom pane shows C6.0 classifier generated rules describing the common error patterns found in the document.

The first step in alleviating this problem is visualizing the mappings produced by the smatch algorithm as part of the scoring process. Figure 1 shows such smatch alignment visualization where gold and silver AMR graphs are first split into the edges, which are further aligned through variable mapping. The smatch metric measures success of such alignment – perfect alignment results in F1 score 100% while incomplete alignment produces lower scores.

The visualization in Figure 1 is good for manual inspection of incomplete AMR alignments in individual sentences. But it still is only marginally helpful for AMR parser debugging, because the data-driven parsers are expected to make occasional mistakes due to the training data incompleteness rather than due to a bug in the parser.

Telling apart the repetitive parser bugs from the occasional training data incompleteness induced errors is not easy and to invoke the required statistical mechanisms we resorted to a rule-based C6.0 classifier (Barzdins et al., 2014; 2015), a modification of the legacy C4.5 classifier (Quinlan, 1993). The

classifier is asked to find most common patterns (rules) leading to some AMR graph edges to appear mostly in the gold, silver, or matched class after the smatch alignment. The bottom part of Figure 1 illustrates few such rules found by C6.0. For example, the second rule relates to the visualized sentence and should be read as “if the instance has type *mountainous*, then it appears 1 time in the gold graphs and 0 times in the silver graphs of the entire document”. Similarly the third rule should be read as “word *Foreign* appears 13 times as :op1 of name in the gold graphs, but only 1 time in the silver graphs of the entire document” – such 13 to 1 ratio likely points to some capitalization error in the parser pipeline. The generated rules can be sorted by their statistical impact score calculated as Laplace ratio  $(p+1)/(p+n+2)$  from the number of correct  $p$  and wrong  $n$  predictions made by this rule.

Classifier generated rules were the key instrument we used to create a bug-fixing wrapper for the CAMR parser, described in Section 3.1. We fixed only bugs triggering error-indicating-rules with the

impact scores above 0.8, because Laplace ratio strongly correlates with the smatch score impact of the particular error.

## 2.2 Smatch Extension for Ensemble Voting

The original smatch algorithm is designed to compare only two AMR documents. Meanwhile CAMR parser is slightly non-deterministic in the sense that it produces different AMRs for the same test sentence, if trained repeatedly. Randomly choosing one of the generated AMRs is a suboptimal strategy. A better strategy is to use an ensemble voting inspired approach: among all AMRs generated for the given test sentence, choose the AMR which achieves the highest average pairwise smatch score with all the other AMRs generated for the same test sentence. Intuitively it means that among the non-deterministic options we choose the “prevalent” AMR.

Multiple AMRs for the same test sentence can be generated also from different AMR parsers with substantially different average smatch accuracy. In this case all AMRs still can participate in the scoring, but weights need to be assigned to ensure that only AMRs from the high-accuracy parser may win.

## 3 AMR Parsers

We applied the smatch extensions described in the previous Section to two very different AMR parsers.

### 3.1 CAMR Parser with Wrapper

We applied the debugging techniques from Section 2.1 to the best available open-source AMR parser CAMR<sup>3</sup>. The identified bug-fixes were almost entirely implemented as a CAMR parser wrapper<sup>4</sup>, that runs extra pre-processing (normalization) step on input data and extra post-processing step on output data. Only minor modifications to CAMR code itself were made<sup>5</sup> to improve the performance on multi-core systems and to fix date normalization problems.

Our CAMR wrapper tries to normalize the input data to the format recognized well by CAMR and to fix some systematic discrepancies of annotation style between the actual CAMR output and the expected gold AMRs. The overall gain from our wrapper is about 4%.

<sup>3</sup> <https://github.com/Juicechuan/AMRParsing>

<sup>4</sup> [https://github.com/didzis/CAMR/tree\(wrapper](https://github.com/didzis/CAMR/tree(wrapper)

The following normalization actions are taken during pre-processing step, together accounting for about 2% gain:

1. number normalization from a lexical (e.g. “seventy-eight”), semi-lexical (e.g. “5 million”) or multi-token digital (e.g. “100,000” or “100 000”) format to a single token digital format (e.g. “100000”);
2. currency normalization from a number (any format mentioned in previous step) together with a currency symbol (e.g. “\$ 100”) to a single token digital number with the lexical currency name (e.g. “100 dollars”);
3. date normalization from any number and lexical mix to an explicit eight-digit dash separated format “yyyy-mm-dd”.

Small modifications had to be made to the baseline JAMR (Flanigan et al., 2014) aligner used by CAMR to reliably recognize the “yyyy-mm-dd” date format and to correctly align the date tokens to the graph entries (by default JAMR uses “yymmdd” date format that is ambiguous regarding century and furthermore can be misinterpreted as a number).

The rules for date normalization were extracted from the training set semi-automatically using C6.0 classifier by mapping date-entities in the gold AMR graphs and corresponding fragments in input sentences.

Additionally, all wiki edges were removed from the AMR graphs prior to training, because CAMR does not handle them well; this step ensures that CAMR is trained without wiki edges and therefore will not insert any wiki entries in the generated AMR. Instead, we insert wiki links deterministically during the post-processing step.

During post-processing step the following modifications are applied to the CAMR parser generated AMR graphs, together accounting for about 2% gain:

1. nationalities are normalized (e.g. “Italian” to “Italy”);
2. some redundant graph leafs not carrying any semantic value are removed (e.g. “null-edge”);
3. wiki links are inserted deterministically next to “name” edges using gazetteer extracted from the training data and extended with the complete list of countries and nationalities (wiki value is selected

<sup>5</sup> Modified CAMR at <https://github.com/didzis/CAMR>

based on the parent concept and content of the “name” instance);

About 1% additional gain comes from the observation that CAMR parser suffers from overfitting: it achieves optimal results when trained for only 2 iterations and with empty validation set.

### 3.2 Neural AMR Parser

For neural translation based AMR parsing we used simplified AMRs without wiki links and variables. Prior to deleting variables, AMR graphs were converted into trees by duplicating the co-referring nodes. Such AMR simplification turned out to be nearly loss-less, as a simple co-reference resolving script restores the variables with average F1=0.98 smatch accuracy.

We trained a modified TensorFlow seq2seq neural translation model<sup>6</sup> with attention (Abadi et al., 2015; Sutskever et al., 2014; Bahdanau et al., 2015) to “translate” plain English sentences into simplified AMRs. For the test sentence in Figure 1 it gives following parsing result:

```
(mountain-01
 :ARG1 (country
 :name (name :op1 "Georgia")))
```

Apart from a missing bracket this is a valid (although slightly incorrect) simplified AMR. Note that this translation has been learned in “closed task” and “end-to-end” manner only from the provided AMR training set without any external knowledge source. This explains overall lower accuracy of the neural AMR parser compared to CAMR, which uses external knowledge from wide coverage parsing models of BLLIP<sup>7</sup> parser (Charniak and Johnson, 2005). The neural AMR parser accuracy is close to CAMR accuracy for short sentences up to 100 characters, but degrades considerably for longer sentences.

We optimized TensorFlow seq2seq model hyperparameters within the constraints of the available GPU memory: 1 layer or 400 neurons, single bucket of size 480, each input and output character tokenized as a single “word”, vocabulary size 120 (number of distinct characters), batch size 4, trained for 30 epochs (4 days on TitanX GPU).

Operating seq2seq model on the character-level (Karpathy, 2015; Chung et al., 2016; Luong et al., 2016) rather than standard word-level improved smatch F1 by notable 7%. Follow-up tests (Barzdzins

| Parser   | F1 on LDC2015E86 test set | F1 on the official eval set |
|--|---------------------------|-----------------------------|
| JAMR (baseline)  | 0.576                     |                             |
| CAMR (baseline)  | 0.617                     |                             |
| CAMR (no valid.set, 2 iter.)                               | 0.630                     |                             |
| Neural AMR (word-level)                                    | 0.365                     |                             |
| Neural AMR (char-level)                                    | 0.433                     | 0.376                       |
| CAMR+ wrapper  | 0.667                     | 0.616                       |
| Ensemble of<br>CAMR+ wrapper<br>and NeuralAMR (char-level) | 0.672                     | <b>0.620</b>                |

**Table 1:** Smatch scores.

et al., 2016) revealed that character-level translation with attention improves results only if the output is a syntactic variation of the input (as is the case for AMR parsing), but for e.g. English-Latvian translation gives inferior results due to attention mechanism failing to establish character-level mappings between the English and Latvian words.

## 4 Results

Table 1 shows smatch scores for various combinations of parsers and thus quantifies the contributions of all methods described in this paper. We improved upon CAMR rather than JAMR parser due to better baseline performance of CAMR, likely due to its reliance on the wide coverage BLLIP parser.

The CAMR parser wrapper (result of Sections 2.1 and 3.1) is the largest contributor to our results. The weighed ensemble of 3 runs of CAMR+wrapper and 1 run of neural AMR parser (Sections 2.2 and 3.2) gave an additional boost to the results. Including the neural AMR parser in the ensemble doubled the gain – apparently it acted as an efficient tiebreaker between the similar CAMR+wrapper outputs.

## 5 Conclusions

Although our results are based on CAMR parser, the described debugging and ensemble approaches are likely applicable also to other AMR parsers.

# DynamicPower at SemEval-2016 Task 8: Processing syntactic parse trees with a Dynamic Semantics core

Alastair Butler

National Institute for Japanese Language and Linguistics

ajb129@hotmail.com

## Abstract

This is a system description paper for a submission to Task 8 of SemEval-2016: Meaning Representation Parsing. No use was made of the training data provided by the task. Instead existing components were combined to form a pipeline able to take raw sentences as input and output meaning representations. Components are a part-of-speech tagger and parser trained on the Penn Parsed Corpus of Modern British English to produce syntactic parse trees, a semantic role labeller and a named entity recogniser to supplement obtained parse trees with word sense, functional and named entity information, followed by an adapted Tarskian satisfaction relation for a Dynamic Semantics that is used to transform a syntactic parse into a predicate logic based meaning representation, followed by conversion to penman/AMR notation required for the task appraisal.

## 1 Introduction

This is a system description paper for a submission to Task 8 of SemEval-2016: Meaning Representation Parsing. Syntactic structures are first obtained by parsing raw language input, from which meaning representations are derived by printing off information accumulated with an adapted Tarskian satisfaction relation for a Dynamic Semantics (Dekker, 2012). This is akin to compositional approaches of formal semantics that view the task of reaching a semantic value as being rooted in first obtaining a syntactic parse. Key advantages are modularity and domain independence.

This paper is structured as follows. Section 2 sketches the method used to obtain a syntactic parse. Section 3 covers reaching a semantic representation. Section 4 outlines conversion to penman/AMR notation. Section 5 reports experiment results. Section 6 is a conclusion. An appendix details how to run the available implementation.

## 2 Obtaining a syntactic parse

The approach first needs a way to obtain syntactic parse trees. Major components used were the Stanford Log-linear Part-Of-Speech Tagger<sup>1</sup> (Toutanova et al., 2003) and the Berkeley Parser<sup>2</sup> (Petrov and Klein, 2003), both trained on data from the years of 1840–1908 of the Penn Parsed Corpus of Modern British English<sup>3</sup> (Kroch et al., 2010). The particular setup followed suggestions of pre-processing and post-processing made by Kulick et al. (2014) and used tools, notably `create_stripped`, from the system of Fang, Butler and Yoshimoto (2014).<sup>4</sup>

Dating from over one hundred years ago, training data for the syntactic parser was not chosen for suitability to a potential task domain, but instead for the practical benefit that parse results would conform to the scheme proposed in the *Annotation manual for the Penn Historical Corpora and the Parsed Corpus of Early English Correspondence (PCEEC)* (Santorini, 2010). This scheme is exceptionally consistent, especially with regards to facilitating identi-

<sup>1</sup><http://nlp.stanford.edu/software/tagger.html>

<sup>2</sup><https://github.com/slavpetrov/berkeleyparser>

<sup>3</sup><http://www.ling.upenn.edu/hist-corpora/PPCMBE-RELEASE-1/index.html>

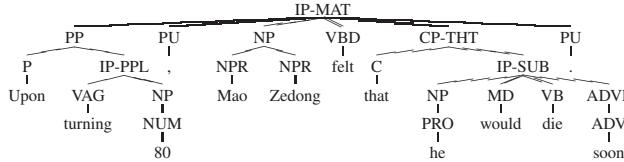

<sup>4</sup><http://www.compling.jp/haruniwa/index.html>

fication of construction types (small clause, comparative, cleft, etc.) and for its handling of coordination, offering the least obstacle for a robust conversion to the structures fed to the semantic component (seen in the next section).

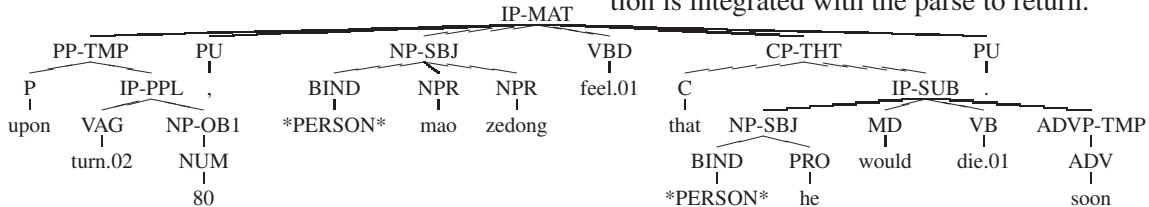

As an example, consider:

- (1) Upon turning 80, Mao Zedong felt that he would die soon.

A parse in tree form returned looks like:

All words are part-of-speech labelled. Clause structure is generally flat with multiply branching nodes and no specified VP level, except with VP coordination. Phrasal nodes (NP, PP, ADVP, etc.) immediately dominate the phrase head (N, P, ADV, etc.) which has as sisters both modifiers and complements.

Despite such flat clause and phrase structure, extended phrase labels marking function enable distinguishing the presence of modifiers (participial clauses (IP-PPL), adverbial clauses (CP-ADV), relative clauses (CP-REL), etc.) from complements (infinitive complements (IP-INF), that-complements (CP-THT), embedded questions (CP-QUE), etc.).

To arrive at a more complete parse for the task, word sense and functional information was obtained with mateplus<sup>5</sup> (Roth and Woodsend, 2014), which is an extended version of the mate-tools semantic role labeller (Björkelund et al., 2009). In addition, named entity information was gathered with the Stanford Named Entity Recognizer<sup>6</sup> (Finkel et al., 2005) using the MUC model that labels e.g., PERSON, ORGANIZATION, and LOCATION. Furthermore, pronouns, e.g., *he*, *she*, *they*, are default

marked PERSON. From (1) as input, the combination of these tools collects the following information:

|        |      |         |        |
|--------|------|---------|--------|
| upon   | TMP  | -       | O      |
| turn   | PMOD | turn.02 | O      |
| 80     | OBJ  | -       | O      |
| ,      | P    | -       | O      |
| mao    | NAME | -       | PERSON |
| zedong | SBJ  | -       | PERSON |
| felt   | ROOT | feel.01 | O      |
| that   | OBJ  | -       | O      |
| he     | SBJ  | -       | PERSON |
| would  | SUB  | -       | O      |
| die    | VC   | die.01  | O      |
| soon   | TMP  | -       | O      |
| .      | P    | -       | O      |

The first column gives word lemmas, the second contains functional information to identify syntactic subjects (SBJ) and objects (OBJ) as well as adjunct roles such as LOC, MSR and TMP, the third column provides word sense information related to PropBank (Bonial et al., 2010) semantic frames ('turn.02', 'feel.02', 'die.01'), and the fourth column provides entity information. This column information is integrated with the parse to return:

The tree now includes extended phrase labels marking function (e.g., NP-SBJ=subject, NP-OB1=direct object, ADVP-TMP=temporal modifier). Terminal nodes are either word lemmas or, whenever available, PropBank word senses. Furthermore entity information is integrated with a BIND tag.

### 3 Obtaining semantic analysis

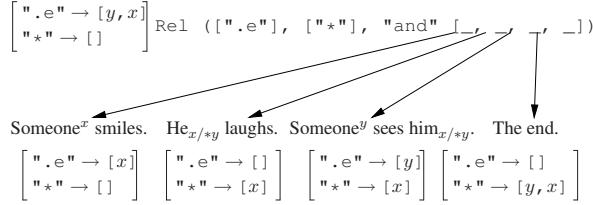

Having syntactic structures, the next step is to reach a level of semantic analysis. This is derived by printing off information accumulated with an adapted Tarskian satisfaction relation for a Dynamic Semantics (Dekker, 2012). Specifically, use is made of the Treebank Semantics implementation,<sup>7</sup> with syntactic structures converted into expressions of a formal language (Scope Control Theory or SCT) with a number of primitive operations (notably, among

<sup>5</sup><https://github.com/microth/mateplus>

<sup>6</sup><http://nlp.stanford.edu/software/CRF-NER.html>

<sup>7</sup><http://www.compling.jp/ts>

others: `Namely` to make available fresh bindings, `T` to create bound arguments, `At` to allocate semantic roles, `Close` to bring about quantificational closures, `Rel` to establish predicate or connective relations, and `If` to conditionalise how calculation of a semantic value proceeds based on assignment state). The full list of operations and details are given in Butler (2015). Operations access or possibly alter a sequence based information state (Vermeulen, 2000) that retains binding information by assigning (possibly empty) sequences of values to binding names. This can be demonstrated with `Rel` creating an "and" relation with four arguments, each of which are processed against a different assignment state determined by instances of `Namely` embedded in occurrences of *Someone*:

Pronouns are able to link to "`*`" bindings, which are accessible bindings that have reached the discourse context because of prior indefinites, while indefinites take bindings from "`.e`", which is a source for fresh bindings. This approach gives a handle on discourse, and more generally governs the interaction of quantification to capture the empirical results of accessibility from Discourse Representation Theory (Kamp and Reyle, 1993), as well as intra-sentential binding conditions (Butler, 2010).

Regarding the running example, the tree for (1) is converted to the following:

```
val ex1 =
( fn fh =>
  ( fn lc =>
    ( npr "PERSON" "mao_zedong" "ARG0"
      ( ( someFact fh ( gensym "TIME") ".e" "FACT"
        ( control lc
          ( ( fn lc =>
            ( some lc fh ( gensym "ENTITY") ".e"
              ( someClassic lc fh ( gensym "ATTRIB") ".e" nil
                ( adj lc "80") "CARDINAL"
                ( nn lc "") ) "ARG1"
              ( verb lc ( gensym "EVENT") ".event" ["ARG1"] "turn.02"))
            [ "CARDINAL", "ARG1", "ARG0", "h"])) ) "TMP"
      ( past ".event"
        ( embVerb lc ( gensym "EVENT") ".event" ["TMP", "ARG0"] "feel.01"
          ( THAT lc
            ( ( fn lc =>
              ( pro [".*"] fh ["PERSON"] ( gensym "PERSON") ".e" "he" "ARG0"
                ( md fh "would" free
                  ( advp lc fh ".event"
                    ( adv lc "TMP_soon")
                    ( verb lc ( gensym "EVENT") ".event" ["ARG0"] "die.01")))))
              [ "FACT", "ARG0", "ARG1", "h"]))
            [ "@e", ".e", ".event"]
          )
        )
      )
    )
  )
)
```

Such an expression is built exploiting the input syntactic structure by locating any complement for the phrase head to scope over, and adding modifiers with scope over the head. During construction information about binding names is gathered and integrated at clause levels with `fn fh =>` and `fn lc =>` acting as lambda abstractions.

With conversion to `ex1`, part of speech tags transform to operations (`some` (indefinite), `nn` (noun predicate), `verb` (predicate with an event argument), `pro` (pronoun), `gensym` (trigger to create a fresh binding), `free` (ensures no quantificational closure), etc.). Also, constructions can bring about the inclusion of operations (e.g., `someFact` with the participial clause, and `THAT` with the that-complement). Conversion also adds (i) information about local binding names (e.g., "`ARG0`" (logical subject role) and "`ARG1`" (logical object role)) and (ii) information about sources for fresh bindings from quantificational closures ("`@e`", "`.e`" and "`.event`"). Once built `ex1` reduces to primitives of the SCT language, the start of which is as follows:

```
Sct.Close ("∃", ["@e", ".e", ".event"],
Sct.Clean (0, ["ARG0"], "*",
Sct.Namely (Lang.C ("mao_zedong", "PERSON"), "@e",
Sct.Lam ("@e", "ARG0",
Sct.Clean (0, ["TMP"], "*",
Sct.QuantThrow (Lang.X (1, "TIME"), ".e",
Sct.Lam ("e", "TMP",
Sct.Rel ([["@e", ".e", ".event"], ["*", "*", "*"], "", [
Sct.Throw ("e",
Sct.Rel ([]), [], "FACT", [Sct.At (Sct.T ("TMP", 0), "FACT"),
Sct.At (
Sct.Lam ("TMP", "",
Sct.Clean (0, ["ARG1", "LGS", "ARG2"], "ARG0",
Sct.Clean (0, ["TMP", "ARG1", "h"], "*",
Sct.If (fn,
Sct.Clean (0, ["ARG1", "LGS", "ARG2"], "ARG0",
Sct.Clean (0, ["TMP", "ARG1", "h"], "*",
...)
```

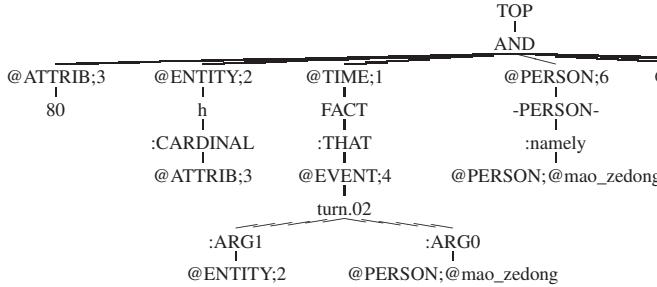

Such an expression is given to the adapted Tarskian satisfaction procedure which, instead of returning a semantic value (e.g., `true` or `false` with respect to a model), is used to produce a meaning representation by printing accumulated information, thus:

```
∃ PERSON[6] ATTRIB[3] TIME[1] EVENT[4] EVENT[7]
  EVENT[5] ENTITY[2] (
  80 (ATTRIB[3]) ∧ is_CARDINAL(ENTITY[2], ATTRIB[3]) ∧
  is_FACT_THAT(TIME[1],
    turn.02(EVENT[4], PERSON[mao_zedong], ENTITY[2])) ∧
  PERSON[6] = he{PERSON[mao_zedong]} ∧
  TMP_soon(EVENT[7]) ∧ past(EVENT[5]) ∧
  feel.01(EVENT[5], PERSON[mao_zedong]),
  MD_would(die.01(EVENT[7], PERSON[6]))) ∧
  is_contained_in(TMP(EVENT[5]), TIME[1]))
```

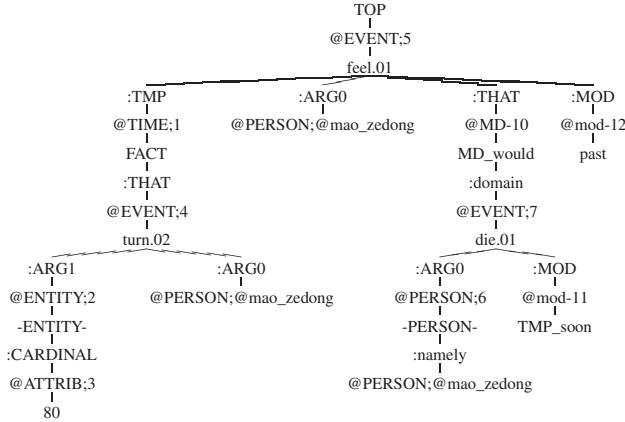

This gives a Davidsonian representation (Davidson, 1967) in which verbs are encoded with minimally an event argument. All bindings are existentially quantified over at the highest level, which is a convenience for reaching penman/AMR notation and not an approach limitation. Also note the pronoun is resolved to the only accessible PERSON antecedent.

#### 4 Conversion to penman/AMR notation

Conversion to penman/AMR notation (Matthiessen and Bateman, 1991; Banarescu et al., 2015) involves transforming obtained semantic structures into trees with explicit argument role information. An argument of each predicate (e.g., ‘@EVENT’ if present, or the sole argument of a one-place predicate) is made the parent of the predicate. Also, binding is made implicit with the removal of quantification levels. Thus, the running example becomes:

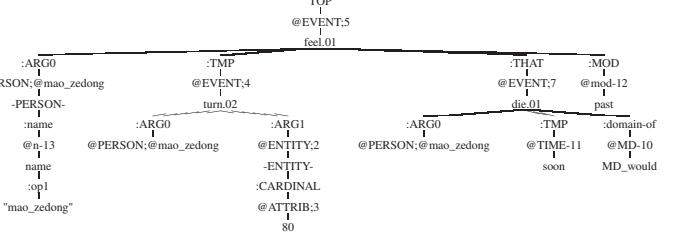

Content is further re-packaged: a daughter D of an AND level is moved inside a sister S when the argument name at the root of D is contained as an argument within S. Movement is to only one location.

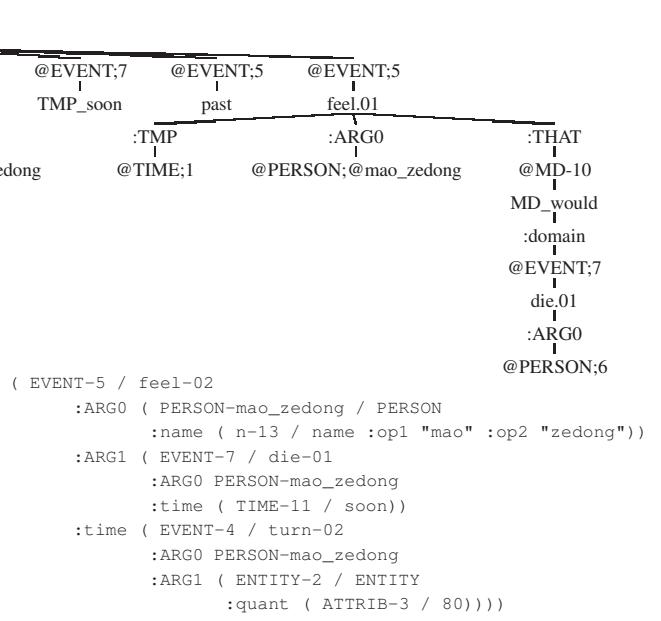

In addition, flatter structures are arrived at by excising redundant linking information, e.g., @TIME;1 FACT :THAT and folding tree material around inverse roles (signalled by ending the role name with

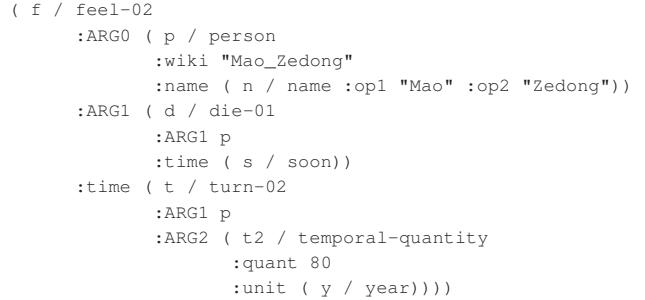

‘-of’). The latter is seen with the modal (*would*), but also serves to compact long distance dependencies that arise with relative clauses, comparatives, clefts, etc. There is also expansion of name information and some reordering of role placement.

The final step involves pretty printing the assembled tree into the penman/AMR format, as well as the removal of tense information and remapping role names, e.g., :THAT changes to :ARG1, :TMP to :time, :ON to :prep-on, :CARDINAL to :quant, :ATTRIBUTE to :mod, and :POS to :poss.

For comparison, the gold analysis from the task training data for the running example is as follows:

**Table 1:** Parsing results on the evaluation data of SemEval-2016 Task 8 and test data of LDC2015E86

|             | Precision | Recall | F-score |
|-------------|-----------|--------|---------|
| Task 8 eval | -         | -      | 0.47    |
| Test        | 0.37      | 0.39   | 0.38    |

It can be seen that gaps remain. In particular, there is no wikification to ground terms, and there is a lack of named entity information. Establishment of arguments as well as multiple roles for the same entity is largely successful, although there are mismatches with `die-01` and `turn-02`, reflecting that the semantic analysis stage lacks information for how PropBank roles for arguments should be allocated.

## 5 Experiments

The method of this paper is evaluated on the shared task evaluation data, which includes 1053 sentences. The smatch score on the evaluation data is 0.47. Table 1 also reports smatch score on the LDC2015E86 dataset, which includes 1371 test sentences. The scores are calculated with Smatch v2.0.2 (Cai and Knight, 2013), which evaluates the precision, recall, and *F1* of the concepts and relations all together. The score for Task 8 is higher than the performance on the LDC2015E86 test data. Reasons for the difference include parser performance being better on the evaluate data, and there being fewer non-compositional aspects of representation in the evaluate data.

## 6 Conclusion

To sum up, this paper has described a modularised approach for building meaning representations, with a key role for an adapted Tarskian satisfaction relation for a Dynamic Semantics as the method to integrate and connect information sourced from a syntactic parser, semantic role labeller and named entity recogniser. Task performance was limited by not using the training data provided by the task, in particular: lacking information to allocate PropBank roles, neglecting wikification, and missing entity information to replicate non-compositional aspects of the Abstract Meaning Representation (AMR) specification (Banarescu et al., 2015). Nevertheless,

this contribution indicates that AMRs are not far removed from what a compositional semantics can achieve, which is of interest for connecting to results from the formal semantics literature, such as gaining a treatment for quantification, as well as for relating to “Sembank” resources built with Discourse Representation Theory/Dynamic Semantics, such as the Groningen Meaning Bank<sup>8</sup> (Basile et al., 2012) and Treebank Semantics Corpus<sup>9</sup> (Butler and Yoshimoto, 2012).

## Appendix: Implementation<sup>10</sup>

Assuming `text` is some original (multi-)sentence segmented data, `text.psd` contains the output from a parser trained on the PPCMME, `text.mate` is output from mateplus, and `text.ner` is output from the Stanford Named Entity Recognizer, the following pipeline creates fully parsed data as described in section 2.

```
cat text.psd | add_functional text.mate |
add_sense text.mate | add_tsv_ner text.ner |
add_lemma text.mate | tree_select_word_2
> fullparse.psd
```

A script to recover the potentially multiple sentence segmentation of `text` obscured by parsing is achieved thus:

```
cat fullparse.psd | parse_discourse_split
text > segment.sh
```

The following pipeline achieves the semantic analysis of section 3, as well as the conversion to penman/AMR notation of section 4.

```
cat fullparse.psd | prepare_PPCMME |
segment.sh | parse_normalize -propbank
-free -bind | see_sct -free -reset |
run_sct -penman | penman_like_amr |
pretty_penman
```

## Abstract

This paper describes our contribution to the SemEval 2016 Workshop. We participated in the Shared Task 8 on Meaning Representation parsing using a transition-based approach, which builds upon the system of Wang et al. (2015a) and Wang et al. (2015b), with additions that utilize a Feedforward Neural Network classifier and an enriched feature set. We observed that exploiting Neural Networks in Abstract Meaning Representation parsing is challenging and we could not benefit from it, while the feature enhancements yielded an improved performance over the baseline model.

## 1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013; Dorr et al., 1998) is a semantic formalism which represents sentence meaning in a form of a rooted directed acyclic graph. AMR graph nodes represent concepts, labelled directed edges between the nodes show the relationships between concepts. The AMR formalism was created in order to explore the semantics behind natural language units for further analysis and application in various tasks.

At the time of writing this paper two AMR parsers are publicly available: graph-based JAMR (Flanigan et al., 2014) and transition-based CAMR (Wang et al., 2015a; Wang et al., 2015b). The latter has served as our baseline model, which we tried to improve by incorporating additional features defined for a wider conditioning context and a neural network (NN) classifier.

Inspired by the results of Chen and Manning (2014) and Weiss et al. (2015), who obtained state-of-the-art results in transition-based dependency parsing using Feedforward Neural Networks (FFNN), and taking into account the transition nature of the CAMR model, we performed a series of experiments in the same direction. Neural networks have been successfully applied to many NLP fields and we were curious to examine their potential in the task of AMR parsing. Specifically, we investigated the possibility of constraining the averaged perceptron algorithm (Collins, 2002) predictions by those of an FFNN at the initial step of the inference process.

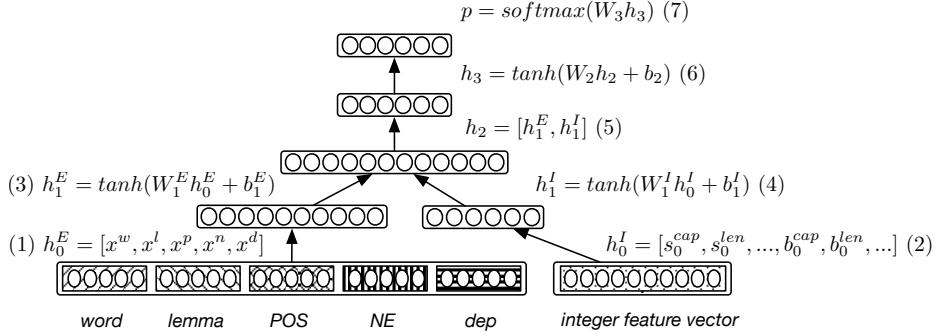

## 2 Preprocessing

We used the Stanford CoreNLP v3.6.0 toolkit (Manning et al., 2014) to get named entity (NE) and dependency information, the latter in the form of Stanford dependencies was obtained from the NN dependency parser (Chen and Manning, 2014).

We used a publicly available semantic role labelling (SRL) system with a predicate disambiguation module (Björkelund et al., 2009). The system is a part of MATE tools<sup>1</sup>, which also include a lemmatizer, a part of speech (POS) tagger, and a dependency parser. We use them to obtain lemmas and POS tags. All the tools were used with the pretrained models.

Using MALT dependencies instead of or in tandem with Stanford dependencies did not change the

<sup>1</sup><https://storage.googleapis.com/google-code-archive-downloads/v2/code.google.com/mate-tools>

**Figure 1:** Schematic view of our NN model.

overall performance of the AMR parser. Due to time limitations, we did not perform a full analysis of the accuracy of both tools, which would be an interesting and important point to investigate further.

All information extracted after the preprocessing step was combined into one CoNLL-format file (Hajič et al., 2009). Finally, we used an AMR graph-to-sentence aligner of Flanigan et al. (2014) to map word spans to concept fragments in the AMR graph.

### 3 Parsing Algorithm

We use the same set of transitions and a parsing algorithm as Wang et al. (2015b). We skip the full description due to space limitations and refer to the original paper. It forms a quadruple  $Q = (S, T, s_0, S_t)$ , where  $S$  is a set of parsing states (or configurations),  $T$  is a set of parsing transitions (or actions),  $s_0$  is the initial state and  $S_t$  is a set of terminal states of the parser. Each state is a triple  $(\sigma, \beta, G)$ , where  $\sigma$  denotes a stack, storing indices of the nodes which have not been processed yet; its top element is  $\sigma_0$ .  $\beta$  is a buffer, storing the children of  $\sigma_0$ . Finally,  $G$  is a partially built AMR graph aligned with the sentence tokens.

At the beginning of the parsing procedure,  $\sigma$  is initialized with a post-order traversal of the input dependency tree with topmost element  $\sigma_0$ ;  $\beta$  is initialized with  $\sigma_0$ 's children or set to null if  $\sigma_0$  is a leaf node.  $G$  is initialized with the nodes and edges of the dependency tree, but all node and edge labels are set to null. The parser processes all nodes and their outgoing edges in the tree in a bottom-up left-right manner, applying some transition to the current node or edge. Parsing terminates when both  $\sigma$  and  $\beta$  are empty.

There are nine basic transitions (*NEXT-EDGE*, *SWAP*, *REATTACH*, *REPLACE-HEAD*, *REENTRANCE*, *MERGE*, *NEXT-NODE*, *DELETE-NODE*, *INFER*), some of which result in assigning either a concept label or an edge label. The sets of concept labels for aligned nodes, unaligned nodes and edge labels ( $S_{aligned\_tag}$ ,  $S_{unaligned\_tag}$ ,  $S_{edge}$ , respectively) are constructed during the preprocessing stage and are later used to provide candidate concept tags or edge labels for the respective transitions. Let's also introduce a set  $S_{total} = S_{aligned\_tag} \cup S_{unaligned\_tag} \cup S_{edge}$ .  $|S_{total}|$  determines the number of classes for our classification algorithm to choose from.

We propose a parsing strategy which first uses an NN classifier to constrain the space of candidate transitions by choosing an unlabelled version of a transition, and then forces the perceptron algorithm to make a prediction only on the label of the chosen transition. We have also tried to completely substitute the averaged perceptron algorithm with an NN, experimenting with various types and architectures of the latter, but experimental results were unsatisfactory. This question is yet to be analysed in full, but presumably we failed to provide our NN classifiers with a sufficiently rich input representation: we used a very simple technique of concatenating embedding vectors (Section 4), which apparently did not capture enough information for an NN to make accurate predictions.

### 4 Neural Network Architecture

During preprocessing, we create a vocabulary  $V$  which stores all unique words, lemmas, POS tags, NE tags and dependency labels from the training set.

| Perceptron model features  |   |
|--|---|
| Singular features  | Feature combination   |
| $\{\sigma_0, \beta_0, \beta_0^{\text{head}+}\}, \{w, l, n, p, d, brown4, brown6, brown10, brown20\}$   | $\{\sigma_0.w, \sigma_0.l, \sigma_0.p, \sigma_0.n, \sigma_0.d, \sigma_0.len\} + t.tag$  |

**Table 1:** Feature sets.  $\sigma_0^{\text{head}}$  is the head of  $\sigma_0$  in the dependency tree;  $\beta_0^{\text{head}+}$  is the node, to which  $\beta_0$  could be attached to as a result of either reentrance or reattachment transition;  $t$  is a transition under consideration – during feature extraction we consider the tag which might be assigned as a result of transition ( $t.tag$ ) or whether this candidate is a verb sense tag ( $t.tag_{is.verb}$ ). The *isnom* feature checks whether the lemma of a corresponding element is in the NomBank dictionary. *nech* is the number of an element’s children which have an NE label from the set {“PERSON”, “LOCATION”, “ORGANIZATION”, “MISC”}. Other features are self-explanatory.

Each of them is mapped to the same  $D$ -dimensional vector space ( $e_i^w, e_i^l, e_i^p, e_i^n, e_i^d \in \mathbb{R}^D$ ). We create one embedding matrix  $E \in \mathbb{R}^{|V| \times D}$ , where  $|V|$  is the total size of the vocabulary and  $D$  is the dimensionality of dense embedding vectors.

In each parsing configuration we consider a set of elements which might be useful in the prediction task. These elements are  $\sigma_0, \beta_0$  and their neighbouring nodes, which for  $\sigma_0$  include  $\sigma_0^p$  (the parent of  $\sigma_0$  in the dependency tree),  $\sigma_0^{lsb}$  (the left sibling),  $\sigma_0^{rsb}, \sigma_0^{rsb2}$  (the first and the second right siblings),  $\sigma_0^{prsl}, \sigma_0^{prs2}$  (the first and the second previous tokens in the sentence); neighbouring nodes for  $\beta_0$  are defined in a similar manner. Thus, the total number of relevant elements is  $n_{elem} = 14$ .

The overall architecture of the network is depicted in Figure 1. The input layer of the network consists of two components. The first one is formed by concatenating all the corresponding embedding vectors for each element’s feature (Figure 1 (1)). Each of the  $x$  components is, in turn, a concatenation of the embeddings of the configuration elements for a particular type of annotation. For example,  $x^w$  is an  $\mathbb{R}^N$  vector, where  $N = d \times n_{elem}$ . We form  $x^l, x^p, x^n, x^d$  in a similar manner and concatenate  $x^w, x^l, x^p, x^n, x^d$  to form the input vector  $h_0^E$ . The second component of the input vector is  $h_0^I$  (Figure 1 (2)), a concatenation of vectors, representing non-embedding numerical features (see Table 1).

We separately map two parts of the input layer to hidden layers using the *tanh* activation function:  $h_0^E$  to  $h_1^E$ ,  $h_0^I$  to  $h_1^I$  (Figure 1 (3) and (4)). We then con-

catenate layers  $h_1^E$  and  $h_1^I$  (Figure 1 (5)) and pass the resultant vector to the last hidden layer  $h_3$ , applying the *tanh* function again (Figure 1 (6)). Finally, a softmax layer is added on top of  $h_3$  in order to calculate probabilities of the output classes (Figure 1 (7)).

## 5 Feature Sets

We have designed two separate feature sets for the NN and perceptron classifiers. The feature set for the latter is roughly the same as in (Wang et al., 2015b) (Table 1). Following the authors of CAMR, we also make use of the NomBank 1.0 dictionary (Meyers et al., 2004)<sup>2</sup>. Unfortunately, we could not obtain the copy of the same SRL system which was used by the authors. Therefore, we also measure accuracy improvement from incorporating the semantic features defined in the original paper but extracted after processing the data with a different SRL system (marked with a \*).

We also measure the improvement from incorporating the features extracted from a wider configuration context – they were not included into the baseline model and are marked with a •.

In the case of the NN classifier we follow a standard feature extraction procedure and discard transition-specific features. Apart from the embedding features, we also include a number of numerical features, which proved to be useful in our exper-

<sup>2</sup><http://nlp.cs.nyu.edu/meyers/NomBank.html>

iments.

## 6 Training Procedure and Parsing Policy

We trained the perceptron with a weight-averaging procedure, described in (Collins, 2002).

For the NN classifier we first prepared a training set  $\{(x_i, y_i)\}_{i=1}^n$ , where  $x_i$  denotes a feature representation of configuration  $i$  and  $y_i$  is the unlabelled version of the correct transition. The training objective is to minimize L2-regularized negative log-likelihood of the model:

$$L(\theta) = - \sum_{i=1}^n \log P(y_i|x_i, \theta) + \lambda \|\theta\|_2^2,$$

$$\theta = [E, W_1^E, W_1^I, W_2, W_3].$$

We randomly initialized the embeddings within  $(-0.01, 0.01)$  and fixed their dimensionality at 32. All weight matrices were initialized using the normalized initialization technique of Glorot and Bengio (2010). Hidden layer sizes were fixed as follows:  $h_0^E = 2,240$ ,  $h_0^I = 32$ ,  $h_1^E = 100$ ,  $h_1^I = 16$ ,  $h_2 = 116$ ,  $h_3 = 64$ . All the biases were set to 0.02.

We train our network using mini-batches of size 200 under the early stopping settings with RMSprop<sup>3</sup> as an optimization algorithm. The learning rate of  $5 \times 10^{-4}$  and  $\lambda = 1.5 \times 10^{-5}$  were found to perform best on the validation set.

Given a feature representation of the current configuration  $s$ , the parsing algorithm first provides a pool of legal transitions  $\mathcal{T} \in S_{total}$ ,  $|\mathcal{T}| \ll |S_{total}|$ . We compute the probabilities of nine unlabelled transitions using the NN. If the network is confident about its prediction (we set an empirically chosen probability threshold of 0.9), we choose the highest scoring candidate and force the perceptron to predict the label of the transition, if it is a transition which assigns a concept tag or edge label. Each candidate  $t \in \mathcal{T}$  is being scored by a linear scoring function  $score(t, s) = \omega \cdot \phi(t, s)$ , where  $\omega$  denotes a weight vector for a particular candidate transition and  $\phi(t, s)$  is a feature function mapping a  $(t, s)$  pair to a real-valued feature vector. The best scoring transition is chosen and applied to the configuration. If the NN chooses a transition which does not assign

| Model                                | P           | R           | F1          |
|--------------------------------------|-------------|-------------|-------------|
| Perceptron (baseline)                | 0.56        | 0.66        | 0.60        |
| Perceptron + SRL                     | 0.57        | 0.68        | 0.62        |
| Perceptron + wide context            | <b>0.58</b> | <b>0.69</b> | <b>0.63</b> |
| Perceptron + SRL + wide context      | 0.58        | 0.68        | 0.63        |
| NN + Perceptron                      | 0.56        | 0.66        | 0.60        |
| NN + Perceptron + SRL + wide context | 0.58        | 0.68        | 0.63        |

**Table 2:** Experimental results.

labels, we apply this transition without asking for the perceptron prediction. Finally, if the network is not confident about the prediction – that is, if the probability for the highest scoring candidate is lower than 0.9 – we disregard the NN prediction and choose the prediction given by the perceptron algorithm.

## 7 Experiments

All the experiments were performed on the LDC2015E86 dataset, provided by the organizers. In our experiments we followed the standard train/dev/test split (16,833, 1,368 and 1,371 sentences, respectively). Parser performance was evaluated with the Smatch (Cai and Knight, 2013) scoring script v2.0.2<sup>4</sup> (Table 2).

As expected, using SRL features resulted in better performance compared to the baseline model (roughly a 2 F1 points gain). Conditioning on a wider context was also beneficial – widening the context to include more configuration elements is often a good feature expansion technique (Toutanova et al., 2003; Chen et al., 2014). In contrast to our expectations, the NN classifier did not improve the parser performance. This might be due to the higher complexity of the AMR parsing task or the peculiarities of the underlying parsing algorithm (as mentioned in Section 3, we discarded some action-specific features due to the difficulty of their integration into the NN model). Further investigation on this matter is required to draw ground conclusions.

## 8 Conclusion

We have performed a range of experiments which resulted in improving the performance of the baseline AMR parsing system. The results show that a richer feature set is very likely to lead to more accurate predictions. Unfortunately, our attempts to further im-

<sup>3</sup>[http://www.cs.toronto.edu/~tijmen/csc321/slides/lecture\\_slides\\_lec6.pdf](http://www.cs.toronto.edu/~tijmen/csc321/slides/lecture_slides_lec6.pdf)

<sup>4</sup><http://alt.qcri.org/semeval2016/task8/index.php?id=data-and-tools>

prove the system using NN were not that successful. This goes against the hypothesis that a small number of dense vector embedding features are sufficient to capture the information necessary for accurate inference, which in traditional approaches is achieved by using a large amount of sparse hand-crafted features (Chen and Manning, 2014). The obtained results will be used in our further investigation on this matter.

## Abstract

We describe our submission system to the SemEval-2016 Task 8 on Abstract Meaning Representation (AMR) Parsing. We attempt to improve AMR parsing by exploiting preposition semantic role labeling information retrieved from a multi-layer feed-forward neural network. Prepositional semantics is included as features into the transition-based AMR parsing system CAMR (Wang, Xue, and S. Pradhan 2015a). The inclusion of the features modifies the behavior of CAMR when creating meaning representations triggered by prepositional semantics. Despite the usefulness of preposition semantic role labeling information for AMR parsing, it does not have an impact to the parsing F-score of CAMR, but reduces the parsing recall by 1%.

## 1 Introduction

Progress in Natural Language Processing has led to a multitude of well-motivated tasks that each represent part of a sentence’s meaning but result in a meaning description spread over separate, unconnected descriptions. These separate levels of semantic annotation, like co-reference or named entities, and the lack of simple human-readable corpora where whole sentence meanings are encoded led to the Abstract Meaning Representation (AMR) formalism (Banarescu et al. 2013). AMR structures capture sentence meanings with rooted, directed and labeled graphs where sentences with the same meaning receive the same AMR. These graphs are encoded in a bracketed format and can be visually represented in a human-understandable way (see Figure

1). AMR structures are organized with nodes representing concepts and the semantic relationships that hold between these concepts<sup>1</sup>. Hence, AMRs can be useful for every NLP component that relies on or exploits semantic meaning resources. Particular application areas are, among others, entity linking (Pan et al. 2015), event detection (Li et al. 2015) and machine translation. An example for a AMR graph is given in Figure 1: there is a concept RECOMMEND-01 which is the root of the graph and there is a concept OFFER-01 that stands in semantic relationship to RECOMMEND-01 with the edge ARG1.

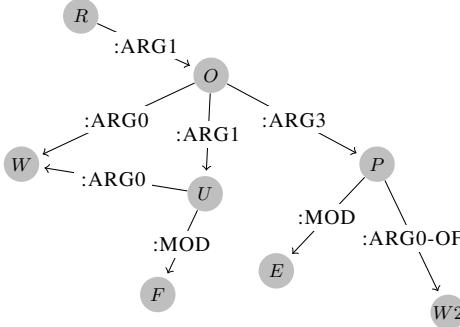

We augment the existing AMR parser CAMR (Wang, Xue, and S. Pradhan 2015a) with a preposition semantic role labeling (prepSRL) neural network with the intention to improve the AMR graph creation accuracy. Prepositions in conjunction with their arguments make a crucial contribution to the meaning of sentences and are therefore a very intuitive supplement to AMR parsing. For example, see how in Figure 2 the meaning of the preposition *in* is involved in the creation of the AMR edge :LOCATION. *in* semantically expresses the *agency*’s spatial location and therefore triggers the identically named AMR edge :LOCATION. Prepositional semantics is a knowledge resource that has not yet been exploited for the domain of AMR parsing. Moreover, CAMR has problems in correctly creating AMR edges triggered by prepositional relations.

<sup>1</sup>Concepts can be PropBank framesets, English words or special words standing for quantities, entity types or logical expressions.

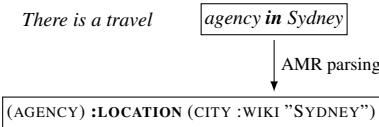

We should offer earthquake workers our full understanding.

## 2 Related Work

The first attempt to automatically generate AMR structures from sentences was the work of Flanigan et al. (2014). They used a graph-based structured prediction algorithm with two stages: the first stage is a semi-Markov model concerned with identification of concepts, the second stage connects these concepts by finding the maximum spanning connected subgraph from a graph where all possible relations between concepts are realized. They achieve an F-score of 0.58 on the LDC2013E117 corpus. Werling, Angeli, and Manning (2015) improve the AMR parsing concept of Flanigan et al. (2014) by supporting the critical task of concept identification with a predefined set of actions for concept subgraph generation that are evoked after a statistical classification procedure. Besides graph-based approaches, there exist also other strategies on AMR parsing: Peng, Song, and Gildea (2015) learn synchronous hyperedge replacement grammar rules from string-

There is nothing sad about old shells.

graph pairs. An Earley algorithm with cube-pruning then performs string-to-AMR parsing with these rules. Pust et al. (2015) treat English and AMR as a language pair and use a machine translation approach to parse AMRs from sentences. They convert AMRs into a grammar of string-to-tree rules that can be handled by syntax-based machine translation formalisms and use these rules with a bottom-up chart decoder to parse AMRs with given local features and a language model. Wang, Xue, and S. Pradhan (2015a) use a transition-based system that transforms dependency graphs into AMR structures by evoking specific actions at each reached state while traversing the dependency tree. As can be seen, there are many different point of views on AMR parsing.

### 2.1 Motivation

The motivation for our system design comes from the error analysis of the transition-based AMR parser CAMR of Wang, Xue, and S. Pradhan (2015a). It turns out that the parser has difficulties on correctly identifying AMR relations which involve prepositional semantics. Therefore, we have chosen to aid CAMR with preposition semantic role labeling (prepSRL) in order to improve AMR parsing results.

### 2.2 Error Analysis of CAMR

Figure 3 shows a CAMR parse error: (b) should indicate a :TOPIC edge label for the edge between the concepts SAD and SHELL. This relation is semantically expressed by the preposition *about*. As can

be seen in Table 1, parsing precision and parsing recall is low for certain relations that can be evoked by prepositional semantics. Where the :LOCATION edge shows an arguably good CAMR performance, other relations like :TOPIC and :DESTINATION fail to be correctly parsed at all. We aim to improve CAMR’s action selection for prepositions by introducing features representing prepositional semantics.

| Relation     | Gold | Parser | Corr. | Prec.  | Rec.   |
|--------------|------|--------|-------|--------|--------|

### 3 System Description

#### 3.1 Baseline System

We used the AMR parser CAMR of Wang, Xue, and S. Pradhan (2015a) as a starting point for our idea of supporting AMR parsing with prepSRL. It converts dependency trees into AMR graphs with a transition-based technique by evoking certain tree transforming actions at reached transition states. In the training procedure, the tokens of the input sentence are first aligned with the nodes of its gold AMR graph using the JAMR aligner (Flanigan et al. 2014). Such aligned AMR graphs are represented as span graphs storing token spans for AMR concept nodes. With these span graphs, a greedy transition-based mechanism learns to rewrite the dependency trees into AMR graphs. In order to learn these transformations, a transition system processes the nodes of the input dependency graphs in a bottom-up left-to-right fashion. It decides at each reached configurations which action to perform next in transforming the dependency graph into an AMR span graph. Configurations are defined as a tuple of buffers holding unprocessed nodes and unprocessed edges and the partial span graph parses for the current input sentence. While traversing the dependency tree, an

- **NEXT-EDGE- $l_r$ :** assigns relation label to current edge and steps on to the next edge
- **SWAP- $l_r$ :** swaps dependency relation between nodes (head transforms to dependent and vice versa)
- **REATTACH $_{k-l_r}$ :** removes an arc, reattaches the former dependent to another node and assigns a label to the new arc
- **REPLACE HEAD:** replaces a head with its dependent
- **REENTRANCE $_{k-l_r}$ :** links a node to another node in the subgraph and therefore has the ability to convert trees into graphs
- **MERGE:** merges two nodes into one node
- **NEXT-NODE- $l_c$ :** assigns a concept label to current node and proceeds to next element in buffer
- **DELETE-NODE:** deletes a node and all its connections
- **INFER- $l_c$ :** inserts a concept node between current node and parent

**Figure 4:** Possible actions for the transition system

averaged perceptron algorithm decides the actions to take by computing scores for all possible actions given specific features<sup>2</sup> and a weight vector. During test time, always the highest scoring action is chosen before moving on to the next state. During training, the algorithm will update the weight vector if it has chosen the wrong action and proceeds parsing with the correct one<sup>3</sup>. The core of the system are the set of actions that can be taken at states by the algorithm. Figure 4 shows an overview and a short description of the eight possible action types<sup>4</sup>. Actions alter the dependency tree by deleting or inserting nodes, merging two nodes into one, assigning relation labels and creating or modifying arcs. Therefore, the averaged perceptron can learn to do the right transformations to end up with a AMR span graph.

#### 3.2 Semantic Role Labeling Features

Wang, Xue, and S. Pradhan (2015b) successfully improve their base system described in chapter 3.1

<sup>2</sup>Feature contexts vary from action type to action type and can include lemmas, words, named entities, POS tags, dependency labels and node span lengths. For a full list of features see (Wang, Xue, and S. Pradhan 2015a).

<sup>3</sup>I.e. the action that is necessary to build the gold span graph.

<sup>4</sup>For more detailed information about the action types see (Wang, Xue, and S. Pradhan 2015a).

by adding SRL features to their model<sup>5</sup>. We also included these features and added our prepSRL information in a similar way. The first SRL feature encodes an action’s compatibility with the predicted frameset from the SRL system. For each action that predicts a concept label (*NEXT-NODE-l<sub>c</sub>*), the predicted SRL frameset is compared to the candidate concept labels. If both match, the value of the feature is set to *true*. Therefore, the system will bias towards choosing the predicted SRL frameset as concept label<sup>6</sup>. The second feature encodes predicted SRL argumenthood for an action’s current edge. For each action that predicts edge labels, the parser has access to the information whether current action’s dependent is predicted by the semantic role labeler. Hence, the system will favor edges that are congruent with the semantic role labeler’s edges.

### 3.3 Preposition Semantic Role Labels

The prepSRL information consists of an attachment according to a dependency parse and a semantic role label for the prepositional phrase head predicted by a neural network. The neural network is trained on data annotated with semantic role labels. A simple feed-forward neural network with one hidden layer is trained in a softmax regression framework on the role labels of Penn Treebank (PTB), the SemEval 2007 Task 6 corpus and the DEFT corpus<sup>78</sup>. Additionally a ‘multi-task’ neural network was trained on all three corpora simultaneously. The network architecture is sketched in Figure 5. All three prediction models share the same two hidden layers. As labels and number of labels vary, softmax regression is performed for each corpus separately.

The neural networks are fed a combination of word embedding<sup>9</sup> and a subset of the hand-crafted

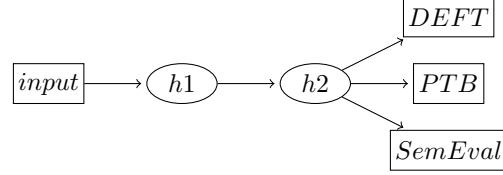

<sup>5</sup>They used the ASSERT SRL system described in (S. S. Pradhan et al. 2004).

<sup>6</sup>Remember that concept labels in AMR can be PropBank framesets.

<sup>7</sup>Used version: LDC2015E86: DEFT Phase 2 AMR Annotation R1

<sup>8</sup>All neural networks are trained with 200 hidden nodes per layer, a learning rate of 0.01 in a gradient descent batch learning environment. The weights are randomly initialized in  $\left[ \pm \sqrt{6 / (\text{input}_\text{dim} + \text{output}_\text{dim})} \right]$ . *Tanh* is used as non-linear activation function.

<sup>9</sup>The word embeddings are taken from (Pennington, Socher, and Manning 2014). For unknown words, a null vector is used

**Figure 5:** ‘Multi-Task’ neural network architecture. Each arrow represents a fully connected link to the next layer. Ellipsoid nodes are subject to non-linear activation, square nodes are subject to softmax regression. The three targets are trained alternating on mini-batches of 20 samples.

features proposed by (D. Hovy, Tratz, and E. H. Hovy 2010). These features include a binary indicator for token capitalization and a binary vector representation of both, the token’s POS-tag and the supersense label according to WordNet<sup>10</sup>. For each sample, these features are extracted for the following tokens: the *preposition token*, the *previous token*, the *preceding verb*, the *preceding verb/adjective/noun*, the *dependency head*, the *dependency child* and a *heuristic child*, for which we choose the ensuing token. All corpora are parsed with the ClearNLP parser<sup>11</sup> to obtain POS-Tags and tokenization. For reasons of compatibility with the AMR-Parsing task, the dependency trees were extracted from parses by the BLLIP parser<sup>12</sup>. Corpus sizes and accuracy measures for the simple neural network can be seen in Table 2.

The neural network predicts a semantic role label for every prepositional phrase head. Comparing the different models by accuracy on these labels is difficult, as the target spaces and number of samples available differ. A list of valid target labels for each corpus can be seen in Table 3. The SemEval corpus comes with a total of 155 labels, where each preposition has a number of senses. These sense labels are reduced in number to create more meaningful target labels for the prepSRL task. The mapping scheme of Srikumar and Roth (2013) was implemented for this reduction. The DEFT corpus comes with a total

instead.

<sup>10</sup>For unavailable information, a null vector is used instead for POS-tags, whereas for supersenses a ‘unknown’ supersense was introduced.

<sup>11</sup>For detailed information, see <https://github.com/clir/clearnlp>.

<sup>12</sup>For detailed information see (McClosky, Charniak, and Johnson 2006) and (Charniak 2000).

of 82 labels. We remove all labels with less than 200 samples from the corpus to ensure training quality.

Given this *prepSRL* system, the AMR parsing results are expected to be improved in the following way. In the AMR of Figure 6 currently the concept *PLACE* is the *ARG3* of *CREATE-01* but it should be the *:LOCATION* of *CONGEST-01*. Because the *prepSRL* feature has the ability to influence the edge creation and labeling actions of the transition system, the AMR parser can decide for the correct actions to take.

**Figure 7:** Preprocessing pipeline for our system. Round nodes depict models, rectangular nodes depict data.

## 4 Experiments

### 4.1 Experimental Setup

We first preprocessed the 16,831 sentences of the DEFT corpus training section (Knight et al. 2014) that we used for training CAMR with the *prepSRL* features. Preprocessing information for the AMR parser includes lemmas, POS tags, named entities and dependency parses<sup>13</sup>. In addition, we preprocessed the training sentences with the ClearNLP toolkit for the training of the neural network. We used the tokenization and POS tag components of ClearNLP and replaced the generated dependencies for compatibility reasons with the dependencies generated by the BLLIP parser.

After preprocessing, the alignments between the AMR graphs and their sentences were created with the JAMR aligner. ASSERT-generated SRL files were provided to us by Sameer Pradhan for the training and test inputs, enabling us to run CAMR with the SRL features. Separately, the neural network for *prepSRL* is trained with PTB-style preposition labels. We parsed our training corpora with the resulting model and generated the feature files for the *prepSRL* information. We trained CAMR in four different feature settings that are shown in Figure 8. The generated models were tested on the DEFT corpus test set that contains 1371 sentences.

<sup>13</sup>Lemmas, POS tags and named entities are generated by the CoreNLP toolkit (Manning et al. 2014). The dependency parses were generated with the BLLIP parser ((McClosky, Charniak,

**Table 4:** Evaluation results

## 4.2 Results

We evaluated our approach of augmenting AMR parsing with a prepSRL system by using the standard evaluation measure for AMR parsing which is the Smatch evaluation metric to date<sup>14</sup>. Smatch uses semantic overlap between AMR parses to measure parsing accuracy. Results of the evaluation are given in Table 4. They reveal that the prepSRL features have a slightly negative influence on the parsing accuracy of CAMR. The Smatch F-score remains the same over all trained models, but the recall is reduced by 1% when adding the prepSRL features. The model with prepSRL achieves a Smatch score of 0.60 on the SemEval-2016 Task 8 test data. One possible explanation for the prepSRL results could be the ambiguity concerned with prepositions:

- (1) *Establishing Models in Industrial Innovation.*
- (2) *There is a travel agency in Sydney.*

In (1), *in* does not indicate an AMR :LOCATION relation, in contrast to its occurrence in (2). At the moment, our system cannot disambiguate between the two appearances of *in* according to the features used.

## 4.3 Error Analysis

A quantitative error analysis of our parser’s output is shown in Table 5. If compared with the previous results in Table 1, the :LOCATION relation shows a minor improvement of precision and recall, where all other relations either show no difference or are parsed worse than before.

## 5 Conclusion

We extended the AMR parser CAMR (Wang, Xue, and S. Pradhan 2015a) with a neural network for prepSRL but did not reach improved AMR results using this method. In fact, the combination with prepSRL slightly reduced the recall of the system. This could be due to the fact that our prepSRL neural network generates parses for all preposition occurrences without disambiguating ambiguous prepositions. Future work has to find a better way to integrate prepSRL information into the architecture of CAMR. One possibility of this could be the refinement of the neural network where only prepositions receive a SRL parse that are likely to produce an AMR relation. Despite our results, we nevertheless think that the inclusion of prepositional semantics could improve AMR parsing results if used in an appropriate way.

## Acknowledgments

We would like to thank Sameer Pradhan for providing us with SRL parses of all task data. Furthermore we would like to thank Chuan Wang for assisting us with detailed questions about CAMR code and parsing pipelines.

## Abstract

We develop a novel transition-based parsing algorithm for the abstract meaning representation parsing task using exact imitation learning, in which the parser learns a statistical model by imitating the actions of an expert on the training data. We then use the imitation learning algorithm DAGGER to improve the performance, and apply an  $\alpha$ -bound as a simple noise reduction technique. Our performance on the test set was 60% in F-score, and the performance gains on the development set due to DAGGER was up to 1.1 points of F-score. The  $\alpha$ -bound improved performance by up to 1.8 points.

## 1 Introduction

In abstract meaning representation parsing (Banarescu et al., 2013), the goal is to parse natural language in a domain-independent graph-based meaning representation (AMR). In the first AMR parsing work, Flanigan et al. (2014) split the task into two sub-tasks; *concept identification* and *graph creation*. The sub-tasks are learned independently, and exact inference is used to find highest-scoring maximum spanning connected acyclic graph that contains all the concepts identified in the first stage. Later work by Wang et al. (2015b) adopted a different strategy based on the similarity between the dependency parse of a sentence and the semantic AMR graph. They start from the dependency parse and learn a transition-based parser that converts it into an AMR graph. To learn the parser, Wang et al. (2015b) define an algorithm that for each instance in the training data infers the action sequence that convert the

input dependency tree into the corresponding AMR graph and train a classifier to predict the actions to be taken during testing. This strategy is also referred to as exact imitation learning, while the algorithm that infers the action sequence in the training instances is commonly referred to as the expert policy.

In our submission to SemEval Task 8 on AMR parsing, we follow the transition-based paradigm of Wang et al. (2015b) with modifications to the parsing algorithm, and also use the DAGGER imitation learning algorithm (Ross et al., 2011) to generalise better to unseen data. The central idea of DAGGER is that the distribution of states encountered by the expert policy during training may not be a good approximation to those seen in testing by the trained policy. Previous work by Rao et al. (2015) used SEARN, a similar imitation learning algorithm, on the AMR problem, with an algorithm that constructs the AMR graph directly from the sentence tokens. Imitation learning has also been used successfully in other semantic parsing tasks (Vlachos and Clark, 2014; Berant and Liang, 2015).

In imitation learning approaches such as DAGGER the previous actions become features for classification learning. However the partial graphs in AMR parsing are rather complex to represent in this way, and combined with the finite amount of training data different actions can be chosen by the expert even though the feature representations for them can be very similar. These decisions appear as noisy outliers in classification learning. To control noise we experiment with the  $\alpha$ -bound discussed by Kharden and Wachman (2007), which excludes a training example from future training once it has been misclas-

| Action Name | Param.   | Pre-conditions                 | Outcome of action   |
|-------------|----------|--------------------------------|---|
| NextEdge    | $l_r$    | $\beta$ non-empty              | Set label of edge $(\sigma_0, \beta_0)$ to $l_r$ . Pop $\beta_0$ .  |
| NextNode    | $l_c$    | $\beta$ empty                  | Set concept of node $\sigma_0$ to $l_c$ . Pop $\sigma_0$ , and initialise $\beta$ .   |
| Swap        |          | $\beta$ non-empty              | Make $\beta_0$ parent of $\sigma_0$ (reverse edge) and its sub-graph. Pop $\beta_0$ and insert $\beta_0$ as $\sigma_1$ .  |
| ReplaceHead |          | $\beta$ non-empty              | Pop $\sigma_0$ and delete it from the graph. Parents of $\sigma_0$ become parents of $\beta_0$ . Other children of $\sigma_0$ become children of $\beta_0$ . Insert $\beta_0$ at the head of $\sigma$ and re-initialise $\beta$ . |
| Reattach    | $\kappa$ | $\beta$ non-empty              | Pop $\beta_0$ and delete edge $(\sigma_0, \beta_0)$ . Attach $\beta_0$ as a child of $\kappa$ . If $\kappa$ has already been popped from $\sigma$ then re-insert it as $\sigma_1$ .   |
| DeleteNode  |          | $\beta$ empty; leaf $\sigma_0$ | Pop $\sigma_0$ and delete it from the graph.  |
| Insert      | $l_c$    |                                | Insert a new node $\delta$ with AMR concept $l_c$ as the parent of $\sigma_0$ , and insert $\delta$ into $\sigma$ .   |
| InsertBelow | $l_c$    |                                | Insert a new node $\delta$ with AMR concept $l_c$ as a child of $\sigma_0$ .  |
| Reentrance  | $\kappa$ | Phase 2                        | Insert edge $(\sigma_0, \kappa)$ . Then apply NextEdge action.  |
| Wikify      | $\omega$ | Phase 2                        | See main text   |

Table 1: Action Space for the transition-based graph parsing algorithm

sified  $\alpha$  times in training. Khordon and Wachman (2007) do not report any experimental results for this, and we are not aware of any previous use of this method.

## 2 System description

In the following subsections we focus on the differences from previous work and in particular that of Wang et al. (2015b) who introduced the transition-based dependency-to-AMR paradigm we follow. We initialise the main algorithm with a stack of the nodes in the dependency tree, root node first. This stack is termed  $\sigma$ . A second stack,  $\beta$  is initialised with all children of the top node in  $\sigma$ . The state at any time is described by  $\sigma, \beta$ , and the current graph (which starts as the dependency tree). Each action manipulates the top nodes in each stack,  $\sigma_0$  and  $\beta_0$ . We reach a terminal state when  $\sigma$  is empty.<sup>1</sup>

### 2.1 The Expert Policy

The expert policy used in training applies heuristic rules to determine the next action from a given state. It uses the training alignments to construct a mapping between nodes in the dependency tree, and nodes in the target AMR. Any unmapped nodes in the dependency tree will be deleted by the expert, and any unmapped nodes in the AMR graph will be

inserted. All our experiments use node alignments from the system of Pourdamghani et al. (2014).

### 2.2 Action Space

Flanigan et al. (2014) and Wang et al. (2015b), both use AMR fragments as their smallest unit, which may consist of more than one AMR concept. Instead, we always work with the individual AMR nodes, and rely on Insert actions to learn how to build common fragments, such as country names. The main adaptations to the actions, summarised in Table 1, stem from this. NextNode and NextEdge form the core action set, labelling nodes and edges respectively without changing the graph structure. Swap, Reattach and ReplaceHead change this structure, but always retain a tree structure. ReplaceHead covers two distinct actions in Wang et al. (2015b); ReplaceHead and Merge. Their Merge action merges  $\sigma_0$  and  $\beta_0$  into a composite node; this is not required without composite nodes and retention of a 1:1 mapping between nodes and AMR concept. Unlike Wang et al. (2015b) we do not parameterise Swap or Reattach actions with a label. We leave that decision to a later NextEdge action. We permit a Reattach action to use parameter  $\kappa$  equal to any node within six edges from  $\sigma_0$ , excluding any that would disconnect the graph or creating a cycle.

The Insert action inserts a new node as a parent of the current  $\sigma_0$ . Wang et al. (2015a) later introduced an ‘Infer’ action similar to our Insert action. Infer inserts an AMR concept node above the current node

<sup>1</sup>Code available at <https://github.com/hopshackle/dagger-AMR>. SemevalSubmission tag bookmarks the version used.

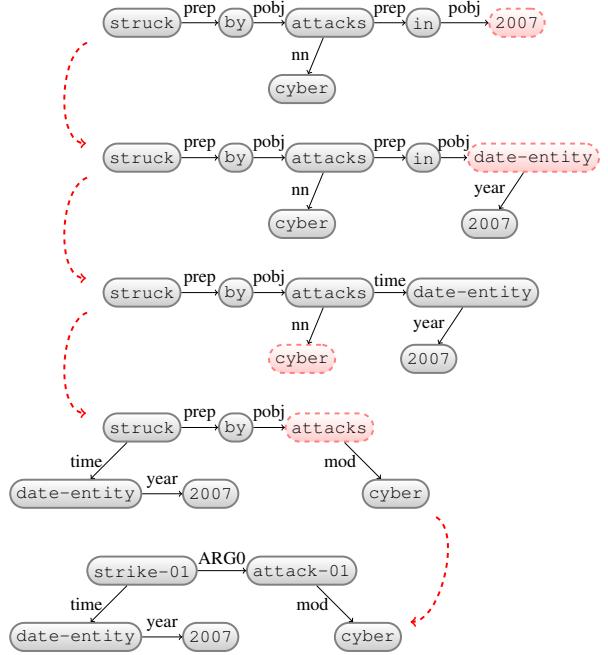

as Insert does, but is restricted to nodes that occur outside of AMR ‘fragments’, which continue to be the base building block.

Reentrance is the one action that will turn a Tree into a non-Tree. We only consider Reentrance actions during a second pass (“Phase Two”) through the AMR graph once the first pass has reached a terminal state. In this second pass we consider each node as  $\sigma_0$  in turn, and each nearby node as a possible  $\kappa$  to insert a new edge  $(\sigma_0, \kappa)$ . We follow any Reentrance action with a NextEdge action to label the new arc. This approach simplifies the first pass, during which the graph is guaranteed to be a Tree. Reentrance makes only a small difference in the final F-Score, and was turned off for our final submission.

Also during Phase Two we decide whether to Wikify  $\sigma_0$ . This adds a new leaf node with a relation of `wiki`. There are three parameter values for  $\omega$  that determine the wiki concept. In turn these use “-”; a concatenation of all child concepts in original word order; a dictionary look-up keyed on a concatenation of the child nodes if these were seen in the training data. An example of the third option is if a name node with a single child node of “Michael” is seen in the training data with a `wiki` relation of “Michael\_Jackson”. This wikification is held in the dictionary, and will be used for any name node with a single child node of “Michael” in test. If instead in test the name node had two children; “Michael”, and “Jackson”, then during  $\omega$  would either add a `wiki` node of “-”, or one of “Michael\_Jackson” by concatenating the two child concepts in the order they appear in the sentence.

Figure 1 shows a parse of a sentence fragment. The current  $\sigma_0$  node is shown dashed and in red. From the top the actions are Insert(date-entity); NextNode(WORD); NextEdge(year); *second diagram*; NextNode(WORD); ReplaceHead to remove “in”; *third diagram*; NextNode(WORD); NextEdge(mod); Reattach to move “date-entity”; *fourth diagram*; NextNode(VERB); ReplaceHead to remove “by”; NextEdge(ARG0); NextEdge(time); NextNode(strike-01).

Wang et al. (2015b) use all AMR concepts and relations that appear in the training set as possible parameters ( $l_c$  and  $l_r$ ) if they appear in any sentence containing the same lemma as  $\sigma_0$  and  $\beta$ . We reduce this to just concepts that have been aligned to the

**Figure 1:** Example parse from dependency tree to AMR of the sentence fragment “... struck by cyber attacks in 2007.”

current lemma. We initially run the expert policy over the training set, and track the AMR concept assigned for each lemma. These provide the possible  $l_c$  that will be used for NextNode actions. Similarly we track the lemmas at head and tail of each expert-assigned AMR relation, and compile possible  $l_r$  from these. There is no direct generalisation between different concepts and relations; so ARG0 and ARG0-of are independently learned relations for example, although they represent the same semantic relationship.

AMR concepts/relations will never be considered during test if they were not aligned to that lemma in the training data. To relax this restriction we allow  $l_c$  to take the values WORD, LEMMA, VERB, which respectively use the word, lemma, or the lemma concatenated with ‘-01’ as the AMR concept. This is inspired by Werling et al. (2015), who use a similar set of actions in a concept identification phase. These options improve performance (by 0.5 to 1.0 points on a validation set) by generalising to unseen tokens in test data, which otherwise would have no mapped AMR concepts. For the  $l_c$  parameters on Insert (InsertBelow) actions, we use all AMR concepts that the expert inserted above (below) any node in

the training set with the same lemma as  $\sigma_0$ .

### 2.3 Additional action constraints

Transition-based parsing algorithms have classically relied on a fixed length of trajectory  $T$  for guarantees on performance, or at least a bounded  $T$  (Goldberg and Elhadad, 2010; Honnibal et al., 2013; Sartorio et al., 2013; McDonald and Nivre, 2007). In our approach  $T$  is theoretically unbounded and the algorithm could Insert, or Reattach *ad infinitum*.

We impose constraints to prevent these situations. A Swap action cannot be applied to a previously Swapped edge; once a node has been moved by Reattach, then it cannot be Reattached again; an Insert action is only permissible if no previous Insert action has been used with that node as  $\sigma_0$ ; an Insert action is not permissible if it would insert an AMR concept already in use as any of the parent, children, grand-parents or grand-children of  $\sigma_0$ .

Any action that would create a cycle is prohibited. We do not prevent duplication of argument relations so that a concept could have two outgoing ARG1 edges. We start with a fully connected graph (the dependency tree), and preserve full connectivity as none of the actions will disconnect a graph.

### 2.4 Imitation Learning

In the first iteration we only use the expert policy to generate a trajectory for each training sentence, and train a classifier  $\pi_1$  from the collected data. At each step in the  $i$ th iteration we randomly choose the expert (with probability  $\beta_i$ ) or else  $\pi_{i-1}$ . The full set of collected data from all iterations is then used to train  $\pi_{i-1}$  to obtain  $\pi_i$ .  $\beta_1 = 1$  and we set  $\beta_i = 0.7\beta_{i-1}$ . Hence each iteration uses the expert policy less and less, with the training trajectories increasingly approximating the states the classifier would encounter without expert knowledge of the target. Formally the DAGGER algorithm is online (Ross et al., 2011), while we use it in a batch mode as described above. We use an averaged AROW classifier for all our experiments, with parameter  $r = 100$  (Crammer et al., 2009). After each batch DAGGER iteration we use 3 iterations of (on-line) AROW training using all the collected data.

As well as the  $\alpha$ -bound for noise reduction, we tried two additional modifications to DAGGER and AROW. Firstly, we considered reducing the num-

ber of actions explored at each stage. The currently trained classifier evaluates all possible actions, and discards any that exceed the best scoring action by some threshold. Only this smaller set, plus the expert action, are included in the training example. This speeds up classifier training. In the first iteration we choose three to five actions randomly. Ross and Bagnell (2014) use a random set of exploratory actions in their AGGREGATE algorithm, but do not use the classifier to focus the exploration.

Secondly, we used only the smallest training sentences in the first iteration, as measured by number of AMR nodes. At each further iteration the AMR size threshold for the training set was increased. The motivation was to train the classifier on ‘easy’ sentences, before introducing more complex ones. We start with up to 30 nodes, and increase this by 10 each iteration. Rao et al. (2015) similarly use the smallest sentences for training, but do not increase the size threshold as training proceeds.

### 2.5 Features

All features used are detailed in Table 2, largely based on Wang et al. (2015b). All are 0-1 indicator functions. *inserted* is 1 if the node was inserted by the parser; *dl* is the dependency label in the original dependency tree; *ner* the named entity tag; *POS* the part-of-speech tag; *prefix* is the string before the hyphen if word is hyphenated; *suffix* is the string after the hyphen; *brown* is the 100-class Brown cluster id with cuts at 4, 6, 10 and 20<sup>2</sup>; *deleted* is the lemma of any child node previously deleted by the parser; *merged* is the lemma of any node merged into this node by a ReplaceHead action; *distance* is the distance between the tokens in the sentence; *path* concatenates lemmas and dls between the tokens in the dependency tree; *POSp* concatenates POS tags between the tokens; *NERpath* concatenates NER tags between the tokens.

The key differences to Wang et al. (2015b) are the inclusion of the brown, POSpath, NERpath, prefix and suffix feature types.

### 2.6 Pre-processing

Pre-processing steps on the training sentences were to: pass the full sentence through the Stanford De-

<sup>2</sup>From <http://metaoptimize.com/projects/wordreprs/> and the code of Liang (2005)

| Context   | Features   |
|---|--|
| $\sigma_0$  | lemma, dl, ner, POS, inserted, prefix, suffix, brown, deleted, lemma-dl  |
| $\sigma_{0P}$   | inserted, lemma, brown   |
| $\sigma_{0C}$   | label, ner, label-brown  |
| $\beta_0$   | inserted, POS, lemma, brown, ner, dl, prefix, suffix, merged   |
| $\kappa$  | ner, POS, lemma, brown, label  |
| $\sigma_0 \rightarrow \beta_0$                              | label, path, lemma-path-lemma, POSpath, inserted-inserted, lemma-POS, POS-lemma, dl-lemma, lemma-dl, lemma-label, label-lemma, ner-ner, distance |
| $\beta_0 \rightarrow \kappa$                                | path, lemma-path-lemma, NERpath, POSpath, distance, lemma-POS, dl-lemma, ner-ner   |
| $\sigma_0 \rightarrow \kappa$                               | distance, lemma-path-lemma, brown-brown, NERpath, POSpath, lemma-dl, lemma-label   |
| $\sigma_{0P} \rightarrow \sigma_0$                          | label, POS-lemma, dl-lemma, ner-ner  |
| $\sigma_{0PP} \rightarrow \sigma_{0P} \rightarrow \sigma_0$ | lemma-lemma-lemma  |
| $\sigma_0 \rightarrow \sigma_{0C}$                          | POS-lemma, lemma-POS, dl-lemma, ner-ner  |

**Table 2:** Features used by context.  $\sigma_{0P}$  is the parent of  $\sigma_0$ ,  $\sigma_{0PP}$  the parent of  $\sigma_{0P}$ , and  $\sigma_{0C}$  a child of  $\sigma_0$ .

pendency Parser v3.3.1 to construct a dependency tree (Manning et al., 2014); remove punctuation tokens; “/” characters are treated as token separators, but hyphenated words are kept as single tokens; simple regex expressions are applied to find common date formats, and convert these to numeric sequences (e.g. 03-Jan-72 to 3 1 1972); similar regex conversions of common numeric expressions e.g. “two thousand” becomes “2000”. The parser was then able to learn to construct date-entity, temporal-quantity and similar AMR moieties.

### 3 Results

In all experiments, the training data was the union of all training and dev sets in the task data, and the union of all test sets was used for validation. Table 3 shows the F-Score of the validation set with and without the Reentrance action (Reent, NoR), and with combinations of reduced search (Red), and incremental data (Inc). All of these give the same result of 0.65 to 2 dp, and the bold entry was submitted. The Baseline entry uses only a single iteration, and the DAGGER experiments report the highest F-Score achieved over 10 iterations (usually reached between the 3rd to 5th iterations).

The reduced information in the first iterations for incremental data and reduced search lead to lower initial performance here, but they still achieve the 0.65 result in time and each iteration is faster. DAGGER provides a gain of 0.6 and 1.1 points of F-Score for experiments with and without Reentrance.

Table 4 shows that the  $\alpha$ -bound helps signifi-

**Table 3:** F-Score results on validation set ( $\alpha = 1$ ).

| Parameter settings | NoR          | Reent. |
|--------------------|--------------|--------|
| Baseline           | 0.642        | 0.640  |
| DAGGER             | 0.648        | 0.651  |
| DAGGER & Inc       | 0.653        | 0.655  |
| DAGGER & Red       | 0.648        | 0.653  |
| DAGGER & Inc & Red | <b>0.651</b> | 0.649  |

cantly, with a gain of 1.8 points of F-Score in this example. We found consistently that the most extreme setting of  $\alpha=1$  worked best.

**Table 4:** Alpha-bound results with DAGGER, Inc and Red

| Alpha-bound | F-Score |
|-------------|---------|
| 1           | 0.655   |
| 2           | 0.649   |
| None        | 0.637   |

### 4 Conclusion

Imitation Learning algorithms like DAGGER help in the AMR task, as in other structured prediction problems. Performance is improved using the  $\alpha$ -bound to reduce the impact of noise in the training examples, and future work could investigate the impact in similar tasks.

The reduction in search space and incremental growth of the training set do not have a significant impact on the results. The speed improvements they provide make little difference here, but could benefit more computationally demanding loss functions than the 0-1 expert loss used in DAGGER.

## Abstract

This paper describes CAMR, the transition-based parser that we use in the SemEval-2016 Meaning Representation Parsing task. The main contribution of this paper is a description of the additional sources of information that we use as features in the parsing model to further boost its performance. We start with our existing AMR parser and experiment with three sets of new features: 1) rich named entities, 2) a verbalization list, 3) semantic role labels. We also use the RPI Wikifier to wikify the concepts in the AMR graph. Our parser achieves a Smatch F-score of 62% on the official blind test set.

## 1 Introduction

AMR parsing is the task of taking a sentence as input and producing as output an Abstract Meaning Representation (AMR) that is a rooted, directed, edge-labeled and leaf-labeled graph that is used to represent the meaning of a sentence (Banarescu et al., 2013). AMR parsing has drawn an increasing amount of attention recently. The first published AMR parser, JAMR (Flanigan et al., 2014), performs AMR parsing in two stages: concept identification and relation identification. Flanigan et al. (2014) treat concept identification as a sequence labeling task and utilize a semi-Markov model to map spans of words in a sentence to concept graph fragments. For relation identification, they adopt graph-based techniques similar to those used in dependency parsing (McDonald et al., 2005). Instead of finding maximum spanning trees (MST) over words, they propose an algorithm that

finds the maximum spanning connected subgraph (MSCG) over concept fragments identified in the first stage.

Wang et al. (2015b) describes a transition-based parser that also involves two stages. In the first step, an input sentence is parsed into a dependency tree with a dependency parser. In the second step, it transforms the dependency tree into an AMR graph by performing a series of actions. Note that the dependency parser used in the first step can be any off-the-shelf dependency parser and does not have to be trained on the same data set as used in the second step.

There are also approaches which utilize grammar induction to parse the AMR. Artzi et al. (2015) presents a model that first uses Combinatory Categorial Grammar (CCG) to construct the lambda-calculus representations of the sentence, then further resolve non-compositional dependencies using a factor graph. Peng et al. (2015) and Pust et al. (2015) formalize parsing AMR as a machine translation problem by learning string-graph/string-tree rules from the annotated data.

Although the field of AMR parsing is growing and several systems (Wang et al., 2015a; Artzi et al., 2015; Pust et al., 2015; Flanigan et al., 2014) have substantially advanced the state of the art, the overall performance of existing AMR parsers is far less accurate than syntactic parsers (Charniak and Johnson, 2005). This makes it difficult to use in downstream NLP tasks. In this paper, we aim to boost the AMR parsing performance by introducing additional features. We mainly experiment with three sets of features derived from: 1) rich named entities, 2) a verbalization list provided by ISI, and 3) semantic role

labels produced by an automatic SRL system.

The rest of the paper is organized as follows. In Section 2 we briefly describe CAMR, and in Section 3 we describe our extensions for the SemEval shared task. In Section 4 we describe the different AMR releases available with some salient characteristics. We report experimental results in Section 5 and conclude the paper in Section 6.

## 2 CAMR Overview

### 2.1 Basic Configuration

CAMR first uses a dependency parser to parse an input sentence, and then performs a small number of highly general actions to transform the resulting dependency tree to an AMR graph. The transition actions are briefly described below but due to the limited space, we cannot provide the full details of these actions here, and the reader is referred to previous work (Wang et al., 2015b) for a detailed description of these actions with illustrating examples. CAMR uses three types of actions: actions performed when an edge is visited, actions performed when a node is visited, and actions used to infer abstract concepts in AMR that does not correspond to any word or word sequence in the sentence.

CAMR performs one of the following six actions when an edge is visited:

- NEXT-EDGE- $l_r$  (ned): Assign the current edge with edge label  $l_r$  and go to next edge.
- SWAP- $l_r$  (sw): Swap the current edge, make the current dependent as the new head, and assign edge label  $l_r$  to the swapped edge.
- REATTACH $_k-l_r$  (reat): Reattach current dependent to node  $k$  and assign edge label  $l_r$ .
- REPLACE-HEAD (rph): Replace current head node with current dependent node.
- REENTRANCE $_k-l_r$  (reen): Add another head node  $k$  to current dependent and assign label  $l_r$  to edge between  $k$  and current dependent.
- MERGE (mrg): Merge two nodes connected by the edge into one node.

From each node in the dependency tree, CAMR performs the following two actions:

- NEXT-NODE- $l_c$  (nnd): Assign the current node with concept label  $l_c$  and go to next node.

- DELETE-NODE (dnd): Delete the current node and all edges associated with current node.

Finally CAMR infers **abstract concepts** that are not aligned to any tokens in sentence with an INFER- $l_c$  action. The INFER- $l_c$  action works as follows: when the parser visits an node in dependency tree, it inserts an abstract node with concept label  $l_c$  right between the current node and its parent. For example in Figure 1, after applying action INFER-have-org-role-91 on node *minister*, the abstract concept is recovered and subsequent actions can be applied to transform the subgraph to its correct AMR.

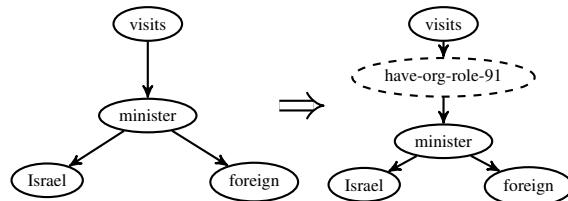

Figure 1: INFER-have-org-role-91 action

## 3 CAMR Extensions

### 3.1 Feature Enrichment

**Rich named entity tags** Since named entity types in AMR are much more fine-grained than the named entity types defined in a typical named entity tagging system, we assume that using a richer named entity tagger could improve concept identification in parsing. Here we use the 18 named entity types defined in the OntoNotes v5.0 Corpus (Weischedel et al., 2011; Pradhan et al., 2013).

**The ISI verbalization list** A large proportion of AMR concepts are “normalized” English words. This typically involves cases where the verb form of a noun or an adjective is used as the AMR concept. For example, the AMR concept “attract-01” is used for the adjective “attractive”. Similarly, the noun “globalization” would invoke the AMR concept “globalize-01”. To help CAMR produce these AMR concepts correctly, we use the verbalization-list provided by ISI<sup>1</sup> to improve the word-to-AMR-concepts alignment. If any alignment is missed by the JAMR aligner and left un-aligned, we simply add

<sup>1</sup><http://amr.isi.edu/download/lists/verbalization-list-v1.01.txt>

an alignment to map the unaligned concept to its corresponding word token if the word token in the input sentence is in the verbalization list.

semantic role labeling:  
wants, want-01,  
ARG0: the boy, ARG1: the girl to believe him

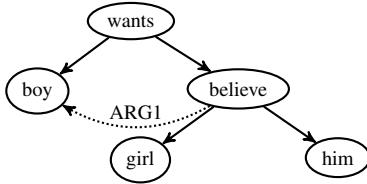

Figure 2: An example of semantic role labeling feature in partial parsing graph of sentence, “The boy wants the girl to believe him.”

**Semantic role labeling features** We use the following semantic role labeling features: 1) EQ\_FRAMESET. For actions that predict the concept label (NEXT-NODE- $l_c$ ), we check whether the candidate concept label  $l_c$  matches the frameset predicted by ASSERT (Pradhan et al., 2004). For example, in the partial graph in Figure 2, when we examine node *wants*, one of the candidate actions would be NEXT-NODE-want-01. Since the candidate concept label want-01 is equal to node *wants*’s frameset want-01 as predicted by ASSERT, the value of feature EQ\_FRAMESET is set to true. 2) IS\_ARGUMENT. For actions that predict the edge label, we check whether ASSERT predicts that the current dependent is an argument of the current head. Note that arguments output by the semantic role labeler are typically constituents in a syntactic tree. We find the head of the argument and match it against the dependent. If the argument predicted by ASSERT matches the dependent, the value of the IS\_ARGUMENT is set to true.

**Word Clusters** For the semi-supervised word cluster feature, we use Brown clusters, more specifically, the 1000-class word clusters trained by Turian et al. (2010). We use prefixes of lengths 4, 6, 10 and 20 of the word’s bit-string as features.

### 3.2 Wikification

We apply an AMR based wikification system (Pan et al., 2015) which utilizes AMR to represent semantic information about entity mentions expressed in their textual context. Given an entity mention  $m$ , this system first constructs a Knowledge Graph  $g(m)$  with  $m$  at the hub and leaf nodes obtained from entity mentions reachable by AMR graph traversal from  $m$ . A subset of the leaf nodes are selected as collaborators of  $m$ . Mentions connected by AMR conjunction relations are grouped into sets of coherent mentions. For each entity mention  $m$ , an initial ranked list of entity candidates  $E = (e_1, \dots, e_n)$  is generated based on a salience measure (Medelyan and Witten, 2008). Then a Knowledge Graph  $g(e_i)$  is generated for each entity candidate  $e_i$  in  $m$ ’s entity candidate list  $E$ . The entity candidates are then re-ranked according to Jaccard Similarity, which computes the similarity between  $g(m)$  and  $g(e_i)$ :  $J(g(m), g(e_i)) = \frac{|g(m) \cap g(e_i)|}{|g(m) \cup g(e_i)|}$ . Finally, the entity candidate with the highest score is selected as the appropriate entity for wikifying  $m$ . Moreover, the Knowledge Graphs of coherent mentions will be merged and wikified collectively.

## 4 Data

Research on AMR parsing so far has reported on two releases of the annotated data. This SemEval evaluation adds another release. The main difference between the SemEval release and the previous two releases is that the SemEval release contains wikification information which was absent from the previous two releases. Since the Smatch scorer uses this information as part of its scoring algorithm, we cannot make comparisons between results on the SemEval release and results previously reported by other systems. We summarize the characteristics of these three releases below.

- a. **LDC2013E117**—This is a non-public release that was used to report the very first results on AMR parsing. The first results were reported only on a subset of the test partition—The newswire proxy section. We do not report performance on this release in this paper.
- b. **LDC2014T12**—This was the first public release of the AMR data through LDC. Comparable numbers have been reported on this release

for the same newswire proxy section as in (a.) as well as the entire test set.

- c. **LDC2015E86**—This is the release specifically made available for the SemEval evaluation. One main difference between this version and the two previous versions is the addition of wikification information. Thus, the performance numbers on the full test set of this release are not directly comparable with previously published results on either of the other two releases.

In the following sections, we will report experiments primarily on the Semeval release (c.). In Section 5.3 we also use the full test set of release (b.) to evaluate the performance improvement made to CAMR as part of the SemEval evaluations against previously reported performance.

| Syntactic Parser | P     | R     | F <sub>1</sub> |
|------------------|-------|-------|----------------|
| Charniak (ON)    | 70.76 | 60.57 | 65.27          |
| Charniak (WSJ)   | 69.88 | 60.24 | 64.70          |

Table 1: AMR parsing performance on the SemEval development set (LDC2015E86) across two Charniak parser models

## 5 Experiments

We use the official release dataset and standard train/dev/test split of SemEval Task 8 for experiments. All the sentences are preprocessed using Stanford CoreNLP (Manning et al., 2014) to get tokenization, lemma, named entity tag, POS tag. And we use the aligner that comes with JAMR (Flanigan et al., 2014) to align the sentence with its AMR graph. We then parse the tokenized sentences using Charniak parser (Charniak and Johnson, 2005)(Its phrase structure output is converted to dependency structure using a slightly modified version of the Stanford CoreNLP converter). Rich named entity tags are generated using Stanford named entity tagger. The semantic role labels are generated using ASSERT—a semantic role labeler (Pradhan et al., 2005), including a frameset disambiguator trained using a word sense disambiguation system—IMS (Zhong and Ng, 2010). All these components viz., the Charniak parser, Stanford named entity tagger, ASSERT, and IMS word sense disambiguator were retrained on the OntoNotes v5.0 training

data<sup>2</sup> (Pradhan et al., 2013)<sup>3</sup>. We use the version of CAMR described in (Wang et al., 2015a) (without the feature extensions) as the baseline. We evaluate our parser with Smatch v2.0.2 (Cai and Knight, 2013) on all the experiments. It should be noted that all the rows in Table 2 except for the last one get implicitly penalized by the scorer for lack of wikification information.

### 5.1 SemEval Development Set

As discussed in (Wang et al., 2015a), the performance of the syntactic parser in the first stage has a high impact on the AMR parsing accuracy. We first do a sanity check to choose the best first stage parser. Here we only consider two scenarios: the Charniak parser trained on WSJ and OntoNotes, as shown in Table 1. As using the Charniak parser trained on OntoNotes yields slightly better AMR parsing result, we will use this set-up for the following experiments.

In Table 2 we present results from extending CAMR. All experiments are conducted on the SemEval development set. we can see that the three major improvements are given by adding the verbalization list, semantic role labels and wikification separately. Rich named entities also yield a 0.4% point improvement, indicating that the more fine-grained named entity tagger is helpful to concept identification. In contrast, Brown cluster features actually hurt the overall performance. Therefore we did not use them in the configuration used for the official run.

### 5.2 SemEval Test Set and Blind Test Set

We evaluate our parser on the SemEval test set and also report the evaluation result on the SemEval blind test set with the best configuration obtained from §5.1, as shown in Table 3.

<sup>2</sup>Details of the training data and the trained models can be found at <http://cemantix.org/data/ontonotes.html> and <https://github.com/ontonotes/conll-formatted-ontonotes-5.0/releases/tag/v12>

<sup>3</sup>We excluded documents from the OntoNotes v5.0 training and development partitions that overlapped with the SemEval AMR data. List of overlapping document IDs is available at <http://cemantix.org/ontonotes/ontonotes-amr-document-overlap.txt>

| Feature configuration | P     | R     | F <sub>1</sub> |
|-----------------------|-------|-------|----------------|
| Baseline              | 70.76 | 60.57 | 65.27          |
| +VERB                 | 71.52 | 60.96 | 65.82          |

| +VERB+RNE+SRL+WIKI    | 71.17 | 63.89 | 67.33          |

Table 2: AMR parsing performance on the official SemEval development set (LDC2015E86). VERB: ISI verbalization list. BROWN: Brown cluster features. RNE: Rich (OntoNotes) named entities. SRL: semantic role labeling features. WIKI: Addition of wikification of named entities in AMR.

| Dataset        | P     | R     | F <sub>1</sub> |
|----------------|-------|-------|----------------|
| Test Set       | 70.36 | 63.12 | 66.54          |
| Blind Test Set | 67.44 | 57.39 | 62.01          |

Table 3: AMR parsing performance on full SemEval Test Set and the Blind Test Set

From Table 3 we can see that our parser remain relatively stable on the SemEval test set. However, the evaluation result on blind test set dropped by around 4 points, indicating the blind test set is much harder and we plan to do further error analysis to gain more insight on the difference.

### 5.3 Previous Release—LDC2014T12

Since the official dataset of SemEval is annotated with wiki relations that previous releases of the AMR Corpus do not have, we conduct additional experiments on the AMR annotation release 1.0 (LDC2014T12) to gain a clear understanding of the impact of the additional feature. We use the training/development/test split recommended in the release: 10,312 sentences for training, 1,368 sentences for development and 1,371 sentences for testing. We re-train the parser on the LDC2014T12 training set with the best parser configuration given in §5.1 — except for the wikification pass — and test the parser on the full test set. The result is shown in Table 4. For comparison, we include the result of our parser in (Wang et al., 2015a) which are also trained on the same dataset. The results show that the new features yield a modest improvement over our (Wang et al., 2015a) parser.

| CAMR version        | P            | R            | F <sub>1</sub> |
|---------------------|--------------|--------------|----------------|
| <b>This paper</b>   | <b>71.35</b> | <b>62.29</b> | <b>66.51</b>   |

Table 4: CAMR parsing performance on the full test set of release LDC2014T12.

## 6 Conclusion

We build our system by taking our existing AMR parser and enriching it with three sets of features: 1) rich named entities, 2) a verbalization list, and 3) semantic role labels. We also use a wikifier to resolve the wiki relation in AMR graph. Our results show that the additional features are helpful to the AMR parsing task and a well-designed wikifier could be a helpful post-processing step to AMR parsing.

## Abstract

We participated in the shared task on meaning representation parsing (Task 8 at SemEval-2016) with the aim of investigating whether we could use Boxer, an existing open-domain semantic parser, for this task. However, the meaning representations produced by Boxer, Discourse Representation Structures, are considerably different from Abstract Meaning Representations, AMRs, the target meaning representations of the shared task. Our hybrid conversion method (involving lexical adaptation as well as post-processing of the output) failed to produce state-of-the-art results. Nonetheless, F-scores of 53% on development and 47% on test data (50% unofficially) were obtained.

## 1 Introduction

With the currently increasing interest in semantic parsing, and the diversity of the meaning representations being used, an important challenge is to adapt existing semantic parsers for different semantic representations. Shared Task 8 of the SemEval-2016 campaign for semantic evaluation is an interesting venue for this, where a system is given an English sentence and has to produce an Abstract Meaning Representation (AMR) for it.

We participated in this shared task with a system rooted in formal semantics based on Discourse Representation Theory (DRT). In particular, we were interested in finding out whether the representations from DRT (Kamp, 1984; Kamp and Reyle, 1993), Discourse Representation Structures (DRSs), could be easily converted into AMRs. In this paper we

outline our method, which is based on the semantic parser Boxer (Bos, 2008; Bos, 2015), and then present and discuss our results.

## 2 Background

Before we outline our method, we will say a little about the open-domain semantic parser that we used in this shared task. We also give an overview of the differences between the meaning representations produced by Boxer and those that are required for the shared task. To get a first taste of these differences, compare the analysis of '*All equipment will be completely manufactured*' carried out by Boxer (Figure 1) and that of the gold-standard AMR (Figure 2).

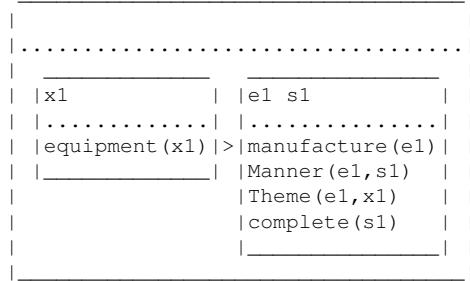

Figure 1: DRS, as produced by Boxer.

```
(m / manufacture-01
  :ARG1 (e2 / equipment
    :mod (a2 / all))
  :ARG1-of (c / complete-02))
```

Figure 2: Gold-standard AMR.

## 2.1 Boxer

The semantic parser that we employed is Boxer (Bos, 2008; Bos, 2015). It is the last component in the C&C tools pipeline (Curran et al., 2007), comprising a tokenizer (Evang et al., 2013), POS-tagger, lemmatizer (Minnen et al., 2001), and a robust parser for CCG, Combinatory Categorial Grammar (Steedman, 2001). Overall, this parsing framework shows many points of contact with the recent work by Artzi et al. (2015), who also use CCG coupled with a formal compositional semantics.

Boxer produces semantic representations based on Discourse Representation Theory (Kamp and Reyle, 1993), known as Discourse Representation Structures (DRSs), as Figure 1 shows. A DRS is a first-order representation, i.e., expressible with first-order logic. Various notations are possible, but widely used are the box-like representations shown in Figure 1. Boxes display scopes of discourse referents and contain properties of and relations between discourse referents. They are recursive structures, hence a box may contain other boxes.

## 2.2 Abstract Meaning Representations

At first glance, an AMR looks quite different from a DRS. Usually, an AMR is displayed as a directed graph with a unique root (Figure 2). However, it is also possible to view an AMR as a recursive structure, and then DRS and AMR have more in common than one perhaps would initially realize (Bos, 2016).

The variables in an AMR correspond to discourse referents in a DRS. The colon-prefixed symbols in an AMR are similar to the two-place relation symbols in a DRS. And the forward slashes in an AMR correspond to one-place predicates in a DRS. So the main commonalities between a DRS (as produced by Boxer) and an AMR (as used at the SEMEVAL-2016 shared task) are:

- both use a neo-Davidsonian event semantics;
- both are recursive meaning representations;
- both expect normalization of date expressions.

There are also some obvious differences between DRS and AMR. Some of them are theoretical and have to do with the expressive power of the chosen formalism. Others have to do with relatively ar-

bitrary choice of labels and encoding of meanings. The most important differences are:

- AMR has no explicit structures for universal quantification and negation;
- AMR expects different labels for thematic roles (Boxer uses the VerbNet inventory);
- AMR assigns no scope for propositional meanings;
- AMR is strongly event-oriented (verbalization);
- AMR has flat lists of coordinated structures;
- AMR has symbol grounding by wikification (for named entities).

These are substantial differences posing a serious challenge when mapping DRSs to AMRs. In the next section we describe how we go about doing this.

## 3 Method

### 3.1 Pre-processing and Tokenisation

All input texts were normalized prior to semantic processing by our pipeline. First of all, double quotes were removed from sentences because they do not contribute to AMR components but they might give rise to suboptimal syntactic parses. Secondly, brackets containing unit conversions were removed (i.e., *30 yards (27 meters)* became *30 yards*) because the converted information does not show in gold-standard AMRs.

Tokenization was done using the Elephant tokenizer (Evang et al., 2013). Some of the documents that were supplied for the shared task had already undergone tokenization, however. Therefore, prior to tokenization, we determine per document whether or not tokenization is needed. This is done with a simple heuristic, applying tokenization if the document does not contain a full stop or comma with whitespace on both sides.

### 3.2 Lexical anticipation

Our key idea was to map DRSs as output by Boxer to AMR, and doing so in a systematic, principled way. However, during the implementation process it

became clear that this mapping would become much easier when certain conversions would have been already made in Boxer’s semantic lexicon. An obvious case is determiners, which receive an elaborate analysis in DRS but a minimal treatment in AMR. Anticipating this in the lexicon saves error-prone conversion steps later in the processing pipeline.

Apart from determiners, lexical conversion (i.e., altering the lexical semantics in order to get closer to AMR structures) was carried out for certain punctuation symbols (question and exclamation marks), all cases of coordination, for some non-logical symbols (for instance, contrastive discourse relations and conditionals), there-insertion, personal and possessive pronouns, demonstratives and quantifiers, comparatives and superlatives, certain temporal modifiers, and copula constructions.

### 3.3 From DRS to AMR

The conversion from DRS to AMR was implemented using a recursive translation function. Apart from some core translation rules mapping DRS to AMR constructs, there is also a set of rules that work on specific phenomena: modal operators in DRSs are mapped to events (recommend-01 and possible-01); the negation operator is mapped to polarity-, and disjunction to an or-instance with op1 and op2 relations.

Boxer’s thematic roles are mapped to ARG0 (Actor) ARG1 (Theme, Topic) or ARG2 (recipient). In addition, we took advantage of Ulf Hermjakob’s lists of have-rel-role and have-org-role predicates to rewrite roles when needed. A similar resource was used to cope with deverbalizations.

The outcome of the mapping is an AMR with possibly more than one root. Therefore the conversion also involves inversion of AMR roles until an AMR with a unique root is obtained. This is a non-trivial process and does not always succeed. In such cases only parts of the AMR are produced as output.

### 3.4 Re-labelling

An additional post-processing step consisted of changing labels where our output AMRs consistently differed from those in the training data. After processing each document in the training data with Boxer, Smatch (v 2.0.2) was used to obtain all matching triples for each AMR parse pair. Us-

ing these triples, we calculate counts of (BOXER-RELATION, GOLD-RELATION, COUNT). If Boxer consistently outputs a relation erroneously, we replace all occurrences of that label with the correct label from the training data.

Examples of phenomena that require re-labelling are: intensifiers, locative adjectives, ordinals, temporal adverbs, morphological mappings of symbols (for instance, historical → history), temporal roles, putting names together, time expressions, units of measurement, nationalities, modal adverbs, verbalizations, negation affixes, and abbreviations.

### 3.5 Wikification

Wikification was done as a post-processing step: each name-relation produced by boxer was initialized with an empty wiki (:wiki -). The value of the wiki was acquired by wikifying the whole sentence and then matching the wikification output to the name. One exception to this regards demonyms, which were assigned the correct wikification by Boxer already.

Wikification was done using DBpedia Spotlight (Daiber et al., 2013) through the web service<sup>1</sup>, because of its high coverage and ease-of-use. Since we used Spotlight only for wikification, and not for NER, a high recall was more important than a high precision. The confidence parameter was optimized on the development set, and the optimal value turned out to be 0.3. This is a low value, which yields a large number of annotations for each sentence, a large proportion of which are incorrect.

The wikification output was then matched to the names in the sentence by using exact string matching, and if that failed, by matching on prefixes. Performance was high, with accuracy of wikification only, tested with the gold-standard AMRs at around 76%. In terms of AMR-parsing F-scores, wikification yielded gains of 2% to 4% on the development set, depending on the nature of the data and the quality of Boxer’s NER. We also experimented with the Illinois Wikifier (Ratinov et al., 2011), but this did not yield any improvements over DBpedia Spotlight.

---

<sup>1</sup><http://spotlight.sztaki.hu:2222/rest/annotate>

**Table 1:** F-scores on the *test* part of the released training data.

|       | DFA         | Xinhua      | Consensus   | Bolt        | Proxy       |
|-------|-------------|-------------|-------------|-------------|-------------|
| Boxer | 39.9        | <b>57.2</b> | 45.8        | 47.0        | 56.0        |
| JAMR  | <b>47.5</b> | 52.8        | <b>49.6</b> | <b>48.7</b> | <b>60.2</b> |

## 4 Results and Discussion

### 4.1 Overall Results

We obtained an F-score of 47% in the official scoring. Due to an error early in our pipeline script, a large amount of our parsing mistakes were caused by erroneous tokenization. Correcting this bug results in an F-score of 50% on the official evaluation data (calculated with Smatch v2.0.2 using 4 restarts).

Table 1 shows the F-scores we obtained on the *test* portion of the data set released for system development for this task. We compare our system with the JAMR parser, trained following released instructions on the *training* portion of the released data. Although our parser obtains a lower score on most sub-corpora, we are able to outperform the JAMR parser on the Xinhua sub-corpus.

### 4.2 Error Analysis

An analysis of the mistakes made on the gold test set reveals that some mistakes can be attributed to annotation mistakes. Figure 3 shows an example in which our AMR is arguably better than the gold AMR. In the sentence ‘*They are thugs and deserve a bullet.*’, the ones deserving a bullet should not be *all thugs* as in the gold parse, but the referent of *they*, as in our output. Figure 4 shows a similar instance, in which *A protester* is incorrectly assigned the modifier :quant 1 in the gold parse. (An anonymous reviewer of an earlier version of this article noted that “the AMR gold seems correct, even though I would have probably accepted the Boxer output as correct, at least without knowing more about the pragmatic context of the sentence.”). We don’t agree here, as many similar cases in the corpus are not annotated with the same attribute, and since there is no context, it is impossible to infer the less likely specific-indefinite reading.)

Another portion of the mistakes made by our system can be attributed to wrong choices of senses, arguments and coordination mistakes. Figure 5 shows an example in which we make a coordination mis-

take with the noun-noun compound *security force*, and interpret this as a possessive. We further also make a labelling mistake, interpreting *america* as an organization. Figure 6 also contains such a labelling mistake, in which we fail to resolve *take part* to *participate-01*. In the example in Figure 7 the wrong sense is chosen for *fall*.

A quantitative analysis of this type of mistake shows that there is quite some room for improvement to be made by correcting these. Assuming perfect Smatch alignment of triples, 18.5% of relations are mislabelled (for instance, ARG1 when ARG2 would be appropriate), and 42.8% of instances are mislabelled (for example, *fall-01* when *fall-07* would be appropriate).

## 5 Conclusion

In this paper we wanted to investigate how feasible it is to map DRSs to AMRs. DRSs and AMRs have a lot of points in common, but there are also significant differences. We approached the problem with a three-fold strategy: lexical adaptation (changing lexical entries of the Boxer system to match AMR), a recursive translation function from DRS to AMR, and a post-processing step (needed because of the differences in verbalization and symbol labelling in AMR).

On the one hand, the overall results are perhaps disappointing. The obtained F-score does not match that of state-of-the-art semantic parsers that are trained on gold-standard AMR datasets. On the other hand, with relatively little effort reasonable output is produced. For notoriously hard constructions such as control and coordination Boxer performs well.

The question remains whether this is a promising way of producing different semantic representations (i.e., AMRs instead of DRSs). It would be interesting for future research to investigate the possibility to make Boxer’s syntax-semantics interface more transparent and transform the three-step process into two phases, eliminating the need for translating DRS to AMR. Needless to say, AMR is not a replacement for DRS, as it has less expressive power, but the ability to switch between the two formats would be a welcome feature.

# UofR at SemEval-2016 Task 8: Learning Synchronous Hyperedge Replacement Grammar for AMR Parsing

Xiaochang Peng and Daniel Gildea

Department of Computer Science  
University of Rochester  
Rochester, NY 14627

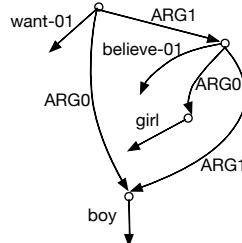

## Abstract

In this paper, we apply a synchronous-graph-grammar-based approach to SemEval-2016 Task 8, Meaning Representation Parsing. In particular, we learn Synchronous Hyperedge Replacement Grammar (SHRG) rules from aligned pairs of sentences and AMR graphs. Then we use Earley algorithm with cube-pruning for AMR parsing given new sentences and the learned SHRG. Experiments on the evaluation dataset demonstrate that competitive results can be achieved using a SHRG-based approach.

## 1 Introduction

Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a semantic formalism where the meaning of a sentence is encoded as a rooted, directed graph. Figure 1 shows an example of the edge-labeled representation of an AMR graph, where the edges are labeled while the nodes are not. AMR utilizes PropBank frames, non-core semantic roles, coreference, named entity annotations and other semantic phenomena to represent the semantic structure of a sentence and abstracts away its syntax form. These properties render AMR representation useful in applications like question answering and semantics-based machine translation.

SemEval-2016 Task 8 is the task of recovering this type of semantic formalism for plain text. A large corpus of annotated English/AMR pairs is provided to learn this mapping. Hyperedge replacement grammar (HRG) is a context-free rewriting formalism for generating graphs (Drewes et al., 1997). Its

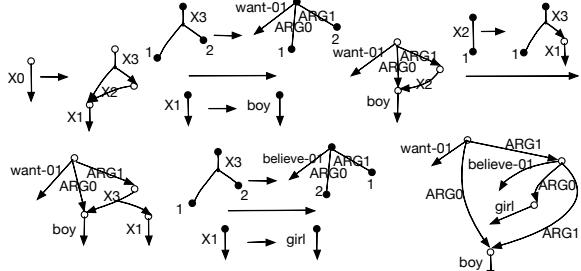

**Figure 1:** An example of AMR graph representing the meaning of: “The boy wants the girl to believe him”

synchronous counterpart, SHRG, can be used for transforming a graph from/to another structured representation such as a string or tree structure. Therefore, an SHRG-based approach can be used for AMR parsing. Previous approaches usually first map the components of the sentence to components of the graph. Then different supervised algorithms are used to assemble these graph components to generate a complete AMR graph (Flanigan et al., 2014; Wang et al., 2015b; Wang et al., 2015a).

Previously, we have developed a system that learns SHRG rules from sentence/AMR graph pairs (Peng et al., 2015), with automatic alignments extracted from JAMR (Flanigan et al., 2014). During the decoding procedure, we also use the concept identification results from Flanigan et al. (2014). The system is evaluated on the newswire section of LDC2013E117, which has around 4000 sentence-AMR pairs as training data.

In this paper, we extend this system by using the alignments from Ulf Hermjakob’s automatic aligner and building a perceptron-based concept identifier where the boundary information of the mapped frag-

**Figure 2:** The series of HRG rules applied to derive the AMR graph of “The boy wants the girl to believe him”. The first rule is directly shown. The other HRG rules are either above or below each right arrow. The white circle shows the root of each hyperedge. The indexes in each rule show the one-to-one mapping between the attachment nodes of l.h.s. nonterminal edges and the external nodes of the r.h.s. subgraph

ments is captured. We first introduce the overall pipeline of our parser. Then we describe the SHRG learning and the AMR parsing procedure in detail in Section 4 and Section 5. Finally we show the experimental results on the SemEval-2016 evaluation datasets.

## 2 Overall System Description

Our system is divided into two major components: SHRG learning and AMR parsing. Given English/AMR pairs and the automatic alignments from Ulf Hermjakob, we build a derivation forest representation of possible derivations. Markov Chain Monte Carlo (MCMC) algorithms are applied to sample a series of SHRG rules that generate each sentence/AMR pair.

Given the extracted SHRG and new sentences, we first identify the component spans on the string side. Then we use a perceptron classifier to find the graph fragment aligned to each of these spans. Finally, we use a decoder similar to those used for Synchronous Context-Free Grammar (SCFG) in machine translation, where the graph-side derivation is composed using HRG derivation instead of CFG, to get the AMR graphs for these sentences.

## 3 Hyperedge Replacement Grammar

HRG is similar to CFG in that it rewrites nonterminals independently. While CFG generates natural language strings by successively rewriting nonter-

rninal tokens, the nonterminals in HRG are hyperedges, and each rewriting step in HRG replaces a hyperedge nonterminal with a subgraph instead of a span of a string.

The rewriting mechanism replaces a nonterminal hyperedge with the graph fragment specified by a production’s righthand side (r.h.s.), attaching each external node of the r.h.s. to the corresponding attachment node of the lefthand side. Take Figure 2 as an example. Starting from our initial hypergraph with one edge labeled with the start symbol “X0”, we select one edge with a nonterminal label in our current hypergraph, and rewrite it using a rule in our HRG. The first rule rewrites the start symbol with a subgraph shown on the r.h.s. We continue the rewriting steps until there are no more nonterminal-labeled edges.

We use the synchronous counterpart of HRG where the source side is a CFG and the target side is an HRG. Given such a synchronous grammar and a string as input, we can parse the string with the CFG side and then derive the counterpart graph by deduction from the derivation. The benefit of parsing with SHRG is that the complexity is bounded by that of CFG parsing. Table 2 shows the rule format of our SHRG. For each nonterminal  $Xi-b_1 \dots b_i$ ,  $i$  defines the type of the nonterminal, while each  $b_i$  indicates whether the  $i$ -th external node will have a concept edge in the rewriting result. This design guarantees that there is exactly one concept edge going out of each node.

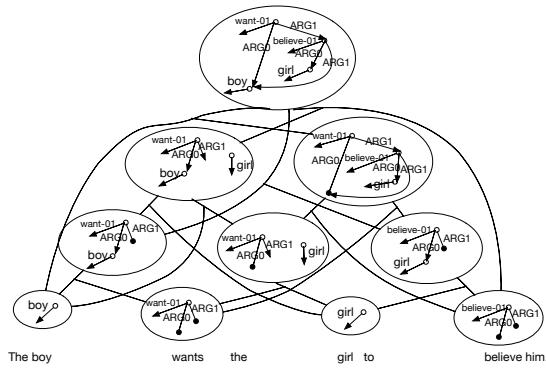

## 4 Learning Synchronous Hyperedge Replacement Grammar

The **fragment decomposition forest** represents all possible ways to decompose the sentence-AMR pairs into component-level alignments. It also encodes a compact representation of possible SHRG derivations that are consistent with the alignments.

Therefore, starting with the component-level alignment pairs, we keep composing large span/fragment pairs from bottom up to build the derivation forest. Then we use Gibbs sampling to sample one derivation from the forest representation.

|              | JAMR                  | Ulf Hermjakob           |
|--------------|-----------------------|-------------------------|
| string side  | span, can be multiple | single token            |
| graph side   | concept fragments     | single concept/relation |
| prepositions | usually not aligned   | relation edges          |
| mapping type | one-to-one            | multiple-to-multiple    |

**Table 1:** Comparisons of English-AMR alignments from JAMR and Ulf Hermjakob

**Figure 3:** The fragment decomposition forest for the (sentence, AMR graph) pair for “The boy wants the girl to believe him”

#### 4.1 Constructing Derivation Forests

We use the alignments from Ulf Hermjakob’s aligner, which are provided for the training data. Some differences between this alignment and the alignment from JAMR (Flanigan et al., 2014) are summarized in Table 1. As the alignment is between a single token and a single concept/relation, we first heuristically identify the mappings of name entities by tracing the `:op` and `:name` relations. For each of the other aligned tokens, we compose its aligned concept or fragment.<sup>1</sup> There are also situations where multiple tokens are aligned to the same concept or relation. If they are adjacent, we compose them on the string side to form a larger span. Otherwise we delete the alignment of the shorter span to make the alignment one-to-one. We additionally use lemma information to retrieve some mappings from unaligned tokens to unaligned concepts.<sup>2</sup>

After we have extracted these alignments, we build the fragment decomposition forest from bottom up and left to right, gradually composing larger

<sup>1</sup>Our parser currently does not support multi-root graph fragments, so for alignments that align one token to multiple disconnected fragments, we only choose the largest fragment as the aligned fragment.

<sup>2</sup>Following Peng et al. (2015), we attach `:ARGS` and `:ops` to their head concepts and `:ARGx-ofs` to their tail concepts.

(span, fragment) pairs from smaller ones until we have reached the root of the forest: the whole sentence-AMR pair. We maintain an ordered list of external nodes for each fragment, which will be used to track the order of the external nodes during the rule extraction phase. Figure 3 shows an example of a fragment decomposition forest. The forest construction procedure is described in detail in Peng et al. (2015).

Each node in the forest represents a span-fragment pair. We extract all span-fragment pairs of length smaller than 7 to construct a span to fragments alignment table  $\Phi$ , which will be used during the concept identification procedure in Section 5.1

#### 4.2 SHRG Learning Using MCMC

The fragment decomposition forest represents possible derivations of the sentence/AMR pairs in terms of minimal rules extracted from the alignments. We use an MCMC algorithm to learn a grammar of larger rules, by sampling both which minimal rules are used, and how minimal rules combine to form larger composed rules.

We sample two types of variables: an edge variable  $e_n$  representing which incoming hyperedge is chosen at a given node  $n$  in the forest (allowing us to sample one tree from a forest) and a cut variable  $z_n$  representing whether node  $n$  in the forest is a boundary between two SHRG rules or is internal to an SHRG rule (allowing us to sample rules/fragments from a tree). We use an MCMC algorithm to sample from top-down and one variable at a time (Peng and Gildea, 2014). Sampling tree fragments from forests is described in detail in Chung et al. (2014). Table 2 shows some examples of the sampled SHRG rules.

### 5 AMR parsing

In Section 4 we have described how we extract the SHRG from the training data. Now given a new sentence, we first use the perceptron algorithm to identify the graph fragments each span in the sentence aligns to. Then we use the Earley algorithm to decode the sentence and recover its AMR graph.

#### 5.1 Concept Identification

First we identify the segmentation of the sentence. We use the Illinois Named Entity Tagger (NER) (Ratinov and Roth, 2009) to identify all the

|   |
|---|
| [A1-1] → ordinary people   (. :p/person :mod (. :o/ordinary ))                              |
| [A0-1] → [A1-1,1] say that [A1-1,2]   (. :s/say-01 :ARG0 (. :[A1-1,1]) :ARG1 (. :[A1-1,2])) |
| [A0-1] → Do [A1-1,1] ?   (. :[A1-1,1] :mode (. :interrogative))                             |

**Table 2:** Some example of learned rules

named entities. We also use heuristic rules to identify dates, time expressions etc. We heuristically build the AMR fragments for these spans and add the mappings to  $\Phi$ .<sup>3</sup> The other spans are of length 1. Then we use the perceptron algorithm to predict the AMR fragment for each span:

$$\hat{g}[e] = \arg \max_{g \in \Phi(e)} w^T f(e, g, c) \quad (1)$$

where  $w$  is the weights, and  $f$  is the feature function.  $e$  is the current span,  $g$  is a candidate graph fragment from the span to fragment table  $\Phi$  or matched using regular expressions.  $c$  is the context of span  $e$ . We use the following context features:

1. 3 words, pos tags, lemmas before and after the current span
2. 3 word, pos tag or lemma bigrams before and after the current span
3. the words, pos tags and lemmas in the current span
4. Length of the span

Our concept identification result is different from Flanigan et al. (2014) in that we are predicting not only the graph fragments but also the external nodes of each fragment. Therefore, each identified mapping is essentially a lexical SHRG rule at the leaf-level of the derivation tree. We add these identified lexical rules to the extracted SHRG locally before decoding each sentence. For lexical rules in  $\Phi$  that cover more than 1 span of the sentence on the string side, we also add them to the SHRG locally.<sup>4</sup>

## 5.2 Decoding

Given the learned SHRG, we are simply parsing on the string side. We use the Earley algorithm with cube-pruning (Chiang, 2007) for the string-to-AMR

<sup>3</sup>As the named entity labels from Illinois NER is only a few, we predict their entity label from an entity label set built on the training data.

<sup>4</sup>We filter some rules that have non-content words on the left or right because such rules introduce a lot of errors from the alignments.

|             | Precision | Recall | F-score |
|-------------|-----------|--------|---------|
| Dev         | 0.57      | 0.55   | 0.56    |
| Test        | 0.56      | 0.55   | 0.55    |
| Task 8 eval | -         | -      | 0.50    |

**Table 3:** Parsing results on dev and test LDC2015E86 and the evaluation data of SemEval-2016 Task 8

parsing. For each synchronous rule with  $N$  nonterminals on its l.h.s., we build an  $N + 1$  dimensional cube and generate the top  $K$  candidates. Out of all the hypotheses generated by all satisfied rules within each span  $(i, j)$ , we keep at most  $K$  candidates for this span. Our glue rules generate a pseudo *m/multi-sentence* concept and use *ARG* relations to connect disconnected components to make the result graph connected. The features used are described in Peng et al. (2015).

## 6 Experiments

We evaluate our parser on the LDC2015E86 dataset, which includes 16833 training, 1368 dev, and 1371 test sentences.

During the sampling procedure, all the cut variables in the derivation forest are initialized as 1 and an incoming hyperedge is sampled uniformly for each node. We run the sampler for 160 iterations and combine the grammar dumped every 10th iteration.

The performance of our SHRG-based parser is evaluated using Smatch v2.0.2 (Cai and Knight, 2013), which evaluates the precision, recall, and  $F1$  of the concepts and relations all together. Table 3 shows the results on the dev and test set. We also report smatch score on the shared task evaluation data, which includes 1053 sentences. The smatch score on the evaluation data is 0.50. This score is much lower than the performance on the dev and test data. The reason might be that the evaluation data is much harder and includes more noise, which can break down the structure of the learned grammar.

The results show that SHRG-based parsing can be a viable approach for AMR parsing. Currently our system only uses a few simple features and all the weights are tuned by hand. The performance could be improved by using more complicated features and tuning their weights automatically. It would also be helpful to use external resources such as the com-

mon organizational roles, relational roles and the verbalization lists<sup>5</sup> and use fallback techniques to deal with unknown words.

## 7 Conclusion

In this paper, we have presented our SHRG-based AMR parsing system for SemEval-2016 Task 8. Our system extends from the work of Peng et al. (2015) and has shown some competitive results for a graph-grammar-based approach for AMR parsing. Currently our system only uses local features for decoding; it would be interesting to extend this system to incorporate a language model on the graph side and use discriminative models to incorporate more global features and tune the weights automatically.

## Abstract

In this paper we describe our approach to the Abstract Meaning Representation (AMR) parsing shared task as part of SemEval 2016. We develop a novel technique to parse English sentences into AMR using Learning to Search. We decompose the AMR parsing task into three subtasks - that of predicting the concepts, the relations, and the root. Each of these subtasks are treated as a sequence of predictions. Using Learning to Search, we add past predictions as features for future predictions, and define a combined loss over the entire AMR structure.

## 1 Introduction

This paper describes our submission to the Abstract Meaning Representation (AMR) Parsing Shared Task at SemEval 2016. The goal of the task is to generate AMRs automatically for English sentences. We develop a novel technique for AMR parsing that uses Learning to Search (L2S) (Ross et al., 2011; Daumé III et al., 2009; Collins and Roark, 2004).

L2S is a family of approaches that solves structured prediction problems. These algorithms have proven to be highly effective for problems in NLP like part-of-speech tagging, named entity recognition (Daumé III et al., 2014), coreference resolution (Ma et al., 2014), and dependency parsing (He et al., 2013). Briefly, L2S attempts to do structured prediction by (1) decomposing the production of the structured output in terms of an explicit search space (states, actions, etc.); and (2) learning hypotheses

\*The first two authors contributed equally to this work.

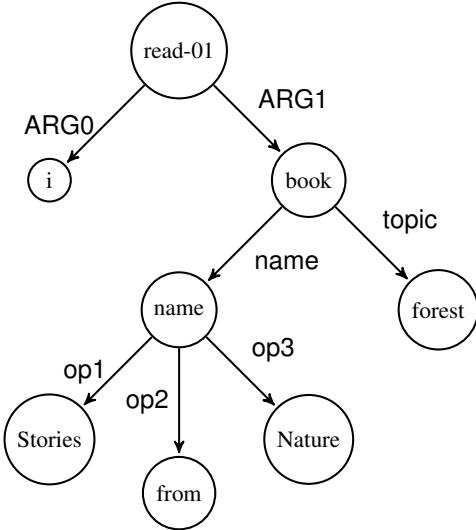

Figure 1: AMR graph for the sentence “*I read a book, called Stories from Nature, about the forest.*”

that control a policy that takes actions in this search space. AMR (Banarescu et al., 2013), in turn, is a structured semantic representation which is a rooted, directed, acyclic graph. The nodes of this graph represent concepts in the given sentence and the edges represent relations between these concepts. As such, the task of predicting AMRs can be naturally placed in the L2S framework. This allows us to model the learning of concepts and relations in a unified setting which aims to minimize the loss over the entire predicted structure.

In the next section, we briefly review DAGGER and explain its various components with respect to our AMR parsing task. Section 3 describes our main algorithm along with the strategies we use to deal with the large search space of the search problem.

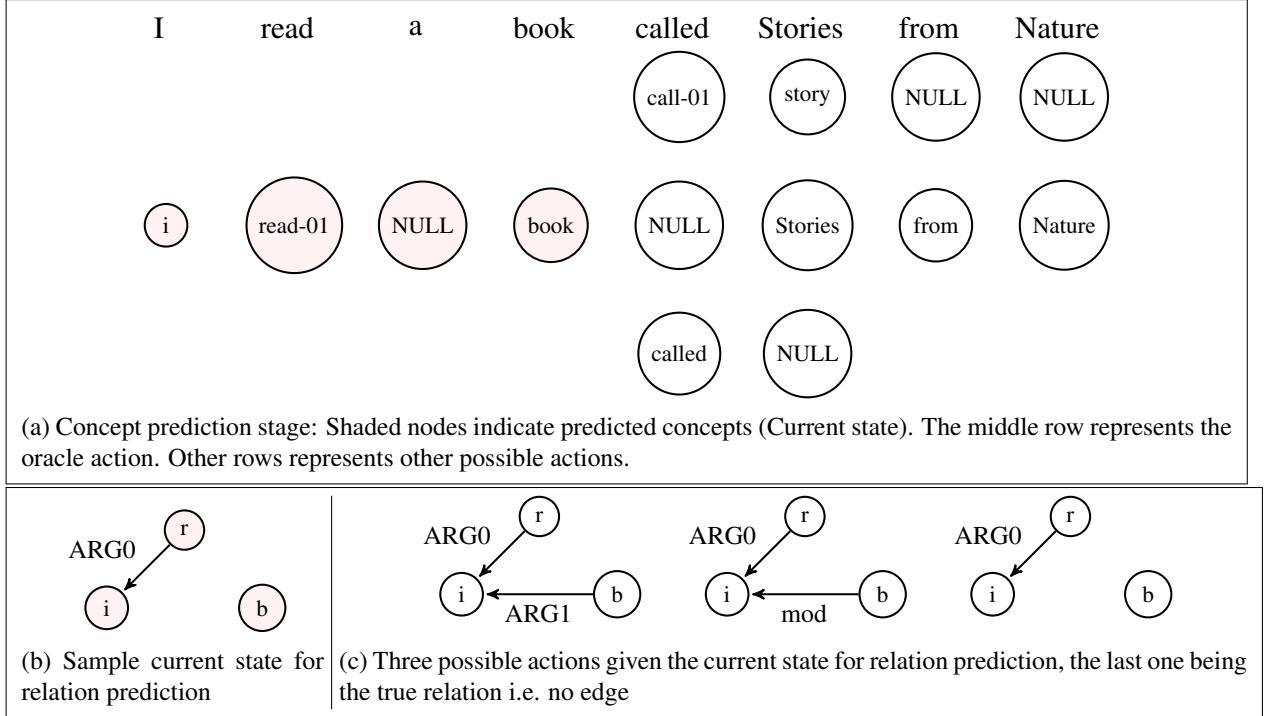

Figure 2: Using DAGGER for AMR parsing

We then describe our experiments and results (Section 4).

## 2 Using L2S for AMR Parsing

L2S works on the notion of a policy which can be defined as “what is the best next action ( $y_i$ ) to take” in a search space given the current state. It starts with an initial policy on a trajectory (called rollin policy), takes a one-step deviation and completes the trajectory with another policy (called the rollout policy). The different variations of L2S are defined based on what kind of policies it uses during rollin and rollout. For example DAGGER uses rollin=learned policy and rollout=reference policy, SEARN uses rollin=rollout=stochastic mixture of reference and learned policy, LOLS uses rollin=learned policy and rollout=stochastic mixture of reference and learned policy.

Next, we describe how we use L2S for AMR parsing. We decompose the full AMR parsing task into three subtasks - that of predicting the concepts, predicting the root, and predicting the relations between the predicted concepts (explained in more detail under section 3). The search space for

concept and relation prediction consists of a state  $s = (x_1, x_2, \dots, x_m, y_1, y_2, \dots, y_{i-1})$ , where the input  $(x_1, x_2, \dots, x_m)$  are the  $m$  words of a sentence.

- During concept prediction, the labels  $(y_1, y_2, \dots, y_{i-1})$  are the concepts predicted up to the index  $(i-1)$  and the next action  $y_i$  is the concept for word  $x_i$  from a  $k$ -best list of concepts. In Figure 2a, the current state corresponds to the concepts  $\{‘i’, ‘read-01’, ‘book’\}$  and the next action is assigning one of  $\{‘call-01’, ‘called’, NULL\}$  to the word ‘called’.
- During relation prediction, the labels are the relations predicted for pairs of concepts obtained during the concept prediction stage. In Figure 2c, the current state corresponds to the relation ‘ARG0’ predicted between ‘r’ and ‘i’ and the next action is assigning one of  $\{‘ARG1’, ‘mod’, NO-EDGE\}$  to the pair of concept ‘b’ and ‘i’.

For the root prediction subtask we train a multi-class classifier which makes a single prediction - that

of choosing the root concept from all the predicted concepts.

Next, we need to define how we learn a policy for AMR parsing. When the reference policy is optimal, it has been shown that it is effective to rollout using the reference policy (Ross and Bagnell, 2014; Chang et al., 2015). This is true for our task and hence we use DAGGER. Below, we explain how we use DAGGER, with a running example in Figure 2.

At training time, DAGGER operates in an iterative fashion. It starts with an initial policy and given an input  $x$ , makes a prediction  $y = y_1, y_2, \dots, y_m$  using the current policy. For each prediction  $y_i$  it generates a set of multi-class classification examples each of which correspond to a possible action the algorithm can take given the current state. Each example can be defined using local features and features that depend on previous predictions. We use a one-against-all classifier to make the multi-class classification decisions.

During training, DAGGER has access to the reference policy. The reference policy during concept prediction is to predict the concept that was aligned to a given span using the JAMR aligner (explained in Section 3.4) For e.g. in Figure 2a, the reference policy is to predict NULL since the span “called” was aligned to NULL by the aligner. The reference policy during relation prediction is to predict the gold edge between two concepts. For e.g. in Figure 2c, the reference policy is to predict NO-EDGE.

DAGGER then calculates the loss between the predicted action and the best action using a pre-specified loss function. It then computes a new policy based on this loss and interpolates it with the current policy to get an updated policy, before moving on to the next iteration. At test time, predictions are made greedily using the policy learned during training.

### 3 Methodology

#### 3.1 Learning technique

We use DAGGER as described in Section 2 to learn a model that can successfully predict the AMR  $y$  for a sentence  $x$ . The sentence  $x$  is composed of a sequence of spans  $(s_1, s_2, \dots, s_n)$  each of which can be a single word or a span of words (We describe how we go from a raw sentence to a sequence of spans

---

#### Algorithm 1

---

```

1: for each span  $s_i$  do
2:    $c_i = predict\_concept(s_i)$ 
3: end for
4:  $c_{root} = predict\_root([c_1, \dots, c_n])$ 
5: for each concept  $c_i$  do
6:   for each  $j < i$  do
7:      $r_{(i,j)} = predict\_relation(c_i, c_j)$ 
8:      $r_{(j,i)} = predict\_relation(c_j, c_i)$ 
9:   end for
10: end for
```

---

in Section 3.4). Given that our input has  $n$  spans, we first decompose the structure into a sequence of  $n^2 + 1$  predictions  $\mathbf{D} = (\mathbf{C}, \mathbf{ROOT}, \mathbf{R})$ , where

$\mathbf{C} = c_1, c_2, \dots, c_n$  - where  $c_i$  is the concept predicted for span  $s_i$

$\mathbf{ROOT}$  is the decision of choosing one of the predicted concepts as the root ( $c_{root}$ ) of the AMR

$\mathbf{R} = r_{2,*}, r_{*,2}, r_{3,*}, r_{*,3}, \dots, r_{n,*}, r_{*,n}$  - where  $r_{i,*}$  are the predictions for the directed relations from  $c_i$  to  $c_j \forall j < i$ , and  $r_{*,i}$  are the predictions for the directed relations from  $c_j$  to  $c_i \forall j < i$ . We constrain our algorithm to not predict any incoming relations to  $c_{root}$ .

During training time, the possible set of actions for each prediction is given by the  $k$ -best list (Section 3.2). We use Hamming Loss as our loss function. Under Hamming Loss, the reference policy is simply choosing the right action for each prediction i.e. choosing the correct concept (relation) during the concept (relation) prediction phase. This loss is defined on the entire predicted output, and hence the model learns to minimize the loss for concepts and relations jointly.

Algorithm 1 describes the sequence of predictions to be made in our problem. We learn three different policies corresponding to each of the functions  $predict\_concept$ ,  $predict\_root$  and  $predict\_relation$ . The learner in each stage uses features that depend on predictions made in the previous stages. Tables 1, 2 and 3 describe the set of features we use for the concept prediction, relation prediction and root prediction stages respectively.

| Feature label                             | Description  |
|---|--|
| $w_{i-2}, w_{i-i}, w_i, w_{i+1}, w_{i+2}$ | Words in $s_i$ and context   |
| $p_{i-2}, p_{i-i}, p_i, p_{i+1}, p_{i+2}$ | POS tags of words in $s_i$ and context   |
| $NE_i$                                    | Named entity tags for words in $s_i$   |
| $s_i$                                     | Binary feature indicating whether $w_i$ is(are) stopword(s)  |
| $dep_i$                                   | All dependency edges originating from words in $w_i$   |
| $b_c$                                     | Binary feature indicating whether $c$ is the most frequently aligned concept with $s_i$ or not                     |
| $c_{i-2}, c_{i-1}$                        | Predicted concepts for two previous spans  |
| $c$                                       | Concept label and its conjunction with all previous features   |
| $frame_i$ and $sense_i$                   | If the label is a PropBank frame (e.g. ‘see-01’, use the frame (‘see’) and the sense(‘01’) as additional features. |

Table 1: Concept prediction features for span  $s_i$  and concept label  $c_i$

| Feature label              | Description  |
|----------------------------|--|
| $c_i, c_j, c_i \wedge c_j$ | The two concepts and their conjunction                     |
| $w_i, w_j, w_i \wedge w_j$ | Words in the corresponding spans and their conjunction     |
| $p_i, p_j, p_i \wedge p_j$ | POS tags of words in spans and their conjunction           |
| $dep_{ij}$                 | All dependency edges with tail in $w_i$ and head in $w_j$  |
| $dir$                      | Binary feature which is true iff $i < j$                   |
| $r$                        | Relation label and its conjunction with all other features |

| Feature label     | Description   |
|-------------------|---|
| $c_i$             | Concept label. If the label is a PropBank frame (e.g. ‘see-01’, use the frame (‘see’) and the sense(‘01’) as additional features. |
| $w_i$             | Words in $s_i$ , i.e. the span corresponding to $c_i$   |
| $p_i$             | POS tags of words in $s_i$  |
| $is\_dep\_root_i$ | Binary feature indicating whether one of the words in $s_i$ is the root in the dependency tree of the sentence                    |

Table 3: Root prediction features for concept  $c_i$

### 3.2 Selecting $k$ -best lists

For predicting the concepts and relations using DAGGER, we need a candidate-list (possible set of actions) to make predictions from.

**Concept candidates:** For a span  $s_i$ , the candidate-list of concepts,  $CL\text{-CON}_{s_i}$  is the set of all concepts that were aligned to  $s_i$  in the entire training data. If  $s_i$  has not been seen in the training data,  $CL\text{-CON}_{s_i}$  consists of the lemmatized span, PropBank frames (for verbs) obtained using the Unified Verb Index (Schuler, 2005) and the NULL concept.

**Relation candidates:** The candidate list of relations for a relation from concept  $c_i$  to concept  $c_j$ ,  $CL\text{-REL}_{ij}$ , is the union of the following three sets:

- $pairwise_{i,j}$  - All directed relations from  $c_i$  to  $c_j$  when  $c_i$  and  $c_j$  occurred in the same AMR,
- $outgoing_i$  - All outgoing relations from  $c_i$ , and
- $incoming_j$  - All incoming relations into  $c_j$ .

In the case when both  $c_i$  and  $c_j$  have not been seen in the training data,  $CL\text{-REL}_{ij}$  consists of all relations seen in the training data. In both cases, we also provide an option NO-EDGE which indicates that there is no relation between  $c_i$  and  $c_j$ .

### 3.3 Pruning the search space

To prune the search space of our learning task, and to improve the quality of predictions, we use two observations about the nature of the edges of the AMR

of a sentence, and its dependency tree (obtained using the Stanford dependency parser (De Marneffe et al., 2006)), within our algorithm.

First, we observe that a large fraction of the edges in the AMR for a sentence are between concepts whose underlying spans (more specifically, the words in these underlying spans) are within two edges of each other in the dependency tree of the sentence. Thus, we refrain from calling the *predict\_relation* function in Algorithm 1 between concepts  $c_i$  and  $c_j$  if each word in  $w_i$  is three or more edges away from all words in  $w_j$  in the dependency tree of the sentence under consideration, and vice versa. This implies that there will be no relation  $r_{ij}$  in the predicted AMR of that sentence. This doesn't affect the number of calls to *predict\_relation* in the worst case ( $n^2 - n$ , for a sentence with  $n$  spans), but practically, the number of calls are far fewer. Also, to make sure that this method does not filter out too many AMR edges, we calculated the percentage of AMR edges that are more than two edges away in dependency tree. We found this number to be only about 5% across all our datasets.

Secondly, and conversely, we observe that for a large fraction of words which have a dependency edge between them, there is an edge in the AMR between the concepts corresponding to those two words. Thus, when we observe two concepts  $c_i$  and  $c_j$  which satisfy this property, we force our *predict\_relation* function to assign a relation  $r_{ij}$  that is not NULL.

### 3.4 Preprocessing

**JAMR Aligner:** The training data for AMR parsing consists of sentences paired with corresponding AMRs. To convert a raw sentence into a sequence of spans (as required by our algorithm), we obtain alignments between words in the sentence and concepts in the AMR using the automatic aligner of JAMR. The alignments obtained can be of three types (Examples refer to Figure 1):

- *A single word aligned to a single concept:* E.g., word ‘read’ aligned to concept ‘read-01’.
- *Span of words aligned to a graph fragment:* E.g., span ‘Stories from Nature’ aligned to the graph fragment rooted at ‘name’. This usually happens for named entities and multiword ex-

pressions such as those related to date and time.

- *A word aligned to NULL concept:* Most function words like ‘about’, ‘a’, ‘the’, etc are not aligned to any particular concept. These are considered to be aligned to the NULL concept.

**Forced alignments:** The JAMR aligner does not align all concepts in a given AMR to a span in the sentence. We use a heuristic to forcibly align these leftover concepts and improve the quality of alignments. For every unaligned concept, we count the number of times an unaligned word occurs in the same sentence with the unaligned concept across all training examples. We then align every leftover concept in every sentence with the unaligned word in the sentence with which it has maximally cooccurred.

**Span identification:** During training time, the aligner takes in a sentence and its AMR graph and splits each sentence into spans that can be aligned to the concepts in the AMR. However, during test time, we do not have access to the AMR graph. Hence, given a test sentence, we need to split the sentence into spans, on which we can predict concepts. We consider each word as a single span except for two cases. First, we detect possible multiword spans corresponding to named entities, using a named entity recognizer (Lafferty et al., 2001). Second, we use some basic regular expressions to identify time and date expressions in sentences.

### 3.5 Connectivity

Algorithm 1 does not place explicit constraints on the structure of the AMR. Hence, the predicted output can have disconnected components. Since we want the predicted AMR to be connected, we connect the disconnected components (if any) using the following heuristic. For each component, we find its roots (i.e. concepts with no incoming relations). We then connect the components together by simply adding an edge from our predicted root  $c_{root}$  to each of the component roots. To decide what edge to use between our predicted root  $c_{root}$  and the root of a component, we get the  $k$ -best list (as described in section 3.2) between them and choose the most frequent edge from it.

| Dataset                | Training | Dev | Test |
|------------------------|----------|-----|------|
| BOLT DF MT             | 1061     | 133 | 133  |
| Broadcast conversation | 214      | 0   | 0    |
| Weblog and WSJ         | 0        | 100 | 100  |
| BOLT DF English        | 6455     | 210 | 229  |
| Guidelines AMRs        | 689      | 0   | 0    |
| 2009 Open MT           | 204      | 0   | 0    |
| Proxy reports          | 6603     | 826 | 823  |
| Weblog                 | 866      | 0   | 0    |
| Xinhua MT              | 741      | 99  | 86   |

Table 4: Dataset statistics. All figures represent number of sentences.

### 3.6 Acyclicity

The post-processing step described in the previous section ensures that the predicted AMRs are rooted, connected, graphs. However, an AMR, by definition, is also acyclic. We do not model this constraint explicitly within our learning framework. Despite this, we observe that only a very small number of AMRs predicted using our fully automatic approach have cycles in them. Out of the total AMRs predicted in all test sets, less than 5% have cycles in them. Besides, almost all cycles that are predicted consist of only two nodes, i.e. both  $r_{ij}$  and  $r_{ji}$  have non-NO-EDGE values for concepts  $c_i$  and  $c_j$ . To get an acyclic graph, we can greedily select one of  $r_{ij}$  or  $r_{ji}$ , without any loss in parser performance.

## 4 Experiments and Results

The primary corpus for this shared task is the AMR Annotation Release 1.0 (LDC2015E86). This corpus consists of datasets from varied domains such as online discussion forums, blogs, and newswire, with about 19,000 sentence-AMR pairs. All datasets have a pre-specified training, dev and test split (Table 4).

We trained three systems. The first was trained on all available training data. The two other systems were trained using data from a single domain. Specifically, we chose *BOLT DF English* and *Proxy reports* since these are the two largest training datasets individually. The system trained on the *Proxy reports* dataset performed the best when evaluated on the dev set. Hence we used this system as our primary system for the task. Additionally, we use DAGGER as implemented in the Vowpal Wab-

bit machine learning library (Langford et al., 2007; Daumé III et al., 2014).

The evaluation of predicted AMRs is done using Smatch (Cai and Knight, 2013)<sup>1</sup>, which compares two AMRs using precision, recall and  $F_1$ . Our system obtained a Smatch  $F_1$  score of 0.46 with a *Precision* of 0.51 and a *Recall* of 0.43 on the test set in the Shared Task (We made a tokenization error during the actual semeval submission and so reported an  $F_1$  score of 0.44 instead). The mean  $F_1$  score of all systems submitted to the shared task was 0.55 and the standard deviation was 0.06.

## 5 Conclusion and Future work

We have presented a novel technique for parsing English sentences into AMR using DAGGER, a Learning to Search algorithm. We decompose the AMR parsing task into subtasks of concept prediction, root prediction and relation prediction. Using Learning to Search allows us to use past predictions as features for future predictions and also define a combined loss over the entire AMR structure. Additionally, we use a  $k$ -best candidate list constructed from the training data to make predictions from. To prune the large search space, we incorporate useful heuristics based on the dependency parse of the sentence. Our system is available for download<sup>2</sup>.

Currently we ensure various properties of AMR, such as connectedness and acyclicity using heuristics. In the future, we plan to incorporate these as constraints in our learning technique.

## Abstract

We describe the system used in our participation in the AMR Parsing task for SemEval-2016. Our parser does not rely on a syntactic pre-parse, or heavily engineered features, and uses five recurrent neural networks as the key architectural components for estimating AMR graph structure.

## 1 Introduction

Abstract Meaning Representation, or AMR (Banarescu et al., 2012) is a graph-based representation of the meaning of sentences which incorporates linguistic phenomena such as semantic roles, coreference, negation, and more.<sup>1</sup>

The process of creating AMR’s for sentences is called AMR Parsing. We used an early version of the system described in this paper to generate our submission to the Semeval-2016 Meaning Representation Parsing Task.<sup>2</sup>

The details of our system will be explained using this example sentence: ***France plans further nuclear cooperation with numerous countries***. A graphical depiction is shown in Figure 1.

The system extracts features from the sentence which are processed by a form of recurrent neural network called BDLSTM to create a set of AMR concepts. Features from these concepts are processed by a pair of BDLSTM networks to compute relation probabilities. All concepts are then connected using an iterative, greedy algorithm to compute the set of relations in the AMR. Another two

BDLSTM networks compute attribute and name categories to complete the estimation of AMR element probabilities.

## 2 Related Work

Most current AMR parsers assume input that has undergone varying degrees of syntactic analysis, ranging from simple part-of-speech tagging to more complex dependency or phrase-structure analysis. (Wang et al., 2015; Vanderwende et al., 2015; Peng et al., 2015; Pust et al., 2015; Artzi et al., 2015; Flanigan et al., 2014; Werling et al., 2015). In contrast, we follow the spirit of minimal feature extraction using pre-trained word embeddings, as in (Collobert et al., 2011) and a recurrent network architecture similar to that described in (Zhou and Xu, 2015).

## 3 System Architecture

### 3.1 Feature Extraction

In our system, all features are represented by embedding vectors, trained and stored in lookup tables. Word feature embeddings are mapped from the words in the sentence, and are trained with back propagation just like other parameters in the network. They are initialized with vectors which are pre-trained on large corpora of english text, we use the word embeddings from (Collobert et al., 2011).

The only explicit features not derived from the raw input are features based on named entity recognition (NER). We first use the Univ. of Illinois Wikifier to find and classify named entities and then encode these features as embeddings.

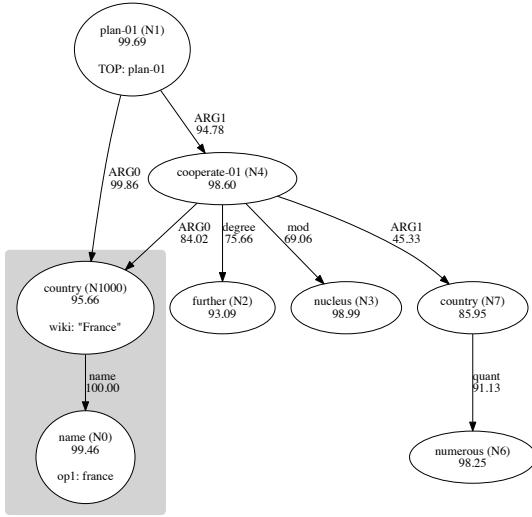

Figure 1: Graphical Representation of the Reference AMR (annotated with probabilities expressed as percentage.)

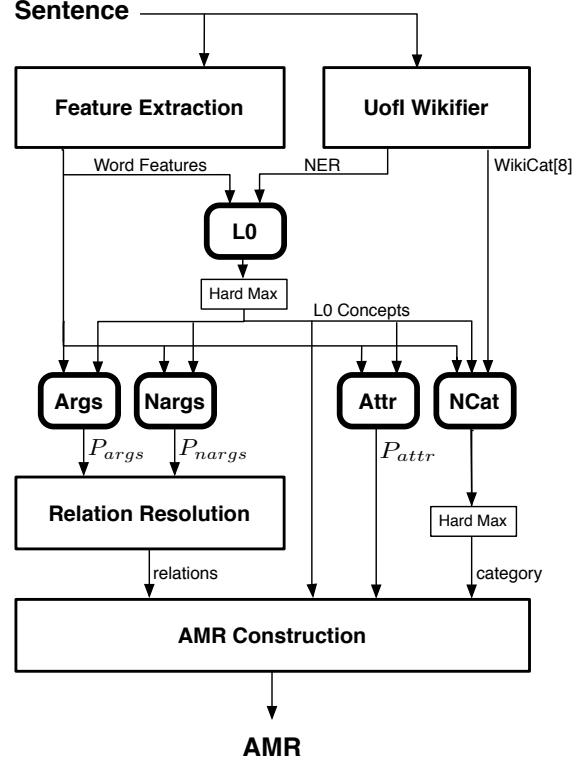

Figure 2: AMR Parser Architecture, BDLSTM networks in bold.

### 3.2 Neural Networks

Unlike relatively simple sequence processing tasks like part-of-speech tagging and NER, semantic analysis requires the ability to keep track of relevant information that may be arbitrarily far away from the words currently under consideration. Fortunately, recurrent neural networks (RNNs) are a class of neural architecture that use a form of short-term memory in order to solve this semantic distance problem. Basic RNN systems have been enhanced with the use of special memory cell units, referred to as Long Short-Term Memory neural networks, or LSTM's (Hochreiter and Schmidhuber, 1997). Such systems can effectively process information dispersed over hundreds of words (Schmidhuber et al., 2002; Gers et al., 2001).

Bidirectional LSTMs (BDLSTM) networks are LSTMs that are connected so that both future and past words in the sentence can be examined. We use the LSTM cell as described in (Graves et al., 2013), Figure 3, configured in a Bi-directional structure, called BDLSTM (Zhou and Xu, 2015), shown in Figure 4 as the core network in our system. Five BDLSTM Neural Networks comprise our parser.

#### 3.2.1 Level 0 Concepts BDLSTM Network (L0)

The first step in our process is to create the set of concepts (nodes) that form the basis for any AMR representation; we call these Level 0, or L0, concepts. For the most part in current AMR training data, these concepts are in a direct relationship to words and sequences of words in a sentence. The task of the L0 network is, therefore, to take the input sequence of words and produce an output sequence of IOB tags that identify and classify the concepts in the AMR output.

For training, AMR concepts are first aligned to words using an AMR-to-word alignment algorithm. We used the alignment provided in the SemEval dataset. In cases where multiple concepts are associated with the same word, we use only the lower level concept and ignore upper level concept(s).

The system classifies each L0 concept as predicate or non-predicate, and predicts the PropBank sense for the predicates. AMR concepts are either

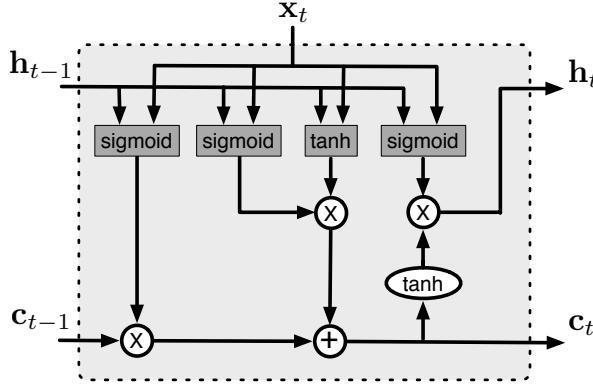

Figure 3: LSTM Cell.

An “unrolled” representation of an LSTM Cell. Rectangles represent linear layers followed by the labelled non-linearity. Each cell learns how to weigh, or gate, the input, previous cell memory, and output.

English words (boy), PropBank framesets (plan-01), or special keywords. A translation table was created from training data by calculating the most probable AMR concept, given the sentence word and the general concept identifier.

The most common multilevel cases, a subgraph composed of a named entity, its related category, and a wiki link when available, are identified as exceptions and tagged as name concepts, which will be expanded.<sup>3</sup>

The features used in the L0 network are:

- word: 130Kx50, the word embedding
- suffix: 430x5, embedding based on the final two letters of each word.
- caps: 5x5, embedding based on the capitalization pattern of the word.
- NER: 5x5, indexed by NER from the Wikifier, ‘O’, ‘LOC’, ‘ORG’, ‘PER’ or ‘MISC’.

The L0 Network produces probabilities for 19 BIOES tagged concept types, and the highest probability tag is chosen for each word, as shown for the example sentence in Table 1.

### 3.2.2 Predicate Argument Relations BDLSTM Network (Args)

The Args Network is run once for each predicate concept, and produces a matrix  $P_{args}$  which defines

<sup>3</sup>For example *France* in the shaded section of Figure 1.

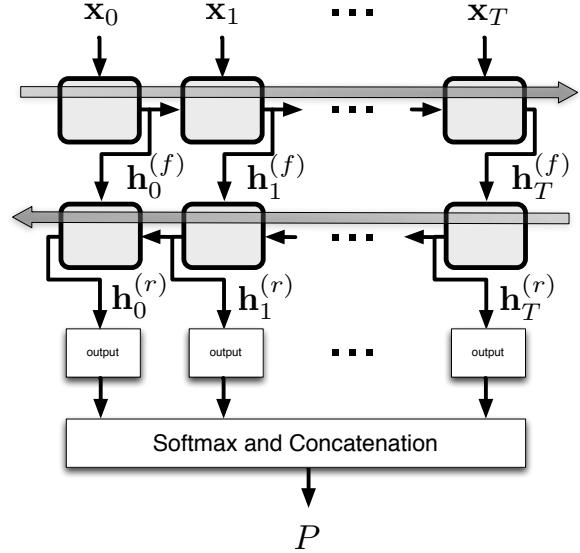

Figure 4: Bi-Directional LSTM.

A general diagram of a BDLSTM network, showing the feature input vectors  $x_i$ , the forward layer (f) and the reverse layer (r). The network generates vectors of log likelihoods which are converted to an array of probabilities.

the probability of a type of predicate argument relation from an L0 predicate concept to any other L0 concept. (See, for example, ARG0 and ARG1 relations in Figure 1.), prior to the identification of any relations.<sup>4</sup> The matrix has dimensions  $a$  by  $c$ , where  $a$  is the number of non-arg relations to be identified, and  $c$  is the total number of concepts.

The Args features, calculated for each source predicate concept, are:

<sup>4</sup>relation probabilities change as hard decisions are made, see section 3.4

| words       | BIOES     | Prob  | kind         |
|-------------|-----------|-------|--------------|
| France      | S_Named   | 0.995 | txNamed      |
| plans       | S_Pred-01 | 0.997 | plan-01      |
| further     | S_NonPred | 0.931 | further      |
| nuclear     | S_NonPred | 0.990 | nucleus      |
| cooperation | S_Pred-01 | 0.986 | cooperate-01 |
| with        | O         | 1.000 | O            |
| numerous    | S_NonPred | 0.982 | numerous     |
| countries   | S_NonPred | 0.860 | country      |
| .           | O         | 0.999 | O            |

Table 1: L0 Network Example Output

- Word, Suffix and Caps as in the L0 network.
- L0: 19x5, indexed by the L0 network identified concept.
- PredWords[5], 130Kx50: The word embeddings of the word and surrounding 2 words associated with the source predicate concept.
- PredL0[5], 19x10: The L0 embedding of the word and surrounding 2 words associated with the source predicate concept.
- regionMark: 21x5, indexed by the distance in words between the word and the word associated with the source predicate concept.

### 3.2.3 Non-Predicate Relations BDLSTM Network (Nargs)

The Nargs Network uses features similar to the Args network, is run once for each concept, and produces a matrix  $P_{nargs}$  which defines the probability of a type of relation from an L0 concept to any other L0 concept, prior to the identification of any relations.<sup>5</sup> The matrix has dimensions  $a_n$  by  $c$ , where  $a_n$  is the number of non-arg relations to be identified, and  $c$  is the total number of concepts.

### 3.2.4 Attributes BDLSTM Network (Attr)

The Attr Network determines a primary attribute for each concept, if any.<sup>6</sup> The attributes (op words) associated with named entities are determined directly during L0 concept identification. This network is simplified to detect only one attribute (there could be many) per concept, and only computes probabilities for the most common attributes: TOP, polarity, and quant.

### 3.2.5 Named Category BDLSTM Network (NCat)

The NCat Network uses features similar to the L0 Network, along with the suggested categories (up to eight) from the Wikifier, and produces probabilities for each of 68 :instance roles, or categories, for named entities identified in the training set AMR’s.

- Word, Suffix and Caps as in the L0 network.
- WikiCat[8]: 108 x 5, indexed by suggested categories from the Wikifier.

<sup>5</sup>Degree, mod, or quant are examples of narg relations in Figure 1.

<sup>6</sup>(TOP: plan-01) and (op1: france) are attribute examples shown in Figure 1.

| Semeval Task 8 Dataset | Smatch F1 |
|------------------------|-----------|
| Test                   | 66.1%     |
| Evaluation             | 56.0%     |

Table 2: Smatch F1 results for Test and Eval Datasets

### 3.3 Wikifier

Named entities in AMR are annotated with a canonical form, using Wikipedia as the standard (see *France* in Figure 1). A :wiki role, or link, should be provided if an appropriate wikipedia page exists, root category (or top-level :instance role) should also be provided. To determine these fields, prior to running the L0 network, we run the sentences through the University of Illinois Wikifier (Ratinov et al., 2011; Cheng and Roth, 2013) which provides a wiki link and a list of possible categories. We insert the link directly as a :wiki role, and use the possible categories as feature inputs to the NCat Network.

### 3.4 Relation Resolution

The generated  $P_{args}$  and  $P_{nargs}$  for each L0 identified concept are processed to determine the most likely relation connections, using the constraints:

1. AMR’s are single component graphs without cycles.
2. AMR’s are simple directed graphs, a max of one relation between concepts is allowed.
3. Outgoing predicate relations are limited to one of each kind (i.e. can’t have two ARG0’s)

We apply a greedy algorithm which repeatedly selects the most probable edge from  $P_{args}$  and  $P_{nargs}$ , then adjusts  $P_{args}$  and  $P_{nargs}$  based on the constraints (hard decisions change the probabilities), until all edge probabilities are below a threshold. From then on, only the most probable edges which span subgraphs are chosen, until the graph contains a single component.

## 4 Results

Semeval task 8 provides aligned, split datasets. Our Smatch F1 result for the test dataset was 66.1%, and 56.0% for the eval dataset (Table 2). Reportedly, the eval dataset is more challenging than the provided test dataset. The mean of all task 8 results for the eval dataset is 55% with a standard deviation of 6%, more detail is not yet available.

## 5 Conclusion

In this paper, we have described our submission to the AMR Parsing task for SemEval-2016. Our parser does not make use of a syntactic pre-parse, and avoids the use of heavily engineered features. Future work will include expanding the identification of concepts and exploring the use of more sophisticated alignments and word embeddings.

## Abstract

We present improvements to the JAMR parser as part of the SemEval 2016 Shared Task 8 on AMR parsing. The major contributions are: improved concept coverage using external resources and features, an improved aligner, and a novel loss function for structured prediction called infinite ramp, which is a generalization of the structured SVM to problems with unreachable training instances.

## 1 Introduction

Our entry to the SemEval 2016 Shared Task 8 is a set of improvements to the system presented in Flanigan et al. (2014). The improvements are: a novel training loss function for structured prediction, which we call “infinite ramp,” new sources for concepts, improved features, and improvements to the rule-based aligner in Flanigan et al. (2014). The overall architecture of the system and the decoding algorithms for concept identification and relation identification are unchanged from Flanigan et al. (2014), and we refer readers seeking a complete understanding of the system to that paper.

## 2 New Concept Fragment Sources and Features

The concept identification stage relies on a function called *clex* in Section 3 of Flanigan et al. (2014) to provide candidate concept fragments. In that work, *clex* has three sources of concept fragments: a lexicon extracted from the training data, rules for named entities identified by the named entity tagger,

and rules for time expressions. We augment these sources with five additional sources:

- **Frame file lookup:** for every word in the input sentence, if the lemma matches the name of a frame in the AMR frame files (with sense tag removed), we add the lemma concatenated with “-01” as a candidate concept fragment.
- **Lemma:** for every word in the input sentence, we add the lemma of the word as a candidate concept fragment.
- **Verb pass-through:** for every word in the input sentence, if the word is a verb, we add the lemma concatenated with “-00” as a candidate concept fragment.
- **Named entity pass-through:** for every span of words of length 1 until 7 in the input, we add the concept fragment “(thing :name (name :op1 word1 … :opn wordn)” as a candidate concept fragment, where  $n$  is the length of the span, and “word1” and “wordn” are the first and last words in the fragment.

We use the following features for concept identification:

- **Fragment given words:** Relative frequency estimates of the probability of a concept fragment given the sequence of words in the span.
- **Length** of the matching span (number of tokens).
- **Bias:** 1 for any concept graph fragment.

- **First match:** 1 if this is the first place in the sentence that matches the span.
- **Number:** 1 if the span is length 1 and matches the regular expression “[0-9]+”.
- **Short concept:** 1 if the length of the concept fragment string is less than 3 and contains only upper or lowercase letters.
- **Sentence match:** 1 if the span matches the entire input sentence.
- **;** **list:** 1 if the span consists of the single word “;” and the input sentence is a “;” separated list.
- **POS:** the sequence of POS tags in the span.
- **POS and event:** same as above but with an indicator if the concept fragment is an event concept (matches the regex “.\*-[0-9][0-9]”).
- **Span:** the sequence of words in the span if the words have occurred more than 10 times in the training data as a phrase with no gaps.
- **Span and concept:** same as above concatenated with the concept fragment in PENMAN notation.
- **Span and concept with POS:** same as above concatenated with the sequence of POS tags in the span.
- **Concept fragment source:** indicator for the source of the concept fragment (corpus, NER tagger, date expression, frame files, lemma, verb-pass through, or NE pass-through).
- **No match from corpus:** 1 if there is no matching concept fragment for this span in the rules extracted from the corpus.

The new sources of concepts complicate concept identification training. The new sources improve concept coverage on held-out data but they do not improve coverage on the training data since one of the concept sources is a lexicon extracted from the training data. Thus correctly balancing use of the training data lexicon versus the additional sources to prevent overfitting is a challenge.

To balance the training data lexicon with the other sources, we use a variant of cross-validation. During training, when processing a training example in the training data, we exclude concept fragments extracted from the same section of the training data. This is accomplished by keeping track of the training instances each phrase-concept fragment pair was extracted from, and excluding all phrase-concept fragment pairs within a window of the current training instance. In our submission the window is set to 20.

While excluding phrase-concept fragment pairs allows the learning algorithm to balance the use of the training data lexicon versus the other concept sources, it creates another problem: some of the gold standard training instances may be unreachable (cannot be produced), because of the phrase-concept pair need to produce the example has been excluded. This can cause problems during learning. To handle this, we use a generalization of structured SVMs which we call “infinite ramp.” We discuss this in the general framework of structured prediction in the next section.

### 3 Infinite Ramp Loss

The infinite ramp is a new loss function for structured prediction problems. It is useful when the training data contains outputs that the decoder cannot produce given their inputs (we refer to these as “**unreachable examples**”). It is a direct generalization of the SVM loss and latent SVM loss.

Let  $x$  be the input,  $\mathcal{Y}(x)$  be the space of all possible outputs given the input  $x$ , and  $\hat{y}$  be the predicted output. Let  $\mathbf{f}(x, y')$  denote the feature vector for the output  $y'$  with the input  $x$ , which is the sum of the local features. (In concept identification, the local features are the features computed for each span, and  $\mathbf{f}$  is the sum of the features for each span.) Let  $\mathbf{w}$  be the parameters of a linear model, used to make predictions as follows:

$$\hat{y} = \arg \max_{y' \in \mathcal{Y}(x)} \mathbf{w} \cdot \mathbf{f}(x, y')$$

To train the model parameters  $\mathbf{w}$ , a function of the training data is minimized with respect to  $\mathbf{w}$ . This function is a sum of individual training examples’ losses  $L$ , plus a regularizer:

$$L(\mathcal{D}; \mathbf{w}) = \sum_{(x_i, y_i) \in \mathcal{D}} L(x_i, y_i; \mathbf{w}) + \lambda \|\mathbf{w}\|^2$$

$$L(x_i, y_i; \mathbf{w}) = - \left( \lim_{\alpha \rightarrow \infty} \max_{y \in \mathcal{Y}(x_i)} \left( \mathbf{w} \cdot \mathbf{f}(x_i, y) + \alpha \cdot \underbrace{\left[ \min_{y'' \in \mathcal{Y}(x_i)} \overbrace{cost(y_i, y'')}^{C(x_i, y_i)} - cost(y_i, y) \right]}_{\text{ramp}} \right) \right) \\ + \max_{y' \in \mathcal{Y}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, y') + cost(y_i, y')) \quad (1)$$

Figure 1: Infinite ramp loss.

Typical loss functions are the **structured perceptron loss** (Collins, 2002):

$$L(x_i, y_i; \mathbf{w}) = -\mathbf{w} \cdot \mathbf{f}(x_i, y_i) + \max_{y \in \mathcal{Y}(x_i)} \mathbf{w} \cdot \mathbf{f}(x_i, y) \quad (2)$$

and the **structured SVM loss** (Taskar et al., 2003; Tsoucharidis et al., 2004), which incorporates margin using a cost function:<sup>1</sup>

$$L(x_i, y_i; \mathbf{w}) = -\mathbf{w} \cdot \mathbf{f}(x_i, y_i) + \max_{y \in \mathcal{Y}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, y) + cost(y_i, y)) \quad (3)$$

Both (2) and (3) are problematic if example  $i$  is unreachable, i.e.,  $y_i \notin \mathcal{Y}(x_i)$ , due to imperfect data or an imperfect definition of  $\mathcal{Y}$ . In this case, the model is trying to learn an output it cannot produce. In some applications, the features  $\mathbf{f}(x_i, y_i)$  cannot even be computed for these examples. This problem is well known in machine translation: some examples cannot be produced by the phrase-table or grammar. It also occurs in AMR parsing.

To handle unreachable training examples, we modify (3), introducing the **infinite ramp loss**, shown in Eq. 1 in Fig. 1. The term labeled  $C(x_i, y_i)$  is present only to make the limit well-defined in case  $\min_{y \in \mathcal{Y}(x_i)} cost(y_i, y) \neq 0$ . In practice, we set  $\alpha$  to be a very large number ( $10^{12}$ ) instead of taking a proper limit, and set  $C(x_i, y_i) = 0$ .

The intuition behind Eq. 1 is the following: for very large  $\alpha$ , the first max picks a  $y$  that minimizes  $cost(y_i, y)$ , using the model score  $\mathbf{w} \cdot \mathbf{f}(x_i, y)$  to break any ties. This is what the model updates *towards* in subgradient descent-style updates, called the “hope derivation” by Chiang (2012). The second max is the usual cost augmented decoding that gives

<sup>1</sup>  $cost(y_i, y)$  returns the cost of mistaking  $y$  for correct output  $y_i$ .

a margin in the SVM loss, and is what the model updates *away from* in subgradient descent, called the “fear derivation” by Chiang (2012).

Eq. 1 generalizes the structured SVM loss. If  $y_i$  is reachable and the minimum over  $y \in \mathcal{Y}(x_i)$  of  $cost(y, y_i)$  occurs when  $y = y_i$ , then the first max in Eq. 1 picks out  $y = y_i$  and Eq. 1 reduces to the structured SVM loss.

The infinite ramp is also a generalization of the latent structured SVM (Yu and Joachims, 2009), which is a generalization of the structured SVM for hidden variables. This loss can be used when the output can be written  $y_i = (\tilde{y}_i, h_i)$ , where  $\tilde{y}_i$  is observed output and  $h_i$  is latent (even at training time). Let  $\tilde{\mathcal{Y}}(x_i)$  be the space of all possible observed outputs and  $\mathcal{H}(x_i)$  be the hidden space for the example  $x_i$ . Let  $\tilde{c}$  be the cost function for the observed output. The **latent structured SVM loss** is:

$$L(x_i, y_i; \mathbf{w}) = -\max_{h \in \mathcal{H}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, \tilde{y}_i, h)) \\ + \max_{\tilde{y} \in \tilde{\mathcal{Y}}(x_i)} \max_{h' \in \mathcal{H}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, \tilde{y}, h) + \tilde{c}(\tilde{y}_i, \tilde{y})) \quad (4)$$

If we set  $cost(y_i, y) = \tilde{c}(\tilde{y}_i, \tilde{y})$  in Eq. 1, and the minimum of  $\tilde{c}(\tilde{y}_i, \tilde{y})$  occurs when  $\tilde{y} = \tilde{y}_i$ , then minimizing Eq. 1 is equivalent to minimizing Eq. 4.

Eq. 1 is related to **ramp loss** (Collobert et al., 2006; Chapelle et al., 2009; Keshet and McAllester, 2011):

$$L(x_i, y_i; \mathbf{w}) = \\ -\max_{y \in \mathcal{Y}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, y) - \alpha \cdot cost(y_i, y)) \\ + \max_{y' \in \mathcal{Y}(x_i)} (\mathbf{w} \cdot \mathbf{f}(x_i, y') + cost(y_i, y')) \quad (5)$$

The parameter  $\alpha$  is often set to zero, and controls the “height” of the ramp, which is  $\alpha + 1$ . Taking

$\alpha \rightarrow \infty$  in Eq. 5 corresponds roughly to Eq. 1, hence the name ‘‘infinite ramp loss’’. However, Eq. 1 also includes  $C(x_i, y_i)$  term to make the limit well defined even when  $\min_{y \in \mathcal{Y}(x_i)} cost(y_i, y) \neq 0$ . Like infinite ramp loss, ramp loss also handles unreachable training examples (Gimpel and Smith, 2012), but we have found ramp loss to be more difficult to optimize than infinite ramp loss in practice due to local minima. Both loss functions are non-convex. However, infinite ramp loss is convex if  $\arg \min_{y \in \mathcal{Y}(x_i)} cost(y_i, y)$  is unique.

## 4 Training

We train the concept identification stage using infinite ramp loss (1) with AdaGrad (Duchi et al., 2011). We process examples in the training data  $((x_1, y_1), \dots, (x_N, y_N))$  one at a time. At time  $t$ , we decode with the current parameters and the cost function as an additional local factor to get the two outputs:

$$h^t = \arg \max_{y' \in \mathcal{Y}(x_t)} (\mathbf{w}^t \cdot \mathbf{f}(x_t, y') - \alpha \cdot cost(y_i, y)) \quad (6)$$

$$f^t = \arg \max_{y' \in \mathcal{Y}(x_t)} (\mathbf{w}^t \cdot \mathbf{f}(x_t, y') + cost(y_i, y)) \quad (7)$$

and compute the subgradient:

$$\mathbf{s}^t = \mathbf{f}(x_t, h^t) - \mathbf{f}(x_t, f^t) - 2\lambda \mathbf{w}^t$$

We then update the parameters and go to the next example. Each component  $i$  of the parameters gets updated as:

$$w_i^{t+1} = w_i^t - \frac{\eta}{\sqrt{\sum_{t'=1}^t s_i^{t'}}} s_i^t$$

## 5 Experiments

We evaluate using Smatch (Cai and Knight, 2013). Following the recommended train/dev./test split of LDC2015E86, our parser achieves 70% precision, 65% recall, and 67%  $F_1$  Smatch on the LDC2015E86 test set. The JAMR baseline on this same dataset is 55%  $F_1$  Smatch, so the improvements are quite substantial. On the SemEval 2016 Task 8 test set, our improved parser achieves 56%  $F_1$  Smatch.

We hypothesize that the lower performance of the parser on the SemEval Task 8 test set is due to drift in

the AMR annotation scheme between the production of the LDC2015E86 training data and the SemEval test set. During that time, there were changes to the concept senses and the concept frame files. Because the improvements in our parser were due to boosting recall in concept identification (and using the frame files to our advantage), our approach does not show as large improvements on the SemEval test set as on the LDC2015E86 test set.

## 6 Conclusion

We have presented improvements to the JAMR parser as part of the SemEval 2016 Shared Task on AMR parsing, showing substantial improvements over the baseline JAMR parser. As part of these improvements, we introduced infinite ramp loss, which generalizes the structured SVM to handle training data with unreachable training examples. We hope this loss function will be useful in other application areas as well.

## Abstract

This paper is a description of our system developed for SemEval-2016 Task 9: Chinese Semantic Dependency Parsing. We have built a transition-based dependency parser with online reordering, which is not limited to a tree structure and can produce 99.7% of the necessary dependencies while maintaining linear algorithm complexity. To improve parsing quality we used additional techniques such as pre- and post-processing of the dependency graph, bootstrapping and a rich feature set with additional semantic features.

## 1 Introduction

Dependency parsing is one of the core tasks in natural language processing, as it provides useful information for other NLP tasks. Traditional syntactic parsing usually represents a sentence as a tree-shape structure and this restriction is essential for most of efficient algorithms developed in the past years. Semantic dependency parsing, on the other hand, deals with acyclic graphs, where words may have multiple incoming dependencies. It significantly complicates the task and requires development of the new algorithms or special adoption of the old ones.

There are two main approaches to dependency parsing (Nivre and McDonald, 2008). The first one is a graph-based approach, for example, spanning tree algorithms (McDonald et al., 2005), where the goal is to find the highest scoring tree from a com-

plete graph of dependencies between words in the sentence. The second approach is transition-based, which, instead of searching for global optimum, greedily finds local optimum with a chain of actions that lead to a parsing tree. The main advantage of the transition-based parsers is that they are in general faster than graph-based ones because of the linear complexity of the algorithm (Nivre, 2003).

As we move from syntactic parsing to semantic parsing, and instead of projective trees have to deal with acyclic graphs, exact inference becomes NP-hard, so some strong independence assumptions or heuristics are needed. A lot of modifications have been proposed for transition-based parsers to support non-projective structures. Nivre and Nilsson (2005) proposed a pseudo-projective parsing technique which consists in modifying the input into a projective dependency tree with extended labels, performing the projective parsing and then applying an approximate back transformation. Attardi (2006) introduced additional actions that add dependencies between the roots of non-adjacent subtrees. Both techniques maintain linear algorithm complexity at the expense of incomplete coverage of all possible dependency trees. Complete coverage of all non-projective trees is achieved by Nivre (2009) with a technique called *on-line reordering* but it increases the worst-case complexity from linear to quadratic.

## 2 System Description

The core of our system is a transition-based dependency parser with on-line reordering in style of Titov et al., (2009). It continues the tradition of At-

tardi (2006) by extending the action-set of the model, but adds only one new action. While this model is not enough to parse any arbitrary structure, it still can successfully reproduce 99.72% of the dependencies in the “sdpv2” corpus and 99.78% of the dependencies in the “text” corpus.

## 2.1 Parsing Algorithm

The state of the parser is defined by the current stack  $S$ , the queue  $I$  of remaining input sentence words, and partial dependency graph constructed by previous actions. The parser starts with artificial  $TOP$  node in  $S$  and all input words in  $I$ . The processing terminates when a state with an empty queue is reached. Parser can change its state with one of the five possible actions:

- Action *Left-Arc* adds a dependency arc from the first word in queue to the word on top of the stack
- Action *Right-Arc* adds a dependency arc from the word on top of the stack to the first word in queue
- Action *Reduce* removes the word from the top of the stack
- Action *Shift* moves the first word from the queue to the stack.
- Action *Swap* swaps two words at the top of the stack.

With additional limitation on the number of times *Swap* operation can be performed for each node, parser with this action set has a linear time complexity.

To convert gold dependencies into gold actions, the following algorithm is used for each state of the parser:

- If stack is empty, perform *Shift* action.
- If the word on the top of the stack has no incoming or outgoing dependencies or the rightmost dependency is located to the left of the first word in the queue, perform *Reduce* action.
- If the rightmost dependency of the word on top of the stack is equal to the first word in queue, but this dependency is already present

in the partial dependency graph, perform *Reduce* action.

- If there is a dependency arc between the top of the stack and the first word in queue and it is not present in the partial dependency graph, perform *Left-Arc* or *Right-Arc* action according to the direction of dependency.
- If the size of the stack is less than two, or two top words in the stack in the same order were already swapped, perform *Shift* action.
- If there is a dependency arc between the second word in stack and the first word in the queue, and it is not present in the partial dependency graph, perform *Swap* action
- Otherwise, perform *Shift* action.

After that, the obtained gold actions are used to train a log-linear classifier with the following set of features:

- Words in stack and queue:  $W(S_0)$ ,  $W(S_1)$ ,  $W(S_2)$ ,  $W(I_0)$ ,  $W(I_1)$ ,  $W(I_2)$
- POS tags:  $T(S_0)$ ,  $T(S_1)$ ,  $T(S_2)$ ,  $T(I_0)$ ,  $T(I_1)$ ,  $T(I_2)$
- Words of the last left child(LC), last right child(RC) and last parent(P) in the partial dependency graph for words in stack and queue:  $W(LC\_S_0)$ ,  $W(RC\_S_0)$ ,  $W(P\_S_0)$ ,  $W(LC\_S_1)$ ,  $W(RC\_S_1)$ ,  $W(P\_S_1)$ ,  $W(LC\_I_0)$ ,  $W(P\_I_0)$
- POS tags of LC, RC and P:  $T(LC\_S_0)$ ,  $T(RC\_S_0)$ ,  $T(P\_S_0)$ ,  $T(LC\_S_1)$ ,  $T(RC\_S_1)$ ,  $T(P\_S_1)$ ,  $T(LC\_I_0)$ ,  $T(P\_I_0)$
- The number of left children, right children and parents:  $N(LC\_S_0)$ ,  $N(RC\_S_0)$ ,  $N(P\_S_0)$ ,  $N(LC\_I_0)$ ,  $N(P\_I_0)$
- Previous action: PA
- Information about existing arcs in partial dependency graph:  $A(S_0, I_0)$ ,  $A(S_1, I_0)$
- Distance between words:  $D(S_0, I_0)$ ,  $D(S_1, S_0)$

- Various combinations of the above features, for example: W(I0)+T(I0), W(S0)+W(I0), T(S3)+T(S2)+T(S1)+T(I0)+T(I1) and other.

One more log-linear classifier is used to set a semantic label to the dependency. The feature set is similar to the one described above, but instead of words in the stack and the queue this model uses a parent and a child of the dependency arc in question.

## 2.2 Bootstrapping

Transition-based parsers use history to predict the next action. In our system the words in the stack, queue and partial dependency graph are used as features of the log-linear classifier. While it is the source of useful information (when past actions are correct), it is also the source of errors (when past actions are incorrect). If statistical model is trained only on gold parses, it has little possibility to recover from mistakes, because it will have to predict next decisions from a state that was never encountered during training. To reduce the gap between gold and real-life parser configurations, Choi and Palmer (2011) proposed to use bootstrapping on automatic parses. In this approach a model trained on gold configurations is used to parse training corpus and generate new training instances, where the current configuration is achieved by automatic parsing.

In our system we split training corpus into 10 parts and parse each part with a model trained with other 9 parts to be as close to real-life as possible. After that a new model is trained with both gold training instances and bootstrapped training instances.

## 2.3 Semantic Features

To analyze the influence of different semantic dependencies on each other, we used some additional features produced from the output of IHS Goldfire Question-Answering system (Todhunter et al., 2013). This system has its own Semantic Processor, which performs complete linguistic analysis of text documents, such as lexical, part-of-speech, syntactic, and semantic analysis and other. The Q-A system is built on top of the semantic labeling of words with basic knowledge types (e.g., objects/classes of objects, cause-effect relations,

whole-part relations etc.). A matching procedure makes use of the aforementioned types of semantic labels to determine the exact answers to the questions and present them to the user in the form of the fragments of sentences or a newly synthesized phrase in the natural language.

For example, one of such semantic labels, originally extracted by Goldfire system from one of the sentences in the training data, looked this way:

我六点钟出门, 以便赶上火车

I left home at six, (in order) to catch the train.

出门 (left) –Effect→ 赶上火车 (catch the train)

In order to convert semantic labels into semantic dependencies, we extracted the main word of the answer and corrected differences in word segmentation. After transformations the example above is represented as the following semantic dependency:

6 赶上 VV 3(出门) Effect

Although the semantic labels, extracted by Goldfire, are different from the ones that should be extracted in SemEval-2016 Task 9 (in the example above the label is supposed to be *ePurp*), we expected them to provide additional information in cases when the context of words in stack and queue is not sufficient.

## 2.4 Dependencies Pre-processing and Post-processing

Error analysis of the base model showed that incorrect extraction of the *eCoo* dependency is one of the most frequent mistakes. It turned out that *eCoo* connections may have different direction: from left to right and from right to left. Further analysis revealed that in most cases the direction correlates with the position of the parent node of *eCoo* chain: if the parent is to the left, the direction is more likely to be from left to right, and if the parent is to the right, the direction is more likely to be from right to left.

The intuition is that the parser is confused with the different direction of the *eCoo* connections. That is why we converted all *eCoo* dependencies into right-to-left direction in the training corpus, and added a post-processing procedure which converts *eCoo* connections in the output dependency graph into left-to-right direction if the parent of the top node of *eCoo* chain is to the left.

### 3 Experiments

In order to evaluate the influence of the methods described above on parsing quality, we have built five different systems and tested them on the development set. The labeled and unlabeled results for 2 types of corpus (“sdpv2” and “text”) are presented in tables from 1 to 4. LP, LR and LF are labeled precision, recall and F1-score for predicted dependencies (parent-child-dependency label triples). NLF is F1-score for non-local dependencies. UP, UR, UF and NUF are unlabeled counterparts. The *base* system is built with the algorithm described in 2.1. BS is bootstrapping (2.2), Sem – Semantic Features (2.3) and PP is pre- and post-processing (2.4). Pre- and post-processing procedures proved to be the most useful, especially on the “sdpv2” corpus. Bootstrapping improves recall, but harms precision and non-local dependencies. Semantic Features, on the other hand, help to ex-

**Table 8:** SemEval results on text (unlabeled)

tract non-local dependencies. The PP\_BS\_SEM system, with all features included, performed better than all other on the “text” corpus and has comparable results on the “sdpv2” corpus. That is why the output of this system was submitted to SemEval-2016 Task 9. The results of our system, compared to other submissions, are represented in tables 5-8. Our submitted system has shown the highest precision, recall and F1-score values for all dependencies, but did not perform well on non-local labeled dependencies, which may be an effect of bootstrapping or shortcomings of the selected model in general.

## 4 Conclusion

We have built a transition-based semantic dependency parser with online reordering, bootstrapping, additional semantic features and graph pre- and post-processing that achieved the best results in SemEval-2016 Task 9. All features proved to improve the overall performance, but some details may need further improvement. Bootstrapping requires a better balance to avoid its bad influence on precision and non-local dependencies. Also some additional restrictions to the base algorithm may be needed, because now it is allowed for some words to have no parent at all, and while it may be normal for semantic dependency parsing in general, it is not the thing for the task at hand. We leave these details for a future work.

# OCLSP at SemEval-2016 Task 9: Multilayered LSTM as a Neural Semantic Dependency Parser

Lifeng Jin    Manjuan Duan    William Schuler

Department of Linguistics

The Ohio State University

{jin,duan,schuler}@ling.osu.edu

## Abstract

Semantic dependency parsing aims at extracting arcs and semantic role labels for all words in a sentence. In this paper, we propose a semantic dependency parser which is based on Long Short-term Memory and makes heavy use of embeddings of words and POS tags. We describe in detail the implementation of the neural parser, including preprocessing, postprocessing and various input features, and show that the neural parser performs close to the top system in the shared task and is very good at capturing non-local dependencies. We also discuss some issues related to the parser and how to improve it.

## 1 Introduction

Semantic dependency parsing is a form of semantic analysis where semantic roles for all words in a sentence are analyzed and specific semantic relations are assigned to each word pair (Che et al., 2012). Chinese semantic dependency parsing is especially of interest as there is a remarkable difference between syntactic and semantic dependencies in Chinese (Che et al., 2012). In the SemEval 2016 Task 9 Chinese Semantic Dependency Parsing shared task, semantic dependency parsing for two text genres, TEXT, which includes sentences from conversations and primary school textbooks, and NEWS, which contains newswire text, is explored. We propose a neural parser with LSTM as the basic units and make heavy use of vectorial representations of basic linguistic units like words and

POS tags. In this paper, we give a detailed description of the neural parser and discuss a few issues related to the current implementation.

## 2 Long Short-term Memory

Recurrent Neural Networks, or RNNs, are good for sequential prediction, but the problem of exploding or vanishing gradients makes learning long distance dependencies very difficult for them (Hochreiter, 1998). The LSTM architecture is proposed to address this problem (Hochreiter and Schmidhuber, 1997). In this paper, we follow the version defined in Graves et al. (2013b).

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \quad (1)$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \quad (2)$$

$$c_t = f_t c_{t-1} + i_t \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \quad (3)$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_{t-1} + b_o) \quad (4)$$

$$h_t = o_t \tanh(c_t) \quad (5)$$

where  $\sigma$  is the sigmoid function, and  $i$ ,  $f$ ,  $o$  and  $c$  are the input gate, forget gate, output gate and the cell respectively.  $x_t$  is the input at time step  $t$ , and  $h_t$  is the hidden state or the output of the LSTM unit at time step  $t$ . With various gates and a cell, the LSTM unit may learn to store and release information inside the cell over many time steps. LSTMs have recently been used for various NLP tasks such as machine translation (Bahdanau et al., 2014; Sutskever et al., 2014), syntactic parsing (Vinyals et al., 2015) and semantic relatedness prediction and

sentiment classification (Tai et al., 2015). In this paper we apply the LSTM architecture to semantic dependency parsing and show that to use LSTM as a semantic dependency parser is both very powerful and very promising.

### 3 Overview of the System

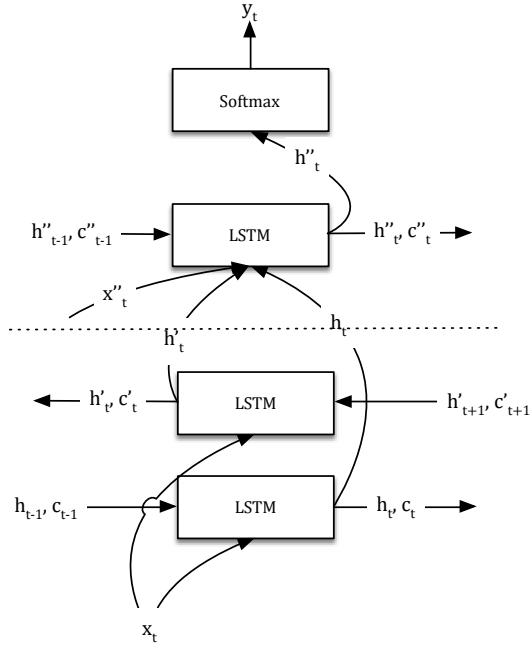

#### 3.1 Parsing Typology

For a sentence  $S = \langle w_1, w_2, \dots, w_i, \dots, w_n \rangle$ , the proposed parser traverses the whole parse chart linearly through all possible pairwise combinations of the elements in the sequence to predict the dependency labels. For example, the parser will first consider the word pair  $\langle w_1, w_1 \rangle$  for dependency label prediction, treating the first in the pair to be the dependent and the second the head in a dependency relation, and then the word pair  $\langle w_1, w_2 \rangle$ , and so on. When it gets to  $\langle w_i, w_n \rangle$ , it proceeds to parse  $\langle w_{i+1}, w_1 \rangle$ , until the final pair  $\langle w_n, w_n \rangle$  is parsed. For cases like  $\langle w_i, w_i \rangle$ , because there is no dependency arc that connects the same word in the same position, we use this for predicting the root of the sentence. Therefore the actual input to the parser is quadratic on the length of the input sequence, making the complexity of the parser  $O(n^2)$ .

#### 3.2 Architecture of the Neural Parser

The neural parser is shown in figure 1. It consists of two main parts: the lower level which has a bidirectional LSTM as its main component and the upper level which has an LSTM and an output layer as its main component.

**Lower Level:** The main component of the lower level system is a bidirectional LSTM (Graves et al., 2013a). The bidirectional LSTM takes the same input sequence with  $n$  time-steps, and runs both forward and backward in time to generate hidden states for each time-step, and concatenates the two hidden states for a single time step to form a single hidden state of the whole system. For example, for a time sequence  $X = \langle x_1, x_2, \dots, x_t, \dots, x_n \rangle$ , the input to the bidirectional LSTM is  $x_t$ , and the output from it is the concatenation of the hidden state from the forward LSTM  $h_t$  and the hidden state of the backward LSTM  $h'_t$ . This bidirectional fea-

**Figure 1:** The OCLSP neural parser.  $x$ ,  $h$ ,  $c$  and  $y$  are the model input, hidden state of a LSTM, cell state of a LSTM and the model output respectively.

ture, which is also exploited by Bahdanau et al. (2014) for neural machine translation, provides information for the current time step with information gathered both from the beginning of the sentence and the end of the sentence in terms of cell states and the hidden states.

**Upper Level:** The main component of the upper level system is an LSTM. The LSTM takes in the output from the lower level ( $h_t, h'_t$ ) as well as a secondary input  $x''_t$  the system and generates a hidden state  $h''_t$  which is then fed into a softmax layer to transform into a probability distribution. If  $x_t = f(w_i, w_j)$  where  $w$  is a word in a sentence,  $f$  is the function from words to input vectors and  $i$  and  $j$  are the indexes of the words, then the final output of the upper level of the system can be viewed as  $p(\text{label}_{i,j}|f(w_1, w_1), \dots, f(w_i, w_j), \dots, f(w_n, w_n), \theta)$ , where  $\theta$  is the model parameters.

#### 3.3 Input Features

The input to the parser consists of two parts: the primary input  $x_t$  which is the input fed to

the lower level system and the secondary input  $x''_t$  which is fed to the upper level system. In development, different kinds of input features are added to the model incrementally to help feature selection. The  $f$  function mentioned in the model description translates word pairs to concatenation of different feature vectors.

The system makes heavy use of vectorial representations trained with *word2vec* (Mikolov et al., 2013). There are two kinds of embeddings used by the parser: word embeddings and Part-Of-Speech embeddings. The word embeddings are all trained with the full Chinese Wikipedia,<sup>1</sup> the Chinese Gigaword (Graff and Chen, 2003) as well as the training and development datasets from both genres in this task. The POS embeddings are trained with the POS tag sequences from training and development datasets from both genres in this task. The embeddings are fixed during training and test.

**Basic features:** The basic features for the lower level system are 300-dimension word embeddings for the current word pair  $\langle w_i, w_j \rangle$ . The basic features for the upper level system are 50-dimension word embeddings for the context words of the current word pair with a window size of 4, i.e.  $\langle w_{i-3}, w_{i-2}, w_{i-1}, w_{i+1}, w_{i+2}, w_{i+3}, w_{j-3}, w_{j-2}, w_{j-1}, w_{j+1}, w_{j+2}, w_{j+3} \rangle$ . The 50 dimensional word embeddings are used because we want the word embeddings at the upper level of the same length as the word embeddings in the lower level, and also we want to keep the number of parameters of the upper level inside a practical range for training. Whenever there is no word at a certain position of the window, an all-zero vector is used to indicate that there is no information from that position for the system to use.

**POS features:** The POS features for the lower level system are 50 dimensional POS embeddings for the current word pair, and for the upper level system, the 50 dimensional POS embeddings are also used for the context words of the current word pair. The all-zero vector is also used whenever a position inside the window has

| Model         | Labeled F | Unlabeled F |
|---------------|-----------|-------------|
| <i>TEXT</i>   |           |             |
| basic         | 61.26%    | 75.31%      |
| basic+pos     | 65.58%    | 78.98%      |

| <i>NEWS</i>   |           |             |
| basic+pos     | 57.94%    | 74.42%      |
| basic+pos+gkg | 58.95%    | 75.44%      |

**Table 1:** Results of models with different feature combinations on development dataset. The performance of the model with only basic features on NEWS is not reported here because it became evident that it never outperformed the other two models with more features.

no word.

**Predicate-argument features:** In previous work, non-local dependencies expressed using a generalized categorial grammar (Bach, 1981; Nguyen et al., 2012) have been used to train an off-the-shelf PCFG parser (Petrov and Klein, 2007) to accurately parse Chinese (Duan and Schuler, 2015). Predicate-argument dependency features were extracted from parsed training sentences using this representation and the trained parser, which gives directed dependencies with 16 different labels, like *arg-1* and *Nmod*, for some pairs of the words. These dependencies are transformed first into undirected dependencies with the original labels. This transform mitigates some problems with arbitrary arc direction discrepancies between two dependency schemes. Then the labels of these dependencies are converted into one hot vectors for the upper level system to use. For the word pairs without a predicate-argument dependency, an all-zero vector of length 16 is used.

Table 1 shows the labeled and unlabeled F scores for models trained with different feature sets on the development dataset. The POS embeddings are good indicators of semantic dependencies as it improves the scores on TEXT by about 4 percent, and the predicate-argument features further improve the F score by another 2 percent on TEXT, and 1 percent on NEWS. The submitted systems use all three feature categories to train and test.

<sup>1</sup><https://zh.wikipedia.org>

### 3.4 Preprocessing and postprocessing

There are a few preprocessing and postprocessing steps that are adopted in the system to generate better results.

**Word Segmentation:** The datasets provided in the task come pre-segmented, but the training data used by *word2vec* need to be segmented first to produce embeddings. We use NLPIR 2015 (Zhang et al., 2003) for segmentation with all words in training and development datasets put into the user dictionary for segmentation. This guarantees that there is no out-of-vocabulary word in development, which also increases parser performance on development data.

**OOV Replacement:** The OOV words are processed in the following way. Suppose there is a large dataset  $D_1$  for training word embeddings. The vocabulary of  $D_1$  is the set  $V_1$ . Suppose there is a new dataset  $D_2$  which has the vocabulary set  $V_2$ . The OOV words from  $D_2$  are  $V_{oov} = V_2 - V_1$ . We first train an embedding model  $W_1$  for  $D_1$  and  $W_2$  for  $D_2$ , and then for each word  $v_{oov}$  in  $V_{oov}$ , we find the word  $v$  in  $V_1$  which has the highest similarity score by cosine to  $v_{oov}$  in  $W_2$ , and replace the  $v_{oov}$  with  $v$  in  $V_2$ . This procedure essentially replaces all the OOV words with the most similar words in the current semantic space of the word embeddings. By doing this, the models do not have to be retrained every time the semantic space of all word embeddings is shifted from  $W_1$  to  $W_2$  with addition of new embeddings. Also the replaced embeddings have more semantic information of the OOV words than a general UNK symbol.

**Graph Generation:** The proposed parser has no guarantee to produce a dependency graph with all nodes connected to the root. In practice, the raw output of the parser is often not a graph. The parser is generally over-conservative, so many words do not have a dependency arc at all. Therefore the Chu-Liu/Edmond’s algorithm<sup>2</sup> is applied to the probability matrix for a complete parse chart of a sentence with the reciprocals of the probability values as costs of edges between nodes, and the

minimal spanning directed graph is generated for the sentence. This guarantees that all final outputs are directed graphs.

The Chu-Liu/Edmond’s algorithm outputs a directed graph with no reentrance, but semantic dependency graphs in the task have reentrant nodes. In order to produce reentrant dependencies, we set a threshold of  $\sigma$  on the probabilities for the arcs of a head word. When the parser decides there are multiple heads for a dependent, and the probabilities of the extra arcs are higher than  $\sigma$ , these arcs will be incorporated into the dependency graph. Two submitted systems use this method to generate final results. One system uses the direct output from the parser and generates an arc for any word without a head by adding an arc with the highest probability between the word and any candidate head.

### 3.5 Training

The loss function of the parser is set to be Negative Log-likelihood function and the training objective is to maximize the log-likelihood of the dependency labels given all word pairs. We use mini-batch update and Adagrad (Duchi et al., 2011) to optimize the parameter learning. Each sentence is a mini-batch. The models used for different datasets are trained separately. We used the F score on the development dataset as the metric to measure convergence. For TEXT, there are in total 10754 sentences in training and for NEWS there are 8301 sentences in training. There are in theory 171 possible dependency labels and 1 no-dependency label in training, but in practice we only observe 158 different semantic dependency labels and 1 no-dependency label in training and development. The models for TEXT are trained for 12 epochs, and the models for NEWS are trained for 8 epochs.

## 4 Task Evaluation Results

Three systems with slightly different configurations for the Graph Generation process were submitted for test. The results are shown in Table 2. The *lbpq* system does not use the Chu-Liu/Edmond’s algorithm for graph generation. Instead it just generates an arc for a word without a head by adding an arc with the highest

<sup>2</sup><https://github.com/mlbright/edmonds>

**Table 2:** Results of the submitted models on test dataset. LF, NLF, UF and NUF are respectively Labeled F, Non-local Labeled F, Unlabeled F and Non-local Unlabeled F scores.

probability between the word and any candidate head. It is the worst performing model among the three in terms of F scores. The *lbpgs* and *lbpg75* are both models with the graph generation algorithm. The difference between them is that *lbpgs* uses a  $\sigma$  value of 100, which means that all words have only one head in its output, whereas *lbpg75* uses a  $\sigma$  value of 75 meaning that the extra arcs of a word must have a probability over 0.75.

For the *lbpgs* system, it is interesting to see that only allowing one head per word does not seem to have a huge impact on the F scores. It actually performs better on the NEWS dataset in terms of LF and UF. This indicates that the systems do not perform very well on the extra arcs, either predicting the wrong labels for the arcs or predicting the wrong arcs altogether. However, the non-local scores see a big drop.

For the *lbpg75* system, it is clear that by choosing a high threshold of extra arc probability, in TEXT at least, we get slightly higher F scores. In both datasets, the non-local scores are the highest with this model, meaning that for the arcs with high confidence, the non-local dependency arcs within them are relatively accurate.

## 5 Discussion and Future Work

**Negative Training Cases:** One of the most obvious drawbacks of systems like this is that

there is a disproportional amount of negative training cases in the training data. In training, the whole parse chart needs to be filled with labels. However, most of the time the number of arcs in a sentence does not exceed  $2n$ . Therefore the number of word pairs with the no-dependency label, or the number of negative cases, is  $n^2 - 2n$ . When  $n$  gets big, for example for some sentences in NEWS  $n$  can be over 200, the number of negative cases gets very large compared to the number of positive cases. It is interesting to see that the parser still captures fairly well the information from positive cases, which are few compared to the negative ones. However, but it may be even better if the number of negative cases can be greatly reduced, the information from positive cases can be even more accessible and the training time can be shorter.

**OOV Words:** The parser relies on word embeddings and POS embeddings to make dependency predictions. Due to different segmentation schemes used by the automatic segmenter and the annotators, about 10% of the vocabulary in test is OOV words even when the word embeddings are trained with Chinese Wikipedia and Chinese Gigaword combined. The OOV strategy adopted in this paper is shown to be better than just replacing all OOVs with a uniform vector like all-ones or all-zeros, in which case the parser just treats all OOVs as punctuation. However the relation between the OOV words and the replacement words do not seem to correspond to any linguistic or world knowledge for most of the replacement-OOV word pairs. For example, the most similar word for replacement of the OOV word “马来语” (Malay language) is “910129”, and the most similar word for “税改” (tax reform) is “面谈成绩” (interview performance). OOVs are a challenge to all parsers, but it is especially important to parsers like the one in this paper, where its performance depends crucially on the quality of the embeddings.

**Parsing Typology:** The parsing typology used in this paper alleviates problems like reentrant nodes and crossing arcs, but at a cost of efficiency and accuracy. Only about 3% of all

the dependency arcs are extra arcs, i.e. they are second or third dependency heads for a given dependent. Such dependencies are very hard to predict, and the typology used here, although able to generate such dependencies naturally, is less than ideal in different ways described above. More research needs to be done for a better parsing typology for neural parsers which addresses these issues without losing the ability to predict extra arcs.

## 6 Conclusion

We present a neural parser with LSTM in this paper for the task of Chinese semantic dependency parsing. We have shown that such a parser may perform close to the top performer in the task with minimal feature engineering. We also discussed places where potential improvements can be made.

{duan, jin, schuler}@ling.osu.edu

## Abstract

This paper introduces our Chinese semantic dependency parsing system for Task 9 of SemEval 2016. Our system has two components: a parser trained using the Berkeley Grammar Trainer on the Penn Chinese Treebank reannotated in a Generalized Categorial Grammar, and a multinomial logistic regression classifier. We first parse the data with the automatic parser to obtain predicate-argument dependencies and then we use the classifier to predict the semantic dependency labels for the predicate-argument dependency relations extracted. Although our parser is not trained directly on the task training data, our system yields the best performance for the non-local dependency recovery for the news data and comparable overall results.

## 1 Introduction

Semantic dependency parsing is an important language processing task which is useful in information extraction and question answering. In this paper, we introduce a Chinese semantic dependency parsing system which is built upon a categorial analysis of the Chinese language.

Categorial grammar annotations are attractive because they have a transparent syntactic-semantic interface and provide a natural account of long-distance dependencies in a language. For this system, we adopt a Generalized Categorial Grammar framework, GCG, (Bach, 1981), for our language

analysis. GCG annotations, compared with other Categorial Grammars, have a larger set of language-specific rules and a smaller set of lexical categories, which on the one hand retains the desirable features of a categorial grammar, such as straightforward compositionality of its syntactic derivations and elegant analysis of filler-gap phenomenon, and on the other hand, mitigates the sparse data problem faced by any heavily lexicalized annotations. Parsers trained with English GCG annotations have been shown to have state-of-the-art parsing performance and better long-distance dependency recovery (Rimell et al., 2009; Nguyen et al., 2012). Parsers trained with Chinese GCG annotations have been shown to achieve better parsing accuracy than the parser trained with Chinese Combinatory Categorial Grammar, CCG, (Steedman, 2000; Steedman, 2012) annotations (Tse and Curran, 2010; Tse and Curran, 2012) for those trees which both grammar annotations assign the same tree structures (Duan and Schuler, 2015).

The current experiment is our first experiment with dependency relations generated from the Chinese GCG annotations. We evaluate them against the manually annotated semantic dependencies in the current SemEval task. Since the purpose of the system is to verify the semantic dependencies generated by the Chinese GCG parser are reasonable, we adopt a minimalist machine learning scheme for this system to accomplish the evaluation. We first train the Berkeley parser (Petrov and Klein, 2007) with GCG annotations converted from the currently

reannotated portion of around 71% of the Chinese Treebank (Xue et al., 2005) sentences. With this parser, we parse the sentences from training sets of the SemEval task and extract dependencies from the parses. Since the dependency labels are more fine-grained in the SemEval task, we train a multinomial logistic regression classifier to predict the dependency labels for the extracted dependencies, using lexical, POS and other position features.

Even though the parser is not directly trained on the gold GCG annotations of the training sentences, this system still yields respectable results compared with other more task dependent systems. Also the official evaluation of the task shows that the current system yields the best non-local dependency parsing accuracy for the newspaper corpus, which supports the findings in English that GCG annotations yield superior performance in long-distance dependency recovery (Nguyen et al., 2012).

## 2 Chinese GCG Parser

This experiment used the Berkeley parser trained on Chinese GCG reannotated trees.

### 2.1 Chinese GCG framework

A generalized categorial grammar (Bach, 1981; Nguyen et al., 2012)<sup>1</sup> is a tuple  $\langle P, O, R, W, M \rangle$  (Oehrle, 1994) consisting of a set  $P$  of primitive category types, a set  $O$  of type-constructing operators, a set  $R$  of inference rules, a set  $W$  of vocabulary items, and a mapping  $M$  from vocabulary items to syntactic categories. A set of complex syntactic categories  $C$  may then be defined as:  $P \subset C$ ;  $C \times O \times C \subset C$ ; nothing else is in  $C$ .

The reannotation of Chinese Treebank into GCG annotations is still an on-going project. So far, we have identified the following set of primitive syntactic categories  $P$  for Mandarin Chinese:

---

<sup>1</sup>Nguyen et al (2012) note the ‘//’ and ‘\\’ operators of Bach (1981) as **-g** and **-h**, mnemonic for ‘gap’ and ‘heavy shift’.

- V:** verb-headed clause
- N:** noun-headed phrase or clause
- D:** *de*-clause headed by 的
- C:** cardinal number
- Q:** quantificational phrase
- A:** adjectival phrase or nominal modifier
- R:** adverbial phrase or verbal modifier
- B:** verbal complement of in *ba*-construction
- E:** verbal complement of in passive voice

The set of type-constructing operators  $O$  for Mandarin Chinese includes **-a** and **-b** operators for unsatisfied requirements of preceding or succeeding arguments, **-c** and **-d** operators for unsatisfied requirements of preceding or succeeding conjuncts, and a **-g** operator for unsatisfied requirements of gap categories.<sup>2</sup>

A GCG category consists of a primitive category followed by one or more unsatisfied dependencies, each consisting of an operator followed by another category. For example the category for a transitive verb is ‘V-aN-bN’, since it is headed by a verb and has unsatisfied dependencies for noun phrases preceding and following it, i.e., the subject and direct object respectively.

As in other categorial grammars, inference rules for local argument attachment apply functors of category  $\varphi_{1..n-1}\text{-ac}$  or  $p\phi_{1..n-1}\text{-bc}$  to initial or final arguments of category  $c$ , where  $c \in C$ ,  $p \in P$  and each  $\varphi \in \{\text{-a}, \text{-b}\} \times C$ :

$$c:g \ p\varphi_{1..n-1}\text{-ac}:h \Rightarrow p\varphi_{1..n-1}:\lambda_x g(\mathbf{f}_n x) \wedge (h x) \quad (\text{Aa})$$

$$p\varphi_{1..n-1}\text{-bc}:g \ c:h \Rightarrow p\varphi_{1..n-1}:\lambda_x (g x) \wedge h(\mathbf{f}_n x) \quad (\text{Ab})$$

These two inference rules stipulate the argument of category  $c$  is the  $n$ -th argument of the head. Inference rules for modifier composition apply preceding or succeeding modifiers of category  $p\text{-bd}$  to modifcands of category  $c$ , where  $p \in \{\text{A}, \text{R}\}$ ,  $d \in \{\text{N}, \text{V}\}$ :

$$p\text{-bd}:g \ c:h \Rightarrow c:\lambda_x \exists_y (g y) \wedge (h x) \wedge (\mathbf{f}_1 y)=x \quad (\text{Ma})$$

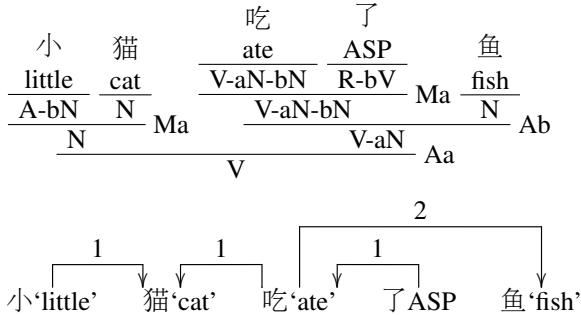

$$c:g \ p\text{-bd}:h \Rightarrow c:\lambda_x \exists_y (g x) \wedge (h y) \wedge (\mathbf{f}_1 y)=x \quad (\text{Mb})$$

Separate modifier composition rules makes it possible to assign the same syntactic category to the modifier regardless of its occurring position. The modifier composition rules Ma and Mb establish a ‘1’-labeled dependency from the modifier to the modifcand. For example, for the sentence ‘小猫吃了

---

<sup>2</sup>Following Nguyen et al (2012), directional operators such as forward and backward slashes (‘\’ and ‘/’) are not used because some operators, such as gap operators in tough constructions, are undirected.

鱼 The little cat ate the fish', we have the derivation and the dependencies extracted from the derivation as follows.

Inference rules for gap composition are:

$$p\varphi_{1..n-1}oc \Rightarrow p\varphi_{1..n-1}\text{-}\mathbf{gc}:\lambda_{vx}\,(g\,x) \wedge (\mathbf{f}_n\,x)=v \quad (\text{Ga})$$

$$c:g \Rightarrow c\text{-}\mathbf{gd}:\lambda_{vx} (g\,x) \wedge (\mathbf{f}_1\,v) = x \quad (\text{Gb})$$

$$N:g \Rightarrow N\text{-}\mathbf{g}N:\lambda_{vx}(g\,x) \wedge \exists_e (\mathbf{de\text{-}asso}\,e\,x\,v) \quad (\text{Gc})$$

where  $p \in P$ ,  $o \in \{-\mathbf{a}, -\mathbf{b}\}$ ,  $c \in C$ ,  $d \in \{\mathbf{A}-\mathbf{b}\mathbf{N}, \mathbf{R}-\mathbf{b}\mathbf{V}\}$  and  $\varphi \in \{-\mathbf{a}, -\mathbf{b}\} \times C$ .

Rule Ga hypothesizes a gap as a preceding or succeeding argument, rule Gb hypothesizes an adjectival or adverbial modifier gap and rule Gc hypothesizes a gap which is associated with the subject in the topicalization construction which does not involve movement.

Non-local arguments, each consisting of a non-local operator and argument category  $\psi \in \{-\mathbf{g}\} \times C$ , are then propagated to consequents from all possible combinations of antecedents. For  $d:g \quad e:h \Rightarrow c:(f\,g\,h) \in \{\mathbf{Aa}-\mathbf{b}, \mathbf{Ma}-\mathbf{b}\}$ :

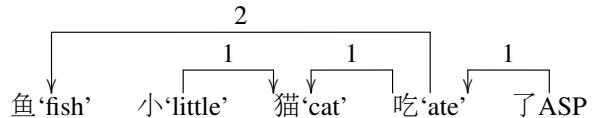

$$\begin{aligned} d\psi_{1..m}:g \ e\psi_{m+1..n}:h \\ \Rightarrow c\psi_{1..n}:\lambda_{v_{1..n}} f(g v_{1..m}) (h v_{m+1..n}) \\ (\text{Ac-d, Mc-d}) \end{aligned}$$

Rules Ac-d and Mc-d stipulate non-local propagation through argument and modifier composition.

Inference rules for filler attachment apply gapped clauses to topicalized phrases as fillers. For  $c \in C$ , and  $p \in P$ :

$$p:g \quad c\text{-}\mathbf{gp}:h \Rightarrow c:\lambda_x \exists_y (g\ y) \wedge (h\ y\ x) \quad (\text{Fa})$$

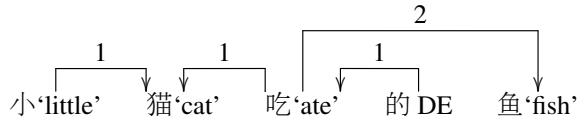

For example, for a topicalized sentence such as “鱼，小猫吃了。The fish, the little cat ate.”, we can extract the dependencies as follows.

In Mandarin relative clauses, the particle 的 ‘de’ takes a preceding clause containing a gap to form a relative clause modifying a succeeding noun. The modified noun is the filler of the gap in the relative clause. The inference rules for relative clauses apply the gapped *de*-clause to the modificant as a filler. For  $c \in C$ :

$$\mathbf{D}\text{-}\mathbf{g}c:g \quad \mathbf{N}\text{:}h \Rightarrow \mathbf{N}\text{:}\lambda_x(h\,x) \wedge \exists_y(g\,x\,y) \quad (\mathbf{R})$$

For a noun phrase such as “小猫吃的鱼 *the fish that the little cat ate*”, we can extract the following dependencies.

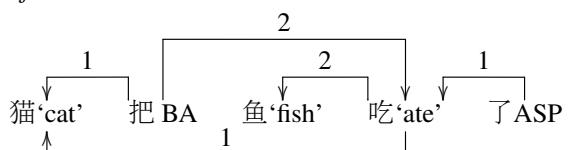

*Ba* constructions in Mandarin Chinese require the affected patients of certain verbs to occur before the verb. In our analysis, we propose that the particle *ba* takes a *ba*-verb as its complement. *Ba*-verbs can be derived from transitive verbs with the type conversion rule, or some verbs, such as some resultative verbs, have *Ba*-verb categories.

The particle 把 *ba* is assigned the category **V-aN-b(B-aN)**, with coindexation between the referent of its subject ( $f_1 x$ ) and the referent of the subject of its complement ( $f_1(f_2 x)$ ).

把 ‘ba’  $\mapsto$ V-aN-b(B-aN):

$$\lambda_x (\mathbf{f}_0 x) = \mathbf{ba} \wedge (\mathbf{f}_1 x) = (\mathbf{f}_1 (\mathbf{f}_2 x))$$

The lexical entry of *ba* gives the following dependencies for the sentence ‘猫把鱼吃了 *The cat ate the fish.*

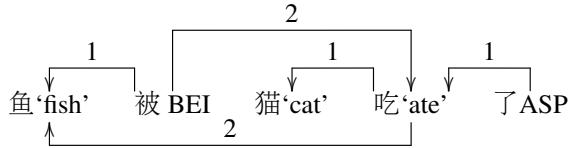

Mandarin Chinese uses the particle *bei* to construct passive sentences. In *bei* constructions, the

patient argument of a verb, usually the second argument of a transitive verb or a *ba*-verb, is moved to the subject position of the clause. We propose the particle 被 *bei* takes a *bei*-verb as its complement, which is converted from a transitive verb with a missing object. Here is the lexical entry we propose for the *bei* particle.

$$\text{被 } 'bei' \mapsto V-aN-b(E-aN-gN)-bN:$$

$$\lambda_x (f_0 x) = \text{bei} \wedge (f_3 x) = (f_1 (f_2 x))$$

For example, the sentence ‘鱼被猫吃了 *The fish was eaten by the cat* gives us the following dependencies.

## 2.2 Training Chinese GCG Parser

The syntactic parser we used for the current semantic dependency parsing is trained by the latent variable PCFG trainer (Petrov and Klein, 2007) on Chinese GCG annotations. Converting Penn Chinese Treebank 5 and 6 into GCG annotations is still an on-going project. We use a set of reannotation rules similar to those described by Nguyen et al. (2012) to reannotate the Penn Chinese Treebank into GCG trees. We currently have fully annotated 71% of sentences (18,505 out of 26,062 sentences) from the Penn Chinese Treebank 5 and 6.<sup>3</sup> With these 18,505, we have trained the Chinese GCG parser which is used for the current semantic dependency parsing task. From the parses, we extracted the raw dependencies as the input for the multinomial classifier in the next stage.

## 3 Multinomial Dependency Label Classifier

As shown in the examples above, the predicate-argument dependencies extracted from GCG derivations do not have fine-grained labels as those dependencies annotated for the task. Also the dependencies identified by the parser sometimes have different directions than those annotated in the task.

<sup>3</sup>The reannotation rules for generating the training set for current parser are available at <http://www.sourceforge.net/projects/modelblocks>.

Therefore, in order to increase the coverage, for each dependency identified by the parser, we also add a dependency which has the reverse direction. For example, if the parser predicts that a dependency such as *I*(eat, cat), in which the head is eat, the dependent is cat, the dependency label is ‘1’, we would add another dependency with inverted direction: *I-inv*(cat, eat). By doing so, we can increase the coverage of the annotated dependencies to around 83%. However, it also doubles the dependencies predicted by the parser and potentially hurts the recall of the accuracy later on.

There are totally 157 semantic dependency labels used in the task. Since the classifier also needs to decide whether a dependency relation exists between each pair of words, we add a “NoRel” label for those pairs of words which, according to the gold annotation, do not hold any dependency relation between them.

We train a one-vs-all multiclass classifier from the Vowpal Wabbit machine learning package.<sup>4</sup> We use the following features to predict the dependency labels:

**Lexical features:** the 300-dimensional word embeddings of the head and dependent words trained with *word2vec* (Mikolov et al., 2013) on the full Chinese Wikipedia, the Chinese Gigaword as well as the training and test datasets in this task;

**POS features:** the 50-dimensional vector representations of the POS tags of the head and dependent trained with the POS tag sequences from training and test datasets in this task;

**Linear distance:** the linear distance of the head and the dependent in the sentence;

**Path distance:** the distance of the nodes of the head and the dependent in the syntactic tree;

**Syntactic categories:** the GCG syntactic categories of the head and the dependent;

**Pred-arg dependency labels:** the dependency labels predicted by the parser, such as ‘1’ or ‘2’;

**Repetition penalty:** the reciprocal of the number of heads that the dependent word has, to penalize proposing too many heads for one word;

**Joint features:** two-way combinational features between GCG syntactic categories of the two words

## 4 Results and Discussion

This Chinese semantic dependency parsing task comes in two domains, the newspaper articles (**News**) and texts selected from Chinese textbooks (**Text**). In our experiment, we found the combining the two training sets yields better accuracy for the textbook corpus and a slightly worse performance for the newspaper corpus. Therefore the **News** results reported in Table 1 and 2 are obtained by a classifier only trained on the newspaper corpus, and the **Text** results are obtained by a classifier trained on the combined training set of the newspaper corpus and the textbook corpus.

The results in Table 1 show that newspaper text is more difficult to parse, even though the GCG parser is trained on a newspaper corpus. However, it also shows that the parser trained on the newspaper corpus can generalize nicely to another domain such as the textbook corpus, where more diverse syntactic constructions are found.

Table 2 shows the results on the test set compared with the system yielding the highest labeled F1 score. We can see that the current system is around 3 percentage lower than the top system in terms of the labeled F1 score. Considering the fact that the parser is not directly trained on the task-

specific dependency annotations and gold POS tags, these results look reasonably good with the rather simplistic machine learning architecture. Table 2 also shows that the current system achieves the best performance on non-local dependencies according to the official evaluation, which supports the corresponding findings in English where parsers trained on GCG English annotations achieve the state-of-the-art performance in long distance dependency recovery (Nguyen et al., 2012).

## 5 Error Analysis

We randomly inspected around 20 sentences from each domain where the predictions of the current system are different from the gold annotations to examine the reason, and we identified the following sources of errors.

**Parsing errors:** Parsing errors caused around half of the wrong predictions we inspected. One type of mistake that we notice the parser often makes is wrong predictions about the internal structure of complex noun phrases. For example, for the noun phrase ‘国际货币基金组织 *International Monetary Fund Organization*’, the parser proposes all first three nouns to be modifiers of the head noun ‘组织 *organization*’, while ‘货币 *monetary*’ actually modifies ‘基金 *fund*’ in gold annotations. The parser also often makes mistakes when parsing questions, since there are not many questions in the Treebank.

**Uncovered linguistic phenomena:** the gold dependency annotations issued by the task contain dependencies involving co-reference.

- (1) 我 觉得 自己 是 世界上 最幸福  
I think myself is in the world happiest  
的 人 了。  
DE person ASP.  
'I think I am the happiest person in the world.'
- (2) 鲁肃 问 他: “你 叫 我 来 做  
Lusu asked him: "you asked me come do  
什么? "  
what? "  
'Lusu asked him: "Why did you ask me to come?"'

In (1), ‘我 *I*’ is annotated to have a *eEqu* relation with ‘自己 *myself*’. In (2), ‘鲁肃 *Lusu*’ has a *eEqu* relation with ‘我 *me*’. Dependencies like these, especially the one in (2), cannot be resolved easily by

a syntactic parser, which means we might need an extra layer of post-processing to do co-reference inference based on discourse information.

**Ambiguous constructions:** In some cases, a sentence can be analyzed in more than one way. All of them are reasonable analyses but each gives different dependencies.

- (3) 我 爱 他 有 志气。  
I love he have aspiration.  
'I love he has aspiration.' or 'I love him to have aspiration.'
- (4) 这里 一定 有 人 来 过。  
here must have people come TENSE.  
'Someone must have come here before'

The current parser parses both (3) and (4) as object control sentences. In (3) '他 he' is the object of '爱 love' and the subject of '有志气 have aspiration'. In the gold annotation of (3), '爱 love' takes a sentential complement 'he has aspiration'. Therefore, for (3), our system proposes a dependency between '爱 love' and '他 he', while in the gold annotations, the dependency is between '爱 love' and '有 have'. In (4), our parser parses '人 person' as the object of '有 have' and the subject of '来过 came'. '有 have', therefore, is the root of the sentence. In gold annotations, '来 come' is the root of the sentence.

**Inconsistent annotations:** There are some cases where our predictions are systematically different from the gold annotations. For example, the current system is consistently different from the gold annotations on the identification of root where some adverbial clauses are involved.

- (5) 万一 明天 下雨, 则 推迟 野游  
If tomorrow rain, then postpone trip  
日期。  
data.  
'If it rains tomorrow, postpone the date of trip'
- (6) 既然 她 讨厌 伦敦, 为什么 他 还  
Given she dislike London, why he still  
在 那里 买 了 房子?  
at there buy ASP house?  
'Given that she does not like London, why did he buy a house there?'

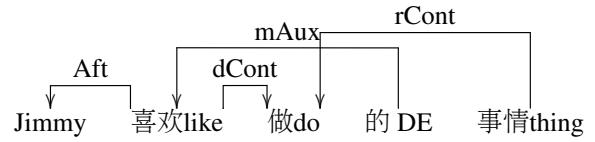

We think both (5) and (6) contain a conditional subordinate clause, and the root of the sentence should

be '推迟 postpone' in (5) and '买 buy' in (6). In gold annotations, '下雨 rain' is annotated to be the root of (5) and '讨厌 dislike' the root of (6). Our assumption is that those clauses are handled as conjunctions in gold annotations.

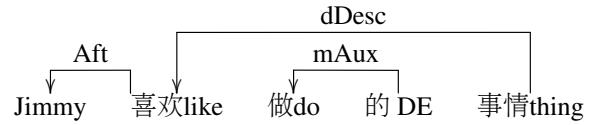

Our predictions also do not agree with the gold annotations in some relative clauses.

- (7) 这 正是 杰里米 喜欢 做 的 事情。  
This is Jimmy like do DE thing.  
'This is the thing that Jimmy likes to do'

Our system predicts the following dependencies for the noun phrase 杰里米喜欢做的事情 things that Jimmy likes to do.

For the same noun phrase, the gold annotation is

For (7), we think there is a dependency between '做 do' and '事情 thing', rather than '喜欢 like' and '事情 thing'.

## 6 Conclusion

This paper introduces the Chinese semantic dependency parsing system based on the predicate-argument dependencies predicted by a Berkeley parser trained on Chinese GCG trees reannotated from the Penn Chinese Treebank. This system achieves comparable performance for the overall labeled dependency prediction and superior performance for the non-local dependency recovery. Our error analysis shows that many dependency parsing errors can be attributed to the syntactic parsing errors. In the future, we will expand the training set of the parser to cover more diverse syntactic constructions such as questions. We will also consider including corpora from different domains to make the parser more adaptable to data from new domains.

## Abstract

Our experiments rely on a combination of machine-learning (CRF) and rule-based (HeidelTime) systems. First, a CRF system identifies both EVENTS and TIMEX3, along with polarity values for EVENT and types of TIMEX. Second, the HeidelTime tool identifies DOCTIME and TIMEX3 elements, and computes DocTimeRel for each EVENT identified by the CRF. Third, another CRF system computes DocTimeRel for each previously identified EVENT, based on DocTimeRel computed by HeidelTime. In the first submission, all EVENTS and TIMEX3 are identified through one general CRF model while in the second submission, we combined two CRF models (one for both EVENT and TIMEX3, and one only for TIMEX3) and we applied post-processing rules on the outputs.

## 1 Introduction

In this paper, we present the methods we used while participating in the 2016 Clinical TempEval task as part of the SemEval-2016 challenge. A few recent NLP challenges focused on temporal expressions within clinical records, such as the 2014 i2b2/UTHealth<sup>1</sup> challenge (Stubbs et al., 2015) or the second task from the 2014 ShARe/CLEF eHealth<sup>2</sup> evaluation lab (Mowery et al., 2014).

## 2 Task description

### 2.1 Presentation

The 2016 Clinical TempEval track<sup>3</sup> proposed six tasks (Bethard et al., 2016). We participated in the first five tasks which concern the identification of: (i) spans of time expressions (TS task), (ii) spans of event expressions (ES task), (iii) the attribute of time expressions (TA task), (iv) attributes of event expressions (EA task), and (v) the relation between each event and the document creation time (DR task). We did not participate in the narrative container relation task (CR).

In both TS and ES tasks, spans of time and event expressions are represented using start and end offsets of characters. In the TA task, time expressions are related to the attribute “class” which specifies the type of time expressions among six possible values: *date*, *duration*, *prepostexp*, *quantifier*, *set*, *time*. In the EA task, event expressions are related to four attributes: “polarity” (either *positive* or *negative*), “modality” (*actual*, *hedged*, *hypothetical* or *generic*), “degree” (*most*, *little* or *N/A*) and “type” (*aspectual*, *evidential* or *N/A*).

Two phases were proposed. In the first phase, all tasks were proposed, based on raw texts. We thus participated to TS ES TA EA and DR tasks. In the second phase, reference annotations were given for tasks TS ES TA and EA, and participants were expected to identify the relations from DR and CR tasks. We also participated in this DR task.

## 2.2 Corpora

The given training corpus was divided into two sub-corpora called *train* and *dev*. Table 1 shows the distribution of each category and its attributes in this corpus. The most frequent ones are in bold font.

|                   | Attributes      | Train | Dev   | TOTAL        |
|-------------------|-----------------|-------|-------|--------------|
| <b>Class</b>      |                 |       |       |              |
| TIMEX             | Date            | 2588  | 1422  | <b>4010</b>  |
|                   | Duration        | 434   | 200   | 634          |
|                   | PrePostExp      | 313   | 172   | 485          |
|                   | Set             | 218   | 116   | 334          |
|                   | Quantifier      | 162   | 109   | 271          |
|                   | Time            | 118   | 59    | 177          |
| <b>Type</b>       |                 |       |       |              |
| EVENT             | N/A             | 36185 | 19414 | <b>55599</b> |
|                   | Evidential      | 2206  | 1314  | 3520         |
|                   | Aspectual       | 546   | 246   | 792          |
|                   | <b>Polarity</b> |       |       |              |
|                   | POS             | 34832 | 18795 | <b>53627</b> |
|                   | NEG             | 4105  | 2179  | 6284         |
| <b>Degree</b>     |                 |       |       |              |
| EVENT             | N/A             | 38698 | 20864 | <b>59562</b> |
|                   | Little          | 143   | 65    | 208          |
|                   | Most            | 96    | 45    | 141          |
|                   | <b>Modality</b> |       |       |              |
|                   | Actual          | 35781 | 22647 | <b>58428</b> |
|                   | Hypothetical    | 1656  | 829   | 2485         |
| <b>DocTimeRel</b> |                 |       |       |              |
| EVENT             | Overlap         | 18297 | 9812  | <b>28109</b> |
|                   | Before          | 14291 | 7896  | 22187        |
|                   | After           | 4189  | 2138  | 6327         |
|                   | Before/overlap  | 2160  | 1128  | 3288         |

**Table 1:** Statistics on the training data.

Corpora are composed of files of two types: “clinic” and “path” files. According to the organizers, annotations are of better quality for “clinic” files than for “path” files. Moreover, adjudication of annotations has been made only for “clinic” files.

## 3 Methods

Our methods mainly rely on machine-learning. We used the Wapiti (Lavergne et al., 2010) toolkit, based on the linear-chain CRFs framework (Lafferty et al., 2001). We considered this challenge as a classification task, where we have to classify each token from a file into a TIMEX or an EVENT category.

Due to the unbalanced distribution of attribute values in the training corpus (see Table 1), we decided not to automatically process three EVENT attributes (“modality”, “degree”, and “type”). For those attributes, we used the most frequent value as a default value: *Actual* for “modality” (89.5%), *N/A* for both “degree” (99.4%) and “type” (92.8%) attributes. As a consequence, we only processed the “polarity” and “doctimerel” EVENT attributes using our CRF systems.

## 3.1 Tasks TS, ES, TA, EA

**CRF system** We merged all tasks of spans and attributes identification into a single task. This process consists in identifying the main category and the related attribute value in one step (e.g., EVENT-POS and EVENT-NEG to identify *positive* and *negative* EVENT expressions).

Since annotations are of better quality in “clinic” files, we compared the results we achieved (ES and TS tasks) on the whole development set (i.e., both “clinic” and “path” files) whether we trained our CRF model on both “clinic” and “path” files from the training set or on the “clinic” files from this training set only. Table 2 presents those results. We observed the CRF model only trained on the “clinic” files outperforms results globally and for each category. As a consequence, we decided to train our CRF models on the “clinic” files only.

| Training set            | Category | P           | R           | F           |
|-------------------------|----------|-------------|-------------|-------------|
| ClinPath<br>(293 files) | EVENT    | <b>.877</b> | .710        | .785        |
|                         | TIMEX    | .801        | .517        | .629        |
|                         | Overall  | <b>.872</b> | .693        | .773        |
| Clin<br>(195 files)     | EVENT    | .845        | <b>.869</b> | <b>.857</b> |
|                         | TIMEX    | <b>.810</b> | <b>.551</b> | <b>.656</b> |
|                         | Overall  | .843        | <b>.842</b> | <b>.843</b> |

**Table 2:** Results on the development set whether the CRF model was trained on both “clinic” and “path” files (ClinPath) from the training set or “clinic” files only (Clin) (P=Precision, R=Recall, F=F-measure). Black font highlights the best results

We thus created three CRF models:

- a first model to identify both spans of EVENT expressions and the associated value of the attribute of polarity: model EVENT/Polarity;
- a second model to identify both spans of

TIMEX expressions and the associated value of the “class” attribute: model TIMEX/Class;

- and a last global model to identify both EVENT and TIMEX expressions (i.e., spans) with the associated values of “polarity” and “class” attributes: model EVENT/Polarity TIMEX/Class.

The following features were used to produce all CRF models: (i) the token itself; (ii) token length, typographic case of the token, presence of punctuation marks in the token, and presence of digits in the token; (iii) part-of-speech tag of the token, provided by the Tree Tagger POS tagger (Schmid, 1994); (iv) cluster ID of each token through an automatic unsupervised clustering of all tokens from the training corpus into 120 clusters,<sup>4</sup> using the algorithm designed by Brown et al. (1992) and implemented by Liang (2005).

**Rule-based post-processing** In order to correct predictions made by the CRF system, we designed a basic post-processing based on rules. This post-processing consists in identifying additional EVENT expressions from a list of 69 most frequent EVENT expressions we collected from the training set. For all EVENT expressions found in this list, we set the “Polarity” value to *positive* as a default value.

### 3.2 Task DR

**HeidelTime tool** HeidelTime (Strötgen and Gertz, 2010; Strötgen and Gertz, 2013) allows to extract and normalize temporal expressions in texts according to the TIMEX3 standard. For the normalization of relative temporal expressions, the document creation time (DCT) is used. In this task, HeidelTime considers the expression indicated as *start date* in the text files as the DCT. Once all TIMEX are normalized, we assigned to each of them one of the four temporal relations: *before*, *after*, *overlap*, *before/overlap* w.r.t the DCT.

<sup>4</sup>We used five distinct versions of each cluster ID: the original cluster ID (e.g., “01011”) and four generalization of each ID, removing the last digit to produce a more generic version from the previous one for each iteration (“0101”, “010”, “01” and “0”). We gave the CRF all those versions.

**CRF system** We considered this relation task as a classification task, where we have to classify each EVENT into a relational class. In order to perform this classification, we gave the CRF additional features, namely the temporal features previously computed by the HeidelTime tool on each TIMEX.

## 4 Design of experiments

Figure 1 presents the design of experiments we followed for the official submissions for the first phase. The grey boxes represent the distinct CRF models we used and the type of expressions processed by each model.

### 4.1 Task TS, TA, ES, EA (phase 1)

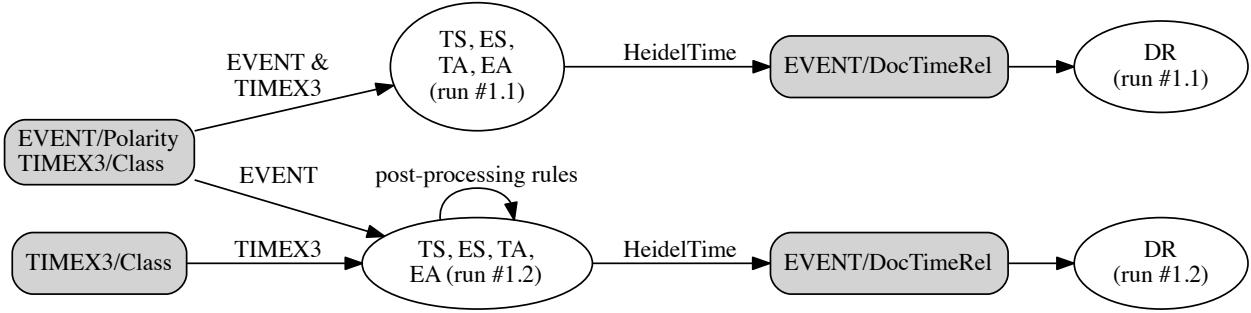

We considered two configurations, based on the results we achieved on the development corpus:

- application of the global model to identify all elements (EVENT/Polarity and TIMEX/Class). In our experiments, we noticed this model allows us to achieve higher values for both precision and F-measure. This constitutes our first submission (run #1.1);
- application of both global model (i.e., EVENT/Polarity and TIMEX/Class) and TIMEX/Class specific model to identify all elements. We merged outputs from both models, giving priority to predictions from the specific model for the TIMEX/Class category, and applied our post-processing. This configuration allows us to obtain higher values for recall. This constitutes our second submission (run #1.2).

### 4.2 Task DR

#### 4.2.1 Task DR (phase 1)

For the first phase, we designed a new CRF model to predict the value of the “DocTimeRel” attribute associated with each EVENT we previously identified. In order to improve the quality of predictions made by our CRF system, we added as features the temporal relations computed by HeidelTime (see Section 3.2): the relations computed by HeidelTime are mapped to TIMEX expressions detected by the CRF models used in phase 1. When the CRF model detects a TIMEX expression that is not extracted by HeidelTime, the default value is used (*overlap*).

**Figure 1:** Design of experiments for phase 1. Grey boxes represent our distinct CRF models

We applied this model on outputs from runs #1.1 and #1.2. In this experiment, we tested how performs our DR CRF model depending on the quality of the outputs from the previous TS/ES/TA/EA tasks. Additionally, we considered the relations computed by HeidelTime and associated with each TIMEX expression would be useful.

#### 4.2.2 Task DR (phase 2)

For the second phase, since gold standard annotations for TIMEX and EVENT expressions were given by the organizers, we trained two CRF models based on two different inputs:

- run #2.1: temporal relations computed by HeidelTime are mapped to the TIMEX entities from the gold standard annotations. If a TIMEX is not extracted by HeidelTime, the default value is used (*overlap*);
- run #2.2: only TIMEX and temporal relations extracted by HeidelTime are used.

## 5 Results and discussion

### 5.1 Official results (test set)

In this section, we present the official results we achieved on the test set. Outputs are evaluated through classical metrics used in information retrieval tasks: precision (positive predictive value), recall (true positive rate), and F-measure (weighted harmonic mean of precision and recall). In order to make the comparison between the results we obtained among our two submissions easier, the bold font pinpoints our best results.

#### 5.1.1 Phase 1

Table 3 presents the official results we achieved on the test set for the tasks TS, ES, TA, EA and

DR based on our first submission (run #1.1) from phase 1.

| Task | Category         | P           | R    | F           |
|------|------------------|-------------|------|-------------|
| TS   | TIMEX            | <b>.840</b> | .510 | .635        |
| ES   | EVENT            | <b>.885</b> | .808 | <b>.845</b> |
| TA   | TIMEX/Class      | <b>.815</b> | .495 | .616        |
| EA   | EVENT/Degree     | <b>.880</b> | .805 | <b>.841</b> |
|      | EVENT/Modality   | <b>.811</b> | .742 | <b>.775</b> |
|      | EVENT/Polarity   | <b>.867</b> | .792 | <b>.828</b> |
|      | EVENT/Type       | <b>.825</b> | .754 | <b>.788</b> |
| DR   | EVENT/DocTimeRel | <b>.635</b> | .580 | <b>.607</b> |

**Table 3:** Official results on the test set (run #1.1) for tasks TS, ES, TA, EA and DR (P = Precision, R = Recall, F = F-measure). Bold font pinpoints best results

Table 4 presents the official results we achieved on the test set for the tasks TS, ES, TA, EA and DR based on our second submission (run #1.2) from phase 1.

| Task | Category         | P    | R           | F           |
|------|------------------|------|-------------|-------------|
| TS   | TIMEX            | .830 | <b>.518</b> | <b>.638</b> |
| ES   | EVENT            | .869 | <b>.816</b> | .842        |
| TA   | TIMEX/Class      | .804 | <b>.503</b> | <b>.619</b> |
| EA   | EVENT/Degree     | .865 | <b>.812</b> | .838        |
|      | EVENT/Modality   | .798 | <b>.749</b> | .772        |
|      | EVENT/Polarity   | .851 | <b>.799</b> | .824        |
|      | EVENT/Type       | .811 | <b>.761</b> | .785        |
| DR   | EVENT/DocTimeRel | .624 | <b>.585</b> | .604        |

**Table 4:** Official results on the test set (run #1.2) for tasks TS, ES, TA, EA and DR (P = Precision, R = Recall, F = F-measure). Bold font pinpoints best results

We achieved our best results in our first submission, which is based on a global CRF model for tasks TS, ES, TA and EA, and a second CRF global model

for task DR. As expected in our experimental setup, our first submission allows us to maximize the precision values, and generally obtains the higher F-measure values, while the second submission maximizes the recall values for all category and attribute.

In comparison with submissions from other participants from this first phase, we succeed to obtain better results than the median F-measure value for tasks TS (median=.637 vs. F=.638 in run #1.2) and ES (median=.830 vs. F=.845 and .842 respectively in runs #1.1 and #1.2). On TA, EA and DR tasks, we obtained lower results w.r.t. the median values. Our system only succeeds to obtain better results than the organizers' baseline on tasks TS (baseline F=.551) and DR (baseline=.604 vs. F=.607 in run #1.1).

### 5.1.2 Phase 2

Table 5 presents the official results we achieved on the test set for the task DR based on our first submission (run #2.1) from phase 2.

| Task | Category         | P    | R    | F    |
|------|------------------|------|------|------|
| DR   | EVENT/DocTimeRel | .687 | .687 | .687 |

**Table 5:** Official results on the test set (run #2.1) for task DR (P = Precision, R = Recall, F = F-measure)

Table 6 presents the official results we achieved on the test set for the task DR based on our second submission (run #2.2) from phase 2.

| Task | Category         | P    | R    | F    |
|------|------------------|------|------|------|
| DR   | EVENT/DocTimeRel | .679 | .679 | .679 |

**Table 6:** Official results on the test set (run #2.1) for task DR (P = Precision, R = Recall, F = F-measure)

On both submissions from phase 2, we did not succeed to obtain better results than the median value (F=.724). Nevertheless, our system obtained better results than the organizers' baseline (F=.675 vs. F=.687 in run #2.1 and .679 in run #2.2). This observation is consistent with the results we achieved on the DR task in phase 1.

### 5.2 Error analysis

**Lack of robustness** Since we trained our CRF models on “clinic” files only (see section 3.1), most of false negatives concern EVENT expressions that are only used in “path” files (e.g., *Description*, *nodes*, *orientation*, etc.). As the CRF failed to

identify those expressions, we can consider that our model failed to generalize the properties of EVENT expressions, despite other features, and experienced difficulties to process unknown elements.

Similarly, due to the differences of structure between “clinic” and “path” files, most of false positives concern predictions made by our CRF system on “path” files exclusively (e.g., our system considered *Hematoxylin* to be annotated as an EVENT in all “path” files). This observation highlights the lack of robustness of our CRF systems on files being of different type.

Table 7 presents the results we achieved on the test set for each “clinic” and “path” files sub-set. Bold font highlights the best results. As expected, results are better on the “clinic” files sub-set than on the “path” files sub-set (on average 4 points more on the EVENT category for each metric).

| Test sub-set          | Category | P           | R           | F           |
|-----------------------|----------|-------------|-------------|-------------|
| Clinic<br>(102 files) | EVENT    | <b>.871</b> | <b>.891</b> | <b>.881</b> |
|                       | TIMEX    | <b>.811</b> | <b>.663</b> | <b>.730</b> |
|                       | Overall  | <b>.866</b> | <b>.867</b> | <b>.866</b> |
| Path<br>(51 files)    | EVENT    | .828        | .853        | .840        |
|                       | TIMEX    | .000        | .000        | .000        |
|                       | Overall  | .828        | .848        | .838        |

**Table 7:** Results on the test set for each “clinic” and “path” files sub-set (P=Precision, R=Recall, F=F-measure)

Additionally, we observed that our CRF model failed to identify any TIMEX expressions on the “path” files from the test set.

**TIMEX extraction with HeidelTime** Evaluation of HeidelTime on TIMEX extraction of the test set gives the following results: P=.479, R=.586 and F=.527. The best scores are obtained for type *date* (P=.687, R=.677 and F=.682) whereas scores are very low for *quantifier* (F=.043), *set* (F=.065) and *time* (F=.083). This can be explained by the fact that some TIMEX annotations in the gold data are not compliant with the TimeML standard as used in HeidelTime. For example, the expression *12-MAY-2001 21:11* is annotated as a date (*12-MAY-2001*) and a time (*21:11*) in the gold data whereas the whole expression should be annotated as a time according to the TimeML standard. These low scores also explain why only 75% of TIMEX expressions in the

gold data are mapped with a temporal relation computed by HeidelTime in run #2.1.

## 6 Conclusion

In this paper, we presented the methods we used while participating in the 2016 Clinical TempEval task as part of the SemEval-2016 challenge. We considered each task from the challenge as a classification task using machine-learning approaches. Our CRF systems allow us to predict both the offsets of each expression (TS and ES tasks) and the attribute of expressions (TA and EA tasks) as well as the temporal relations (DR task). Due to an unbalanced distribution of some EVENT attributes (namely “degree”, “modality” and “type”), we gave the most frequent used value in the training corpus as a default value.

We designed two experiments. The first one is based on a single CRF model which identifies all expressions and attributes at the same time. The second one is based on a merge of two CRF models (one for EVENT, the other for TIMEX) and post-processing rules to identify new EVENT expressions.

We achieved our best results through the first experiment (higher precision values for all tasks and the best F-measure values for all EVENT related tasks,  $F=.845$  on ES) while the second experiment allows us to obtain higher recall values for all tasks and the best F-measure values for all TIMEX related tasks ( $F=.638$  on TS). Our systems succeed to identify more correctly EVENT expressions than TIMEX expressions.

Our system achieved better results on the “clinic” files sub-set rather than on the “path” files sub-set. Future work is thus needed, first to improve the generalization of features used (in order to predict unknown expressions based on features), and second to ensure the robustness of our system (in order to process different files, namely “path” files).

## Abstract

This paper describes the system developed for the task of temporal information extraction from clinical narratives in the context of 2016 Clinical TempEval challenge. Clinical TempEval 2016 addressed the problem of temporal reasoning in clinical domain by providing annotated clinical notes and pathology reports similar to Clinical TempEval challenge 2015. The Clinical TempEval challenge consisted of six subtasks. Hitachi team participated in two time expression based subtasks: time expression span detection (TS) and time expression attribute identification (TA) for which we developed hybrid of rule-based and machine learning based methods using Stanford TokensRegex framework and Stanford Named Entity Recognizer and evaluated it on the THYME corpus. Our hybrid system achieved a maximum F-score of 0.73 for identification of time spans (TS) and 0.71 for identification of time attributes (TA).

## 1 Introduction

Temporal information extraction has been a trending topic of research interest in the field of information extraction. It is crucial for improvement of systems used in number of applications ranging from question answering, search engines, text classification etc. to the systems that establish timelines and explicitly ground events that occurs in clinical narratives.

This work focuses on the automatic identification of time expressions from clinical texts. Time expressions are words and phrases that correspond to points or spans on a timeline, such as Dates, Time, Durations, Quantifiers, Set, and PrepostExp. Table 1 shows the time expression clas-

ses used in this work, with examples given for each class.

| Time Class | Example                               |
|------------|---------------------------------------|
| Date       | February 2 2010, Friday morning       |
| Time       | 5:30 PM, 20 minutes ago               |
| Duration   | For the next 24 hours, nearly 2 weeks |
| Quantifier | twice, three times                    |
| Prepost    | postoperatively, post-surgery         |
| Set        | twice daily, weekly                   |

Table 1: Examples of time expressions.

Research work on temporal information extraction has been carried out in both general NLP domain (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013) and in clinical domain (Raghavan et al., 2012; Sun et al., 2013; Miller et al., 2013; Bethard et al., 2015; Velupillai et al 2015). In clinical domain, temporal information extraction has seen much research interest with assignment of medical events to time bins (Raghavan et al, 2012), i2b2 (Informatics for Integrating Biology and the Bedside) shared task (Sun et al., 2013) with the best performing system (Xu et al., 2013) using CRF (Conditional Random Field) and SVM (Support Vector Machines) and development of a hybrid system (Kovacevic et al., 2013) that used CRF and rule-based methods. Further tasks similar to i2b2 that involve temporal reasoning were also attempted in ShARe CLEF 2013/2014 eHealth challenges (Pradhan et al., 2015) and Clinical TempEval 2015 (Bethard et al., 2015; Velupillai et al., 2015).

Clinical TempEval 2016 continues with the task of temporal information extraction from clinical notes in similar lines to previously described

works. The 2016 Clinical TempEval challenge consisted of six subtasks (i) identification of spans of the time expression (TS) (ii) identification of spans of the event expression (ES) (iii) identification of attributes of time expression (TA) (iv) identification of attributes of event expression (EA) (v) identification of relation between an event and document creation time (DR) and (vi) identification of narrative container relation (CR). Participants were provided with THYME corpus (Styler et al., 2014) which consisted of de-identified clinical notes and pathology reports of cancer patients from Mayo clinic and corresponding annotation files. The participating systems were compared against two rule-based systems namely Memorize and Closest (only for CR task) which were used as baseline. The evaluation was done in two phases. In phase-1, only raw clinical text documents were given and participants were asked to identify time expressions, event expressions and temporal relations. In phase-2, access to raw text documents as well as manual event and time annotations was given and participants were asked to identify only temporal relations.

The 2015 Clinical TempEval results and discussion reveals that top results were mostly dominated by machine learning based systems (Bethard et al., 2015). However historical works on temporal extraction have achieved success using rule-based systems (Tang et al., 2012; Kovacevic et al., 2013). Thus in this work we developed a hybrid system leveraging the best out of machine learning and rule-based systems and evaluated this hybrid system against the THYME corpus.

The rest of the paper is organized as follows. In section 2 we describe the clinical TempEval 2016 data set and our approach to identify time expression. Section 3 and 4 explains results, describing the limitations of the methods used and issues that were present in the given THYME corpus.

## 2 Data and Method

The THYME corpus released for TempEval 2016 totaled 600 records which were divided into three sets namely train dataset, dev dataset and test dataset with 297, 150 and 153 records in each set respectively.

We tackled the tasks as named entity recognition (NER) problem with the aim to identify relevant

text spans and assign classes to texts corresponding to the identified spans for which we developed a hybrid system that combines a rule-based method and a machine learning based method that relies on simple lexical, syntactic features and domain specific words. The rule-based system was developed using the Stanford TokensRegex framework (Chang et al., 2014) and the machine learning based system employed Stanford CRF classifier (Finkel et al., 2005), which are both available as part of the Stanford CoreNLP (Manning et al., 2014) tool set.

### 2.1 Rule-based approach

The rules for the rule-based approach were designed using combination of dictionaries and lexical formation formats of sentences. We started development of the rule-based system by evaluating the THYME corpus against existing Stanford SUTime (Chang et al., 2012) rule based tagger which is built on top of Stanford TokensRegex framework to understand its performance and shortcomings on THYME corpus. The obtained result showed that SUTime gave good result for Date when compared to other temporal classes. Hence we retained some of the rules for identification of Date from SUTime, while the rules for Time, Duration, and Quantifier and Set classes were developed as explained.

- **Time rules:** For time rules we manually crafted dictionaries that consisted of constituents of time expressions that were present as part of the given Time class annotations namely the word “time”, times of a day, time period qualifiers like “am”, “pm” etc. and common time expression references (today, yesterday, previously, earlier, later, future etc.). Most of the annotations for Time class were phrases that contained word “time” or a time expression references prefixed by words such as “this”, “that” etc. and suffixed with time period qualifiers. All in all 16 different rules were developed to identify the time expressions using above said dictionaries.
- **Duration rules:** The duration rules used manually crafted dictionaries that consist of different constituents that were present as part of the annotations of duration class, namely weekdays and months, times of a

day and common time expression references (today, yesterday, previously, earlier, later, future etc.). In addition we created a dictionary of words that refers to time periods like (hours, minutes etc.) and their equivalent short forms and words that signify time references such as (since, dating back etc.). Totally we designed 43 different rules for identifying duration expressions using above said dictionaries.

- **Quantifier rules:** Most of the quantifier terms had an explicit dependency on words pertaining to domain specific or general events within in the same sentence where they are present .For example, in sentence "Four cups of coffee in the morning" the term "Four" is the quantifier that quantifies the event "cups of coffee". Similar to previous cases we handcrafted dictionaries that consist of domain specific and general events. Additionally a dictionary of commonly occurring suffixes such as "pack-year", "pack-a-day" etc. that is part of the word that contained the quantifier value was created. Totally we created 15 unique rules for the quantifiers using above said dictionaries.
- **Prepost rules:** Prepost expressions had a common characteristics where each expressions begin with words such as "pre", "post", "intra", "prior" etc. followed by a domain specific event term such as "operative" etc. Further we observed very few variants of prepost expressions being present in dev dataset. However to avoid unseen words that might follow the above mentioned prefixes in test dataset, we extracted domain specific words that commonly follow these prefixes by mining ICD9 website and in addition we also created a dictionary of various words that is related to surgical procedures by mining Wikipedia. Using above said dictionaries and prefix words we created 5 rules to extract prepost expressions. Once the quantifiers and prepost expressions were extracted we have set of post processing modules that were designed to improve the spans by removing certain words from extracted expressions.
- **Set rules:** The set rules used previously handcrafted dictionaries for time rules. In

addition we created a dictionary containing words such as "annual", "weekly", "monthly", "daily" etc. that qualifies a Set. Most of the set expressions were either single words from previously described dictionary or a simple sentence of form "XX-times-a-{time period qualifier}", "XX-{ time period qualifier }" etc. where XX is numeric quantifier. Totally 20 different rules were designed for identifying set expressions.

The results of the rule-based system that was developed using above mentioned rules on test dataset are as shown in Table 2.

| Subtask            | P     | R     | F1    |
|--------------------|-------|-------|-------|
| TIMEX3             | 0.415 | 0.629 | 0.500 |
| TIMEX3: Span       | 0.433 | 0.655 | 0.522 |
| TIMEX3: Class      | 0.415 | 0.629 | 0.500 |
| TIMEX3: Date       | 0.457 | 0.690 | 0.550 |
| TIMEX3: Duration   | 0.298 | 0.455 | 0.360 |
| TIMEX3: Prepost    | 0.986 | 0.637 | 0.774 |
| TIMEX3: Quantifier | 0.256 | 0.348 | 0.295 |
| TIMEX3: Set        | 0.536 | 0.541 | 0.538 |
| TIMEX3: Time       | 0.110 | 0.378 | 0.171 |

Table 2: Results for TS and TA tasks on the test dataset using rule-based system.

## 2.2 Machine learning approach

We created separate models for all six types of time classes using Stanford CRF classifier which is an implementation of arbitrary order linear chain conditional random field classifier. The data for training consisted of 447 records (train and dev datasets) which were preprocessed by tokenizing using the Penn Tree bank tokenizer and BIO encoding each of the tokens.

We used simple features such as N-Grams, word shape features, word window of size  $\pm 1$ , sequence words from Stanford NER Feature factory for creating the model and tested using 153 records from test dataset. The results that were obtained are as shown in Table 3.

| Subtask          | P     | R     | F1    |
|------------------|-------|-------|-------|
| TIMEX3           | 0.79  | 0.655 | 0.720 |
| TIMEX3: Span     | 0.821 | 0.669 | 0.737 |
| TIMEX3: Class    | 0.798 | 0.655 | 0.720 |
| TIMEX3: Date     | 0.823 | 0.749 | 0.784 |
| TIMEX3: Duration | 0.650 | 0.455 | 0.535 |
| TIMEX3: Prepost  | 0.969 | 0.832 | 0.895 |

|                    |       |       |       |
|--------------------|-------|-------|-------|
| TIMEX3: Quantifier | 0.500 | 0.167 | 0.250 |
| TIMEX3: Set        | 0.732 | 0.369 | 0.491 |
| TIMEX3: Time       | 0.385 | 0.167 | 0.233 |

**Table 3:** Results for TS and TA tasks on the test dataset using machine learning system (CRF).

### 3 Results

During system development phase we were able to see that rule based system performed well for Quantifier and Set while CRF performed well for the rest of the classes. Hence for the submission runs we used a hybrid of our rule-based and machine learning based systems (CRF) with the test data. For Quantifier and Set classes we used rule-based systems and for Date, PrepostExp, Duration, and Time class we used CRF classifier models.

| Subtask            | P     | R     | F1    |
|--------------------|-------|-------|-------|
| TIMEX3             | 0.759 | 0.671 | 0.712 |
| TIMEX3: Span       | 0.781 | 0.685 | 0.73  |
| TIMEX3: Class      | 0.759 | 0.671 | 0.712 |
| TIMEX3: Date       | 0.823 | 0.749 | 0.784 |
| TIMEX3: Duration   | 0.65  | 0.455 | 0.535 |
| TIMEX3: Prepost    | 0.969 | 0.832 | 0.895 |
| TIMEX3: Quantifier | 0.256 | 0.348 | 0.295 |
| TIMEX3: Set        | 0.536 | 0.541 | 0.538 |
| TIMEX3: Time       | 0.385 | 0.167 | 0.233 |

**Table 4:** Hitachi team results (run-1) for TS and TA tasks in Clinical TempEval 2016.

For run-1 we used 447 records (train & dev datasets) for training our hybrid system and the result which was obtained when evaluated on test data is shown in Table 4. For run-2 we decided to do an estimation of how well the CRF model has been trained and its property: accuracy dependency on number of training records. Hence we replaced the CRF classifier with models trained only on 297 records (train dataset). The results on test data for run-2 were similar to run-1 except a drop in overall F-score of 0.1.

### 4 Discussion

Our hybrid system outperformed the baseline systems for TS and TA tasks. We also obtained results that were above the median result of the challenge as shown in Table 5.

| Subtask                      | P     | R     | F1    |
|------------------------------|-------|-------|-------|
| TIMEX3: Span (Hitachi run-1) | 0.781 | 0.685 | 0.730 |

|  |       |       |       |
|--|-------|-------|-------|
| TIMEX3: Span (Hitachi run-2)             | 0.781 | 0.668 | 0.720 |
| TIMEX3: Span (TempEval 16 baseline)      | 0.744 | 0.428 | 0.551 |
| TIMEX3: Span (TempEval 16 top score)     | 0.84  | 0.75  | 0.795 |
| TIMEX3: Span (TempEval 16 median score)  | 0.779 | 0.539 | 0.637 |
| TIMEX3: Class (Hitachi run-1)            | 0.759 | 0.671 | 0.712 |
| TIMEX3: Class (Hitachi run-2)            | 0.758 | 0.654 | 0.702 |
| TIMEX3: Class (TempEval 16 baseline)     | 0.746 | 0.413 | 0.532 |
| TIMEX3: Class (TempEval 16 top score)    | 0.815 | 0.735 | 0.772 |
| TIMEX3: Class (TempEval 16 median score) | 0.755 | 0.499 | 0.618 |

**Table 5:** Comparison of Clinical TempEval 2016 results.

Table 2 shows the results of our rule-based system on test data for which we observe an F-score of 0.50 with date, prepost and set expression having recall higher than 0.5. During the system development we tuned the rule-based components towards the patterns of temporal expressions that were pre-identified in the training and dev dataset, but there were words such as “time” for Time class and “MO”, “hrs” etc. for Duration class which led to increase in the number false positives thereby reducing the precision and overall F-score. Furthermore, the rule-based method, extracted many time expressions like “7:45 AM”, “24-May-2010 15:12:00”, “10 Units” etc. that were valid but not present in the annotations which led again to reduction in F-scores.

Table 3 shows the results of our machine learning system (CRF) on test data. The result obtained using CRF classifier is consistent with the previous works that is based on CRF. CRF gave an average F score of 0.72 on test data. In fact CRF gave very good results for all classes except those belonging to Time and Quantifier class. For instance when tested with the test data for Duration class, CRF predicted 140 patterns out of which 91 were correct leading to a precision of 0.65. For the same attribute rule-based system extracted

305 patterns out of which only 91 were correct giving a low precision of 0.298.

We started our system development to understand how rule-based method and CRF performs individually for extraction of time expression present in the dev dataset of the THYME corpus. We were able to observe that the rule-based and machine learning systems gave good results only on subset of time expressions when used individually which can also be observed with the result on test dataset shown in Table 2 and 3. Further, based on results from Table 3 and 4 we can say that CRF alone has higher performance than the hybrid system, however we observed opposite results during system development process using dev dataset. Thus for the final submission we developed a hybrid system of rule-based and CRF by combining top performing systems on dev data, which lead to the results shown in Table 5.

Adaptation of Stanford TokensRegex framework for rule-based system performed fairly well giving an average F-score 0.5 for test data. Yet our rule-based method of the hybrid system had major limitation where our rules were highly syntax dependent which was unavoidable. Simple lexical features were useful for CRF classification approaches on TS and TA tasks. Further, the overall impact of reduction in training data for run-2 was negligible which is evident from the result. Also we observed that performance of CRF for classes like Quantifier remained unimproved even with addition of higher level syntactic features, which is evident from results in Table 3. Thus our aim of evaluating our hybrid system against THYME corpus which was developed using Stanford TokensRegex Framework and Stanford CRF Classifier was successful. As a future work we plan to evaluate performance of our hybrid system on other similar corpora and explore various strategies to combine rule-based and machine learning methods.

## Acknowledgements

We thank Mayo clinic and clinical TempEval organizers for providing access to THYME corpus and other helps provided for our participation in the competition.

## Abstract

In this paper, we demonstrate our approach for identification of events, time expressions and temporal relations among them. This work was carried out as part of SemEval-2016 Challenge Task 12: Clinical TempEval. The task comprises six sub-tasks: identification of event spans, time spans and their attributes, document time relation and the narrative container relations among events and time expressions. We have participated in all six sub-tasks. We have provided with a manually annotated dataset which comprises of training dataset (293 documents), development dataset (147 documents) and 151 documents as test dataset. We have submitted our work as two systems for the challenge. One system is developed using machine learning techniques, Conditional Random Fields (CRF) and Support Vector machines (SVM) and the other system is developed using deep neural network (DNN) techniques. The results show that both systems have given relatively same performance on these tasks.

## 1 Introduction

The interest on extracting temporal information is well versed from the creation of time bank corpus (Pustejovsky et al., 2003b) in 2003. A specification language has been developed, TimeML (Markup Language for Temporal and Event Expressions) (Pustejovsky et al., 2003a) to conceptualize the events, time expressions and temporal relations using tags (EVENT, TIMEX, TLINKS, ALINKS, SLINKS). Various algorithms have been developed

to tag events and time expressions on time bank corpus. Initial works used machine learning algorithms with manually extracted features (Mani et al., 2006), syntax and clausal features on inter-sentential events. Later, automated feature selection were used for extracting events and finding the temporal relation(Chambers et al., 2007; Lapata and Lascarides, 2006). TARSQI (Verhagen and Pustejovsky, 2008) is a project employed by the creators of TimeML to develop algorithms for tagging these tags in text.

A series of challenges have been organized on TempEval comprising evaluation tasks on events, time expressions and temporal relations on news data. I2b2 2012 (Sun et al., 2013) is the first conference to study the temporal information extraction in clinical domain using THYME corpus. It is followed by Clinical TempEval tasks in semEval2015. Most of the participants of these challenges used CRF and SVM for event extraction with features including the information gathered from different resources like UMLS (Unified Medical Language System), output of TARSQI toolkit, Brown Clustering, Wikipedia and Metamap (Aronson and Lang, 2010). For time expression extraction, various existing tools like SUTIME (Chang and Manning, 2012), HeidelTime (Strötgen and Gertz, 2010) and GUTIME were used. And for temporal relation extraction various machine learning methods ranging from MaxEnt, Bayesian and SVM to CRF were used incorporating the heuristics and rule based components. Out of many participants of these challenges/workshops, the top performing systems used hybrid approaches with machine learning techniques and rule based tools.

## 2 Methods

The SemEval 2016 Clinical TempEval challenge (Bethard et al., 2016) is on identification of event spans (ES), time spans (TS) and their attributes (EA and TA), document time relation (DR) and narrative container relations (CR) among events and time expressions. In this paper, we describe two approaches using machine learning techniques for these tasks. First, we broadly classify the tasks into three tasks:

1. Sequence labeling tasks: These tasks involves tagging the sequence of words with the output tags. For example, tasks like part of speech tagging (POS), Named Entity recognition (NER) are sequence labeling tasks.
2. Classification tasks: Classification tasks focuses on classifying the entities into one of the output classes.
3. Relation Extraction Tasks : These tasks involves extracting relation of the entities with the other entities. That is, identifying temporal relations among event/time expressions.

In the following sections, we group the SemEval tasks into one of the above three tasks and provide the methodology dealt with each of these tasks.

**Table 1:** Event and Time attributes and their values

| Attributes     | Values  |
|----------------|---|
| EVENT:Modality | ACTUAL, HEDGED,<br>HYPOTHETICAL or GENERIC                |
| EVENT:Degree   | N/A, MOST or LITTLE                                       |
| EVENT:Polarity | POS or NEG  |
| EVENT>Type     | N/A, ASPECTUAL,<br>EVIDENTIAL                             |
| TIMEX:Class    | DATE, TIME, DURATION,<br>QUANTIFIER,<br>PREPOSTEXP or SET |

### Identification of events spans (ES) and Time Spans (TS)

Identifying events spans and time spans comes under sequence labeling. We use Conditional Random Field (CRF) which is a popularly used probabilistic graphical model for sequence labelling to extract event spans and time expressions. We use CRF++ suite (CRFPP,) tool for training conditional

random field model with the features:

**Term feature:** The word itself and its stem are used as features.

**POS and Chunk tags:** Parts of speech and chunk tags of the word. OpenNLP tagger is used for POS and Chunk tagging (Baldridge, 2005).

**Orthographic features:** Orthographic features like AlphaNumeric, IsNumeral, isUpperCase, startsWithUpperCase, etc.

**Stopword:** We use our custom English and Medical stopword list to tag this binary feature.

**Train Events Dictionary:** Dictionary of events build from the training dataset is used as a feature to check an event has already occurred in training dataset.

In addition to the above features, HeidelTime and HeidelTime Class are used as features for the identification of time expression.

### Identifying Events Attributes (EA) and Time Attributes (TA)

Table 1 shows the Event and Time attributes and their classes. Assigning these attributes to one of its values is an classification task. We train a separate Support Vector Machine (SVM) (Chang and Lin, 2011) for each of the attributes to classify in to their respective classes. We use word representations or word embeddings as the features for training the SVM classifier. The word representations are generated based on the co-occurrence count modeling using Stanford Glove tool (Pennington et al., 2014). We trained this count-based model on a text window size of 5, to obtain words vector representations of dimension 25. These word representations are used to train separate SVM classifier for each attribute.

### Identify Document Time Relation (DR) and Narrative Container Relation (CR)

Document Time Relation (DR) is the temporal relation of the entities with respect to the document create time. The document relations can take BEFORE, OVERLAP, BEFORE-OVERLAP or AFTER temporal relations.

Temporal links are used to identify the temporal ordering of the events in the timeline. These links are only provided for the events that happen within a temporal bucket, called narrative container, to avoid

**Table 2:** Phase 1 Evaluation on events, times and temporal relations

| Task                  | Approach 1 (CRF and SVM) |        |         | Approach 2 (DNN) |        |         |
|-----------------------|--------------------------|--------|---------|------------------|--------|---------|
|                       | Precision                | Recall | F-Score | Precision        | Recall | F-Score |
| EVENT:<span> (ES)     | 0.835                    | 0.797  | 0.815   | 0.838            | 0.786  | 0.811   |
| EVENT:Modality        | 0.764                    | 0.729  | 0.746   | 0.779            | 0.731  | 0.754   |
| EVENT:Degree          | 0.830                    | 0.793  | 0.811   | 0.834            | 0.783  | 0.807   |
| EVENT:Polarity        | 0.750                    | 0.716  | 0.733   | 0.813            | 0.764  | 0.788   |
| EVENT>Type            | 0.806                    | 0.769  | 0.787   | 0.814            | 0.765  | 0.789   |
| TIMEX3:<span> (TS)    | 0.752                    | 0.515  | 0.612   | 0.614            | 0.560  | 0.586   |
| TIMEX3:Class          | 0.644                    | 0.439  | 0.522   | 0.468            | 0.426  | 0.446   |
| EVENT:DocTimeRel (DR) | 0.481                    | 0.460  | 0.470   | 0.643            | 0.604  | 0.623   |
| TLINK:Type (CR)       | 0.431                    | 0.167  | 0.241   | 0.285            | 0.225  | 0.252   |

**Table 3:** Phase 2 Evaluation on temporal relations

| Task                  | Approach1 (CRF and SVM) |        |         | Approach2 (DNN) |        |         |
|-----------------------|-------------------------|--------|---------|-----------------|--------|---------|
|                       | Precision               | Recall | F-Score | Precision       | Recall | F-Score |
| EVENT:<span>          | 0.935                   | 0.912  | 0.923   | 0.994           | 0.994  | 0.994   |
| EVENT:DocTimeRel (DR) | 0.724                   | 0.705  | 0.714   | 0.588           | 0.588  | 0.588   |
| TIMEX3:<span>         | 0.965                   | 0.794  | 0.871   | 0.999           | 0.999  | 0.999   |
| TLINK:Type (CR)       | 0.348                   | 0.284  | 0.313   | 0.493           | 0.185  | 0.269   |

the heap of links between all possible events in the document (Styler IV et al., 2014). In an example sentence, “When *compared* with *ECG* of yesterday no significant change is found.”. Here, temporal link “BEFORE” is used to notify the event “*ECG*” is occurred BEFORE the event “*compared*”. The temporal relations BEFORE, OVERLAP, BEGINS-ON and CONTAINS are used for Narrative Container Relation (CR). We train CRF model similar to that of event span (ES) model to identify DR and CR.

### Another Approach using Deep Neural Networks (DNN)

Recent advances in deep learning architecture made us to try an another approach for this challenge. We have used deep neural networks (DNN) for all of the six sub-tasks of the challenge. Given a input sentence and output tags, the neural network learns the weights of nodes of each word of the sentence. The input words are represented as word embeddings which are same as that of word representations used for SVM classifier. A separate neural network is trained for each of the tasks using *deepnl* (Attardi, 2015) library. This neural network architecture follows the convolution method used for natural language processing (Collobert et al., 2011).

## 3 Results

The dataset used for the challenge comprises of de-identified cancer patient records from the Mayo Clinic with train dataset (195 clinical notes and 98 pathology reports), development dataset (98 clinical notes and 49 pathology reports) and test dataset (100 clinical notes and 51 pathology reports). All of the above described machine learning models are trained on the train and development dataset (340 documents) of THYME-corpus. The evaluation of the task is carried out in two phases. In the first phase, only plain clinical documents are provided. In the second phase, events and time expressions of clinical document are provided and the task is to find the document creation relation and narrative container relation. The results on extracting event, attributes and temporal relations on the test dataset (151 documents) are given in Table 2. Even though the values of DocTime Relation and Container relation are relatively less, they are comparable with the top performing system of SemEval challenge (Bethard et al., 2015). As the phase 2 of evaluation, we are provided with events, time expressions and their attributes, the results on extracting temporal relations are shown in Table 3.

## 4 Conclusion

In this paper, we present our work on Clinical TemEval task of SemEval 2016 challenge. We have used two approaches, first approach is based on CRF and SVM, and the second approach uses deep neural network to solve the tasks of the challenge. The results show that both approaches relatively same performance on the provided train and test datasets of the challenge.

# VUACLTL at SemEval 2016 Task 12: A CRF Pipeline to Clinical TempEval

**Tommaso Caselli and Roser Morante**  
CLTL Lab - Vrije Universiteit Amsterdam  
De Boelelaan 1105  
1081 HV Amsterdam, The Netherlands  
`{t.caselli, r.morantevallejo}@vu.nl`

## Abstract

This paper describes VUACLTL, the system the CLTL Lab submitted to the SemEval 2016 Task Clinical TempEval. The system is based on a purely data-driven approach based on a cascade of seven CRF classifiers which use generic features and little domain knowledge. The challenge consisted in six subtasks related to temporal processing clinical notes from raw text (event and temporal expression detection and attribute classification, temporal relation classification between events and the Document Creation Time, and narrative container detection). The system was initially developed to process newswire texts and then re-trained to process clinical notes. This had an impact on the results, which are not equally competitive for all the subtasks.

## 1 Introduction

Temporal Processing is becoming more and more important for improving access to content. The availability of timelines (either event-centric or entity-centric) can help improving more complex semantically-focused tasks such as Question Answering, Text Summarization, and Textual Entailment, among others. Furthermore, timelines can be further exploited for monitoring the development in time of different phenomena, e.g. the opinions in debates. Temporal Processing research has mainly focused on the newswire domain (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013) in the framework of several shared tasks where systems were challenged to extract the relevant components of a document timeline: temporal expressions,

event mentions, and temporal relations. Several evaluations have shown the capabilities and limits of both the annotated resources and the systems. For instance, the best system in TempEval-3 (Bethard, 2013) reports 0.398 F1 on Temporal Relation Detection and Classification from raw text. The development of temporally annotated corpora has boosted research in languages other than English such as Italian (Caselli et al., 2014), French (Arnulphy et al., 2015), and Spanish (Llorens et al., 2010), among others. Recently, interest in temporal processing has moved forward in two directions: cross-document timeline extraction (Minard et al., 2015) and domain adaptation (Sun et al., 2013; Bethard et al., 2015).

The setting of the 2015 and 2016 SemEval Clinical TempEval Tasks is similar to previous TempEval campaigns, with the two main differences: i.) the domain , i.e. (colon) cancer clinical notes; and ii.) the annotation scheme, i.e. the THYME annotation scheme (Styler IV et al., 2014), an extended version of TimeML (Pustejovsky et al., 2003a). Similarly to the previous edition, the SemEval 2016 Clinical TempEval task (Bethard et al., 2016) consists of the following six subtasks: temporal expression detection (TS) and attribute classification (TA), event detection (ES) and attribute classification (EA), temporal relation detection and classification of an event with respect to the Document Creation Time (DR), and, finally, narrative container relation identification (CR). Systems are evaluated in two phases: Phase 1, which addressed all six subtasks from raw data, and Phase 2, where target entities, such as events and temporal expressions (including their attributes), were given and the systems were evaluated

only against the temporal relation subtasks (DR, and CR). Our team participated in all subtasks and in both submission phases. Our main goals were:

- To test how our full system for temporal processing (from raw text to temporal relations) developed for the newswire domain would perform in another domain using minimal domain specific knowledge, both in terms of lexical resources and tools could achieve a competitive performance;
- To test the robustness of a system that uses simple morpho-syntactic features provided by a standard NLP pipeline(s);

The remainder of the paper is structured as follows: in Section 2, we provide an extensive description of the system and the features we have used.<sup>1</sup> Section 3 reports the results of the submitted runs and their comparison with respect to the baseline system, the median, and the maximum values as provided by the organizers. In Section 4 we perform an error analysis in order to better understand the limits of our system and gain insights for future improvements. Finally, Section 5 puts forward some conclusions.

## 2 System Description

The task organizers provided 293 training reports, 147 development reports for system development, and 151 testing reports for blind system evaluation. The training and development data had been used in the previous edition of the task.

The general structure of our system can be described as a pipeline of basic NLP tools on top of which we apply several Conditional Random Field (CRF) classifiers (Lafferty et al., 2001). We have used the CRF++ tool with default settings for the regularization algorithm (L2)<sup>2</sup> for all tasks. The final output is obtained by converting the output of 7 different classifiers into the task representation format, i.e. anafora xml files. In the following subsections, we describe the preprocessing steps, which is common for all subtasks, and the specific system for each subtask.

---

<sup>1</sup>For obtaining scripts and trained models contact the authors.

<sup>2</sup><https://taku910.github.io/crfpp/#links>

### 2.1 Preprocessing

All text files have been preprocessed by using two different tools: the IXA-pipeline (Agerri et al., 2014)<sup>3</sup> and the Stanford CoreNLP tool (Manning et al., 2014). From the IXA pipeline, we used the tokenization, offset and sentence splitting modules. We then passed the tokenized data to the Stanford CoreNLP tool in order to extract additional basic annotation layers such as lemmatization, part-of-speech tagging, and dependency parsing. The preprocessing step outputs the texts in a tab separated column format.

After preprocessing the text files, we merged the preprocessed text with the gold annotations, which were exported from the anafora xml files into a tab-column separated files.

### 2.2 Span Detection (ES, TS) and Attributes Classification (EA, TA) Tasks

We addressed the ES and TS task as a sequence labeling problem. As for the ES subtask, given an input text, each token is classified as being at the beginning of an event (B-event), inside an event (I-event), or outside an event (O). For this subtask, we have minimally adapted an event classifier developed for the newswire domain (NewsC), by adding domain specific features. We then developed a dedicated classifier for the EA subtasks. The TS and TA tasks have been addressed in a similar way to the ES and EA subtasks though, in this case, the temporal expression detection (TS) and type classification (TA) have been performed in one step by classifying all tokens in a text as being at the beginning or inside of a specific type (B-DATE or B-DURATION, I-DATE, I-DURATION, ...) or outside a temporal expression (O).

The ES and TS/TA subtasks share a set of basic morphosyntactic, namely:

- Token’s word, lemma, part-of speech, and dependency relation.
- Full dependency syntax path from the token to the root token.
- A combination of the token’s part-of-speech, dependency relation and dependency syntax path to the root token.

---

<sup>3</sup><https://github.com/ixa-ehu/vmc-from-scratch>

The specific features for ES are the following:

- Lemma and part-of-speech of the token’s head in the dependency tree.
- Semantic features (PropBank classes, FrameNet frames, and WordNet classes).
- A context window of size +/-2 for word, lemma, and part-of-speech.
- Domain specific feature 1: UMLS entity types<sup>4</sup>. The UMLS types have been assigned by means of a dictionary look-up. The dictionary has been created by means of the manually UMLS annotation from the training and development data.
- Domain specific feature 2: DBpedia “disease” class. Similarly to the UMLS, the DBpedia “disease” class has been assigned by means of a dictionary look-up. The dictionary has been created by extracting all mentions belonging to the class “disease” from DBpedia.<sup>5</sup>

As for the TS/TA specific features we have selected:

- A combination of the token’s dependency relation, lemma of its head, and part-of-speech.
- Semantic information (WordNet class and UMLS entity type, only).
- A context window of size +/-5 for token word, lemma, and part-of-speech.
- A context window of size +/-1 with a combination of the token’s dependency relation, head’s lemma and governor’s part-of-speech.

As for the EA subtask, we focused only on the EA:type. We have used a reduced set of lexical features with respect to the ES task along with new features from the IXA pipeline, namely:

- The token’s word, lemma, and part-of speech;
- A combination of the token’s part-of-speech, dependency relation and dependency syntax path to the root.

---

<sup>4</sup>[https://www.nlm.nih.gov/research/umls/META3\current\\\_semantic\\\_types.html](https://www.nlm.nih.gov/research/umls/META3\current\_semantic\_types.html)

<sup>5</sup><http://web.informatik.uni-mannheim.de/DBpediaAsTables/DBpediaClasses.htm>

- Semantic features (PropBank class, FrameNet frame, WordNet class, UMLS entity types and DBpedia “disease”).
- The predicate-argument structure from the IXA pipeline.<sup>6</sup>

As for the other EA values, we have assigned to each predicted event the most frequent attribute value as obtained from the training and development data.

### 2.3 Relation between Event and Document Creation Time Relation (DR)

The DR task was addressed as a multi-class classification task by considering pairs of *[event, time]* where each event was paired with the Document Creation Time (DCT). Following the THYME annotation guidelines, we set the DCT to the temporal expression in the first line of the document with the expression “head start date”. To represent the DCT, we have used only one feature, the predicted class. For each predicted event (as described above), the following features were used :

- The event word, lemma, and part-of-speech;
- The event’s dependency relation, the event’s head lemma and part-of-speech.
- A combination of the event part-of-speech, dependency relation, and the event’s head part-of-speech.
- The predicted class of the event (as described above).
- A context window of +/-2 consisting of lemma, part-of-speech, and whether the token has been predicted either as an event or as a temporal expression.
- Semantic features (PropBank class, FrameNet frame, WordNet class, UMLS entity types, and DBpedia “disease”).

### 2.4 Identifying Narrative Container Relations (CR)

Similarly to the DR task, the CR task was addressed as a classification task involving pairs of *[event, event]* and pairs of *[time, event]*. We restricted the pairs to intrasentential relations.

---

<sup>6</sup><https://github.com/newsreader/ixa-pipe-srl>

We developed two different approaches. The first approach (CLTLVUA-run1) addresses the problem of CR identification and classification in two steps: first, it automatically identifies candidate events or temporal expressions which can be eligible for being containers, and then it uses this information to create the candidate pairs, i.e.  $[event, event]$  and  $[time, event]$ , to detect the presence of a CR relation. On the other hand, the second approach (CLTLVUA-run2) detects and classifies CR relations in a single step. In both approaches the classifiers use the same set of features. The CR detection and classification tasks have been performed with two classifiers: one for  $[event, event]$  pairs and another for  $[time, event]$  pairs.

We used basic morpho-syntactic and semantic features for the container detection model, namely:

- The event/temporal expression’s word, lemma and part-of-speech.
- Semantic features (PropBank class, FrameNet frame, WordNet class, UMLS entity types, and DBpedia “disease”).
- The temporal expression’s class;
- A context window of +/-2 consisting of lemmas and parts-of-speech.
- A combination of the token’s part-of-speech, dependency relation and syntactic path to the root.

The CR classifier for  $[event, event]$  pairs uses three sets of features:

- Basic morpho-syntactic and semantic features for each event in the pair (text, lemma, part-of-speech, a combination of part-of-speech, dependency relation and head’s part-of-speech, PropBank class, FrameNet frame, WordNet class, UMLS entity types, and DBpedia “disease”).
- The syntactic path connecting the two events in the relations (enriched with parts-of-speech).
- Contextual features: temporal prepositions connecting the two events, temporal preposition at the beginning of the sentence and the presence of other events between the element in the pair.

The CR classifier for  $[time, event]$  pairs uses the same set of features as for the  $[event, event]$  classifier plus the temporal expressions class and the textual order of the pair.

### 3 Results

We report the results on the test set for all subtasks. For clarity’s sake we will illustrate in different tables the results for all subtasks. Results have been computed in terms of Precision (P), Recall (R) and F1. For comparison we will also report the baseline provided by the organizers (Bethard et al., 2015), and the median and maximum scores of the participating systems.

Table 1 contains the system scores for ES and EA:type for Phase 1 of the evaluation. As for EA:type we will report only the F1 score. We also report the results obtained by our system on the newswire domain (test set of the TempEval-3 evaluation).

| ES System       | P     | R     | F1           | type-F1 |
|-----------------|-------|-------|--------------|---------|
| VUACCTL         | 0.868 | 0.828 | <b>0.847</b> | 0.819   |
| Baseline        | 0.878 | 0.834 | 0.855        | 0.833   |
| Median          | 0.887 | 0.846 | 0.874        | 0.844   |
| Maximum         | 0.915 | 0.891 | 0.903        | 0.882   |
| VUACCTL - NewsC | 0.861 | 0.858 | 0.859        | n.a.    |

**Table 1:** VUACCTL Results for ES and EA:type subtasks - Phase 1.

The results obtained are below the baseline (-0.017 for P and -0.006 for R) and median scores (-0.019 for P and -0.018 for R). In absolute terms, the results are not much different from the NewsC version of the system.

The results for TS and TA are reported in Table 2. We include also an out-of-competition version (VUACCTL\_OC), with a bug correction in the conversion script for the final format. The VUACCTL\_OC has a lower score for P for the baseline (-0.013) and median (-0.018), while R outperforms baseline and basically equals the median score.

| TS System  | P     | R     | F1           | class-F1 |
|------------|-------|-------|--------------|----------|
| VUACCTL    | 0.660 | 0.372 | 0.476        | 0.462    |
| VUACCTL_OC | 0.761 | 0.540 | <b>0.632</b> | 0.619    |
| Baseline   | 0.774 | 0.428 | 0.551        | 0.532    |
| Median     | 0.779 | 0.539 | 0.637        | 0.618    |
| Maximum    | 0.840 | 0.758 | 0.795        | 0.772    |

**Table 2:** VUACCTL Results for TS and TA subtasks - Phase 1.

Table 3 reports the results for the DR for Phase 1 and Phase 2. For Phase 2 the organizers provided only R scores. In Phase 1 the system scores median results, while in Phase 2 the system R scores above baseline and below median.

| DR System          | P            | R            | F1           |
|--------------------|--------------|--------------|--------------|
| VUACLTL phase 1    | <b>0.655</b> | <b>0.624</b> | <b>0.639</b> |
| Baseline - phase 1 | 0.620        | 0.589        | 0.604        |
| Median - phase 1   | 0.655        | 0.624        | 0.639        |
| Maximum - phase 1  | 0.766        | 0.746        | 0.756        |
| VUACLTL phase 2    | 0.724        | <b>0.701</b> | 0.712        |
| Baseline - phase 2 | -            | 0.675        | -            |
| Median - phase 2   | -            | 0.724        | -            |
| Maximum - phase 2  | -            | 0.843        | -            |

**Table 3:** VUACLTL Results for DR - Phase 1 and 2.

Finally, Table 4 reports the results for the CR subtask for Phase 1 and 2. In both evaluation phases, both runs of the systems outperform the baseline and median scores for P and R. The VUACLTL\_OC also obtains competitive score for P with respect to the maximum score (-0.008). Similar observations hold for Phase 2 of the evaluation where VUACLTL-run1, though performing below the maximum scores, obtains the median scores for R and F1, and a higher P. On the other hand, VUACLTL-run2 tends to maximize R with a minor downgrading of P.

| CR System               | P            | R            | F1           |
|-------------------------|--------------|--------------|--------------|
| VUACLTL-run1 phase 1    | <b>0.497</b> | 0.241        | 0.325        |
| VUACLTL-run2 phase 1    | 0.493        | <b>0.268</b> | <b>0.347</b> |
| VUACLTL_OC-run1 phase 1 | <b>0.523</b> | 0.253        | 0.341        |
| Baseline - phase 1      | 0.403        | 0.067        | 0.115        |
| Median - phase 1        | 0.491        | 0.235        | 0.318        |
| Maximum - phase 1       | 0.531        | 0.471        | 0.479        |
| VUACLTL-run1 phase 2    | <b>0.642</b> | 0.345        | 0.449        |
| VUACLTL-run2 phase 2    | 0.589        | <b>0.368</b> | <b>0.453</b> |
| Baseline - phase 2      | 0.459        | 0.154        | 0.231        |
| Median - phase 2        | 0.589        | 0.345        | 0.449        |
| Maximum - phase 2       | 0.823        | 0.564        | 0.573        |

**Table 4:** VUACLTL Results for CR - Phase 1 and 2.

## 4 Discussion

Overall, our system obtains competitive scores only in the DR and and CR subtasks while in the other substasks the performances are low.

As for the ES and EA:type subtasks, our approach was clearly not the best solution as our system cannot outperform the baseline. We have identified at least three different sources of errors: i)

wrong output of the pre-processing modules, especially the tokenization module; ii) limitations of the features selected; and iii) lack of domain specific knowledge (i.e. semantics) and rules to add robustness to the data-driven approach (Valenzuela-Escárcega et al., 2015).

A per-document evaluation of the ES subtask has shown that out of the 151 testing reports half of them have an F1 equal or higher than the median score, 13 have an F1 between the baseline and the median score and 75 have an F1 below the baseline. In this latter group, we have a subset of 7 files with F1 below or equal 0.50. A detailed analysis of these subset has shown that the source of errors (between 46% - 67%) is due to wrong offsets. Different problems, such as lack of domain specific knowledge, errors in parsing<sup>7</sup>, and lack of post-processing rules, affect the other 68 files. In particular, an analysis of a subset of the 47 files with P and R below the baseline shows that the false negatives represent between 20% and 37% of the system errors while false positives are only between 8% and 26%. Most of the false negatives are mentions of events that are illnesses (e.g. *tumor*, *adenocarcinoma*) or events with a limited number of annotated examples in the training and development data (e.g. *Grossed* 9 annotated cases out of 32 mentions; *labeled* 15 annotated cases out of 34 mentions). We have also noticed that errors derived from wrong tokenization (and offset) are still present with percentages ranging between 1% to 9%.

Despite the modest performance of the system, it is interesting to observe that features which work for the newswire domain<sup>8</sup> can be easily used to obtain good results also in other domains for this task. It is clear that the results of the ES subtask affects the performance on the EA:type subtask. Furthermore, the lack of rules and good domain specific knowledge have also affected the robustness of the system.

A main factor that affects the performance of the system in the TS and TA subtasks is the choice of tackling span and class identification in one step, instead of two. Nevertheless, the VUACLTL\_OC version obtains comparable results for TS for R and F1

<sup>7</sup>For some sentences, the Stanford CoreNLP parser was not able to provide a dependency output.

<sup>8</sup>See the performance of the NewsC system in Table 1.

with respect to the baseline and the median score, but not for P (-0.013 for the baseline, -0.018 for the median) and has a higher F1 score (+0.001 point) for the TA subtask.

In the DR subtask, the system achieved the median score in Phase 1 and obtained a lower R in Phase 2, but in both cases it performs better than baseline. A detailed evaluation by DR type shows that the system performs better for OVERLAP (0.643 F1) and BEFORE (0.736 F1), which is logical, since these types are more frequent than the other two types, AFTER (0.675 F1) and BEFORE/OVERLAP (0.438 F1). The system tends to overpredict BEFORE, which has the highest recall (0.823) while it obtains the highest precision for OVERLAP (0.809). In order to improve the results for this task, different features might be needed related to the section where the event occurs, temporal expressions surrounding the event, and tense and aspect features of the predicates in the event context.

As for the CR subtask, the two versions of our system perform well outperforming both baseline and median scores in both evaluation phases. The low R values are in part due to the fact that we paired *time* and *event* expressions within the same sentence only, ignoring cross-sentence relations. The two-step strategy implemented in VUACLTL-run1 clearly pays in terms of P with a minor impact on R. Notice that the bug in the final format conversion for temporal expressions has an impact also on the overall evaluation of the CRs. The P results of the VUACLTL\_OC-run1 version show that the two-step approach scores only -0.008 with respect to the maximum score. Although the difference between the two approaches is not statistically significant ( $\chi^2 > 0.05$ ), the VUACLTL-run1 (and VUACLTL\_OC-run1) approach is to be preferred over VUACLTL-run2 because of the way it identifies narrative containers. The method focuses on [*event*, *event*] pairs for CRs in order to narrow down the search of possible pair relations and identify semantic properties of candidate containers. The set of features used to identify CRs is a valid one as the results on Phase 2 show (P and R are higher or equal to the median score for both version of the system).

Looking back at our initial goals, we can conclude that the temporal processing system developed for the newswire domain is portable to the clinical do-

main, although to achieve a top performance it is necessary to use domain specific tools and lexical resources to improve the feature generation. The system proved to be more robust for the CR and DR tasks, than for the ES and TS tasks.

## 5 Conclusions

We have described the VUACLTL system for the SemEval-2016 Clinical TempEval. The system is based on a combination of different CRFs classifiers, trained with basic morphosyntactic features and domain specific knowledge. Performances for the basic tasks, although competitive, leave room for improvement. Lack of domain specific knowledge and lack of postprocessing rules have affected the system robustness. However, the system has obtained competitive results for the CR task. Although the performances of the two versions of the system are not statistically significant, we prefer the two-step approach (VUACLTL-run1) because it is more precise and it reflects a more linguistically informed notion of narrative container.

There are many options to improve the system, ranging from fine tuning the pre-processing phase in order to avoid offset misalignments, to the generation of better features for the ES and DR subtasks, or the extension of the CR relations to cross-sentence relations. Very important is to integrate more domain specific knowledge.

As future work, we plan to implement all the improvements mentioned above, and additional improvements that might arise from the in-depth error analysis that we are carrying out in order to gain insight into the limitations of the system and to make informed decisions in the engineering of new features.

## Abstract

Extraction and interpretation of temporal information from clinical text is essential for clinical practitioners and researchers. SemEval 2016 Task 12 (Clinical TempEval) addressed this challenge using the THYME<sup>1</sup> corpus, a corpus of clinical narratives annotated with a schema based on TimeML<sup>2</sup> guidelines. We developed and evaluated approaches for: extraction of temporal expressions (TIMEX3) and EVENTS; TIMEX3 and EVENT attributes; document-time relations; and narrative container relations. Our approach is based on supervised learning (CRF and logistic regression), utilizing various sets of syntactic, lexical and semantic features with addition of manually crafted rules. Our system demonstrated substantial improvements over the baselines in all the tasks.

## 1 Introduction

SemEval-2016 Task 12 (Clinical TempEval) is a direct successor to 2015 Clinical TempEval (Bethard et al., 2015) and the past I2b2 temporal challenge (Sun et al., 2013). Clinical TempEval is designed to address the challenge of understanding clinical timeline in medical narratives and it is based on the THYME corpus (Styler IV et al., 2014) which includes temporal annotations.

<sup>1</sup>Temporal Histories of Your Medical Event.  
[https://clear.colorado.edu/TemporalWiki/index.php/Main\\_Page](https://clear.colorado.edu/TemporalWiki/index.php/Main_Page)

<sup>2</sup>TimeML is a standard specification language for events and temporal expressions in natural language.  
<http://www.timeml.org/>

Researchers have explored ways to extract temporal information from clinical text. Velupillai et al. (2015) developed a pipeline based on ClearTK<sup>3</sup> and SVM with lexical features to extract TIMEX3 and EVENT mentions. In I2b2 2012 temporal challenge, all top performing teams used a combination of supervised classification and rule based methods for extracting temporal information and relations (Sun et al., 2013). Besides THYME corpus, there have been other efforts in clinical temporal annotation including works by Roberts et al. (2008), Savova et al. (2009) and Galescu and Blaylock (2012). Previous work has also investigated extracting temporal relations. Examples of these efforts include: classification by SVM (Chambers et al., 2007), Integer Linear Programming (ILP) for temporal ordering (Chambers and Jurafsky, 2008), Markov Logic Networks (Yoshikawa et al., 2009), hierarchical topic modeling (Alfonseca et al., 2012), and SVM with Tree Kernels (Miller et al., 2013).

Clinical TempEval 2016 was focused on designing approaches for timeline extraction in the clinical domain. There were 6 different tasks in the TempEval 2016, which are listed in Table 1. Per TimeML specifications (Pustejovsky et al., 2003), we refer to temporal expressions as TIMEX3 and events as EVENT throughout the paper. Attributes of TIMEX3 and EVENTS are outlined according to the THYME annotations (Styler IV et al., 2014). 16 teams participated in TempEval 2016 (Bethard et al., 2016).

For extracting temporal information from clinical text, we utilize supervised learning algorithms

| Task     | Description  |
|----------|--|
| TS       | TIMEX3 spans   |
| ES       | EVENT spans  |
| TA       | Attributes of TIMEX3   |
| Class    | $\langle$ DATE, TIME, DURATION, QUANTIFIER, PREPOSTEXP, SET $\rangle$                                  |
| EA       | Attributes of EVENTS   |
| Modality | $\langle$ ACTUAL, HYPOTHETICAL, HEDGED, GENERIC $\rangle$  |
| Degree   | $\langle$ MOST, LITTLE, N/A $\rangle$  |
| Polarity | $\langle$ POS, NEG $\rangle$   |
| Type     | $\langle$ ASPECTUAL, EVIDENTIAL, N/A $\rangle$   |
| DR       | Relation between EVENT and document time<br>$\langle$ BEFORE, OVERLAP, BEFORE/OVERLAP, AFTER $\rangle$ |
| CR       | Narrative container relations  |

Table 1: Tasks of clinical TempEval 2016

(Conditional Random Fields (CRF) and logistic regression) with diverse sets of features for each task. We also utilize manually-crafted rules to improve the performance of the classifiers, when appropriate. We show the effectiveness of the designed features and the rules for different tasks. Our system outperforms the baselines across all tasks, and is above the median results of all the teams in all tasks but one (CR in precision)<sup>1</sup>.

## 2 Methodology

Our approach to all tasks is based on supervised learning using lexical, syntactic and semantic features extracted from the clinical text. We also designed custom rules for some tasks when appropriate. Details are outlined below:

### 2.1 TIMEX3 and EVENT Span Detection (TS, ES)

To extract TIMEX3 and EVENT spans (TS and ES), we use a combination of linear-chain CRFs (Lafferty et al., 2001) with manually-crafted rules<sup>1</sup>. Linear-chain CRFs are one of the most robust structured prediction approaches in natural language processing. We train the CRF for detecting TIMEX3s and EVENTS using BIO (Begin Inside Outside) labeling. That is, for the TIMEX3 classifier, after tokenizing the text, each token is labeled as

<sup>1</sup>The official ranking of participating teams is unknown at the time of writing and would be announced at the SemEval workshop.

|          |  |
|----------|--|
| Features | lowercase; token letter case; if token is title; if token is numeric; if token is stopword; POS tag; brown cluster; prefix; suffix; noun chunk shape of the token; lemma |
|----------|--|

Table 2: Base feature set for supervised algorithms

either “O,” “B-TIMEX3,” or “I-TIMEX3”. Similarly, the event classifier labels the tokens as either “O” or “B-EVENT,” as virtually all EVENT annotations are only one token long. We use the CRF-Suite toolkit (Okazaki, 2007) for our experiments.

The main features that we use for CRF in TS and ES tasks are outlined in Table 2. Among these features is Brown clustering (Brown et al., 1992) which is a form of hierarchical clustering based on the contexts in which the words appear. Brown clusters mitigate lexical sparsity issues by considering the words in their related cluster. We constructed fifty clusters across the the train and test datasets and passed the binary identifier of a token’s cluster as the feature.

In addition to these features, we use domain specific features for EVENT span detection. Our domain feature extraction is based on the Unified Medical Language System (UMLS) ontology (Bodenreider, 2004). We use MetaMap<sup>2</sup> (Aronson and Lang, 2010), a tool for mapping text to UMLS concepts, for extracting the concepts. The semantic types of the extracted concepts are then used as features. Since UMLS is very comprehensive, considering all the semantic types causes drift. Thus, we limit semantic types to those indicative of clinical events (e.g. diagnostic procedure, disease or syndrome, and therapeutic procedure). For each feature set, we expand the features by considering a context window of +/- 3 tokens (The context window of size 3 yielded the best results on the development set).

For EVENT spans, we supplement the CRF output spans with manually crafted rules designed to capture EVENT spans. Particularly, we add rules to automatically identify EVENTS relating to standard patient readings. For example in: “*Diastolic=55 mm[Hg]*”, using simple regular expressions, we isolate the word “Diastolic” as an EVENT span.

For TIMEX3 spans, we use regular expressions that were designed to capture standard formatted

<sup>2</sup><https://metamap.nlm.nih.gov/>; we used the 2014 version

| Features |  |
|----------|--|
| Set 1    | UMLS semantic type; tense of the related verb in dependency tree; dependency root of the sentence  |
| Set 2    | class, text and brown cluster of closest DATE, PREPOSTEXP and TIMEX3; comparison with section time; comparison with document time; sentence tense and modals |

Table 3: Additional feature sets used for document-time relation (DR) extraction.

dates. These rules improved the results of ES and TS considerably, as shown in Section 3.2.1.

## 2.2 Time and Event Attribute Detection

The main attribute for TIMEX3 mentions is their “class,” which can be one of the following six types: DURATION, DATE, QUANTIFIER, PREPOSTEXP, SET, or TIME. EVENTS have four attributes each of which includes different types (Table 1). Full description of the types of the attributes are described by Styler IV et al. (2014). To properly classify each TIMEX3 and EVENT attribute, we train a separate logistic regression classifier<sup>1</sup> for each TIMEX3 and EVENT attribute value. These classifiers are trained on the TIMEX3 and EVENT spans that were previously extracted from the span CRFs (Section 2.1), and employ a similar feature set as the others.

In addition to the base feature set, we also incorporate rules as features in our classifier. We consider words that are indicative of certain EVENT attributes. For example, words such as “complete” or “mostly” indicate DEGREE:MOST, “possibly” indicates MODALITY:HEDGED and “never” shows POLARITY:NEG. We add such contextual features for DEGREE, MODALITY, and POLARITY.

In addition to the rules mentioned above, we further devise rules that lead to immediate classification as a specific class or attribute value. For example, TIMEX3 annotations in the format “[number] per [number]” are classified as SET automatically. We use the most probable predicted class as the final assigned label.

<sup>1</sup>We used the scikit-learn implementation. With L1 regularization and Liblinear solver.

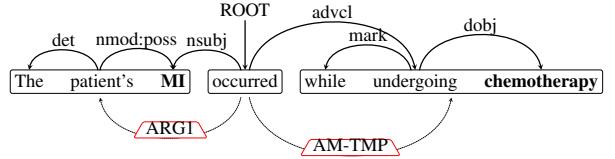

Figure 1: Example of dependency parse tree and semantic roles in the sentence. Dependency relations are shown by arrows above the sentence and semantic roles below it. The boldface terms in the sentence are event mentions. Per human annotation, the following relation exists in this sentence: *[MI]CONTAINS[chemotherapy]*.

## 2.3 Document-time Relation (DR)

Document-time relations (DR) are specific attributes of EVENTS indicating their temporal relation with the document creation time. There are 4 different types of DRs, namely, BEFORE, AFTER, OVERLAP, and BEFORE/OVERLAP. For identifying the DR attribute types, we use the same general classification approach as EVENT and TIMEX3 attributes; we train separate classifiers for each DR type using an extended set of features to what was used for EVENT attributes detection.

Table 3 describes the additional features that we use for DR extraction. In addition to the base features, we consider features specific to the EVENT annotation. These features are illustrated as Set 1 in table 3. We furthermore expanded the features by considering contextual features from the sentence and nearby time and date mentions (Set 2 in Table 3). Medical narratives often follow a chronological order. Therefore, nearest TIMEX3 mentions, and their comparison with the section timestamp or document timestamp can be good indicators of DRs. Similarly, verb tense and the modals in the sentence are also indicative of the sentence tense and can help in identifying the document-time relation. These additional features improved the results, as shown in Section 3.2.3.

## 2.4 Narrative Container Relations (CR)

Narrative containers (Pustejovsky and Stubbs, 2011) are TIMEX3s or EVENTS that subsume other EVENTS in a section of the text. They serve as temporal buckets into which other EVENTS fall. For example in the sentence: “*The patient recovered well after her first [surgery] on [December 16th]*”, [December 16th] is the narrative container and the

| Evaluation |      | Phase 1 |      |      |      |      |      |          |      |      |        |      |      |          |      |      |      |      |      |      |      |      |      |      |
|------------|------|---------|------|------|------|------|------|----------|------|------|--------|------|------|----------|------|------|------|------|------|------|------|------|------|------|
| Task       | TS   | ES      |      |      | TA   |      |      | MODALITY |      |      | DEGREE |      |      | EA       |      |      | DR   |      |      |      |      |      |      |      |
|            |      | CLASS   |      |      |      |      |      |          |      |      |        |      |      | POLARITY |      |      | TYPE |      |      |      |      |      |      |      |
| Metric     | P    | R       | F1   | P    | R    | F1   | P    | R        | F1   | P    | R      | F1   | P    | R        | F1   | P    | R    | F1   |      |      |      |      |      |      |
| Baseline   | .774 | .428    | .551 | .878 | .834 | .855 | .746 | .413     | .532 | .810 | .770   | .789 | .874 | .831     | .852 | .812 | .772 | .792 | .885 | .813 | .833 | .620 | .589 | .604 |
| Median     | .779 | .539    | .637 | .887 | .846 | .874 | .755 | .499     | .618 | .830 | .780   | .810 | .882 | .838     | .869 | .868 | .813 | .839 | .854 | .813 | .844 | .655 | .624 | .639 |
| Our system | .802 | .678    | .735 | .891 | .872 | .881 | .775 | .655     | .710 | .836 | .818   | .827 | .887 | .868     | .877 | .875 | .856 | .866 | .868 | .849 | .858 | .719 | .704 | .711 |

Table 4: Phase 1 evaluation results on test set for the tasks Time Span (TS), Event Span (ES), Time Attribute (TA), Event Attribute (EA) and Document-time Relation (DR). Baseline refers to the *memorize* baseline described in Section 3.1

following containment relation exists: “{December 16th} CONTAINS [surgery]”.

To extract narrative container relations, we use the semantic frames of the sentences. We only consider the intra-sentence containment relations (appearing in the same sentence) and do not handle inter-sentence relations (crossing sentences). According to the THYME annotation guidelines (Styler IV et al., 2014), both EVENTS and TIMEX3s can provide boundaries of narrative containers. The first step in identifying narrative container relations is to identify the *anchor*, the EVENT or TIMEX3 span which contains all the other related EVENTS (*targets*). To learn the *anchor*, *target* and containment relation, in addition to the base features for *anchor* and *target*, we use Semantic Role Labeling (SRL) and dependency parse tree features of the sentence.

SRL assigns semantic roles to different syntactic parts of the sentence. Specifically, according to PropBank guidelines (Palmer et al., 2005), SRL identifies the semantic arguments (or predicates) in a sentence. If the *anchor* or the *target* fall in a semantic argument of the sentence, we assign the argument label as the feature to the associated *anchor* or the *target*. Using semantic roles, we extract the semantics of constituent parts of the sentence in terms of features which help to identify the container relations. For SRL, we use Collobert et al. (2011) neural model<sup>1</sup>. An example of semantic role labels is outlined in figure 1, in which labels below the sentence indicate the semantic labels.

Next, we consider the dependency parse tree of the sentence. Given the *anchor* and the *target* we traverse the dependency parse tree of the sentence to identify if they are related through a same root. In the sample sentence shown in figure 1,

chemotherapy is the *anchor* and MI is another event which is the *target*. As shown, they are connected through the root of the sentence (“occurred”).

Per annotation guidelines, TIMEX3 spans should receive higher priority over EVENTS for being labeled as the *anchor*. Therefore, we also consider the type of the expression (TIMEX3 or EVENT) as feature. Additional features such as UMLS semantic types, POS tags, dependency relations and verb tense of the sentence’s root are also considered. To extract POS, syntactic and dependency-based features, we use the Spacy toolkit (Honnibal and Johnson, 2015).

### 3 Experiments

The 2016 Clinical TempEval task consisted of two evaluation phases. In phase 1, only the plain text was given and the TIMEX3 and EVENT mentions were unknown. In phase 2, which was only for DR and CR tasks, the TIMEX3 and EVENT mentions were revealed. In phase 1, we participated in all tasks, except for CR. In phase 2, we participated in both the DR and CR tasks.

#### 3.1 Baselines

The baselines are two rule-based systems (Bethard et al., 2015) that are provided along with the corpus. The *memorize* baseline, which is the baseline for all tasks except for narrative containers, memorizes the EVENT and TIMEX3 mentions and attributes based on the training data. Then, it uses the memorized model to extract temporal information from new data. For narrative containers, the *closest match* baseline, predicts a time expression to be narrative container, if it is the closest EVENT expression.

#### 3.2 Results

Our system’s results on test set for all tasks are presented in Table 4 (phase 1) and Table 5 (phase 2).

<sup>1</sup>SENNA implementation: <http://ml.nec-labs.com/senna/>

| Evaluation phase | Phase 2 |      |      |      |      |      |
|------------------|---------|------|------|------|------|------|
|                  | DR      |      |      | CR   |      |      |
| Metric           | P       | R    | F1   | P    | R    | F1   |
| Baseline         | -       | .675 | -    | .459 | .154 | .231 |
| Median           | -       | .724 | -    | .589 | .345 | .449 |
| Our results      | .816    | .813 | .815 | .546 | .471 | .506 |

Table 5: Phase 2 evaluation results for Document-time Relation (DR) and narrative Containment Relations (CR) (The values indicated by (-) were not reported in SemEval official results). Baseline for DR is the *memorize* baseline and for CR is the *closest match* baseline (Section 3.1).

| Model       | P    | R    | F1   |
|-------------|------|------|------|
| CRF         | .758 | .616 | .679 |
| CRF + rules | .777 | .654 | .710 |

Table 6: Effect of manually-crafted rules for TIMEX3 span (TS) on development set.

Our results in all tasks outperform the baselines, and in all but one case (CR-Precision) are above the median of all the participating teams.

### 3.2.1 TIMEX3 and EVENT spans (TS, ES)

For TS and ES, our system achieved F1 scores of 0.735 and 0.881 (on the test set) which gives +33.4% and +3.0% improvement over the baseline. While the improvement for TS is much larger, we observed less improvement on the ES task. For ES, Table 6 shows the effect of incorporating manually crafted rules to the output of CRF. These rules improved the F1 performance by 4.6%. In addition, as illustrated in Table 7, adding domain specific features (UMLS semantic types) improved the performance of base features (+2% F1). Adding manual rules to the output of CRF resulted in further improvement (additional +1% F1).

### 3.2.2 TIMEX3 and EVENT attributes (TA, EA)

For TA and EA, our system achieved an F1 of 0.710 and an average F1 of 0.856, respectively (Table 4). Our results improve over the baseline by 33.5% in TA and 4.8% in EA, respectively (for baseline, the average F1 of EA over all attribute types is 0.817). For EA, while performance of all types of attributes is comparable, the best performance relates to DEGREE attribute class with F1 of .887. The results of the TA and EA tasks for development set are also reported in Table 8. Generally, our results on the test set are marginally higher than on the development set which shows

| Model         | P    | R    | F1   |
|---------------|------|------|------|
| base features | .863 | .836 | .849 |
| + UMLS        | .879 | .854 | .866 |
| + rules       | .886 | .864 | .875 |

Table 7: EVENT span (ES) results on development set based on different features.

| Category    | P    | R    | F1   |
|-------------|------|------|------|
| TA:CLASS    | .752 | .632 | .687 |
| EA:MODALITY | .832 | .816 | .824 |
| EA:DEGREE   | .879 | .863 | .871 |
| EA:POLARITY | .864 | .848 | .856 |
| EA:TYPE     | .854 | .838 | .846 |

Table 8: Results of the TIMEX3 and EVENT attributes (TA and EA) on the development set.

that we have successfully avoided over-fitting on the training and development sets.

### 3.2.3 Document-time relation (DR)

The DR task was included in both evaluation phases. Its F1 score in phase 1 was 0.711 and in phase 2 was 0.815. Naturally, since in phase 1, the spans of EVENTS were unknown, lower performance is expected in comparison with phase 2. The DR results in both phases show substantial improvements over the baseline (+17.7% F1 in phase 1 and +20.4% recall in phase 2).

The effect of context window size on DR performance on development set is reported in Table 9. As the window size increases, more contextual features are added and therefore performance increases. However, after a certain point, when the window becomes excessively large, the performance decreases. We attribute this to overfitting the training data because of too many features. The optimal context window size is 6 which we used for our final submission. As far as features, we evaluated three primary feature sets (using a window of 6), the results of which are outlined in Table 10. The features are defined in tables 2 and 3. As illustrated, the addition of Set 1 and Set 2 features resulted in improvements in all DR types.

Error analysis for DR showed that many of the misclassified examples were for the BEFORE/OVERLAP relations, as also reflected in the low relative performance of BEFORE/OVERLAP relations (Table 10). In many cases, these relations are wrongly classified as either BEFORE or OVERLAP categories. For some cases, it is

| w (+/-) | P    | R    | F1   |
|---------|------|------|------|
| 1       | .781 | .780 | .781 |
| 2       | .790 | .789 | .790 |
| 3       | .794 | .793 | .794 |
| 4       | .799 | .798 | .798 |
| 5       | .801 | .800 | .801 |
| 6       | .804 | .802 | .803 |
| 7       | .802 | .801 | .802 |
| 8       | .795 | .793 | .794 |

Table 9: DR results on development set by window size.

not clear even for human whether the EVENTS had happened before the creation time of the document or they continued at document creation time. For example in the following: “*Resected rectal [adenocarcinoma], with biopsy-proven local [recurrence]*”, the EVENT [adenocarcinoma] is of document relation type BEFORE/OVERLAP whereas our classifier wrongly classified them as BEFORE.

### 3.2.4 Narrative Container relations (CR)

The CR results are presented in Table 5. Our approach substantially improves over the baseline, especially in terms of recall (+2.06 times recall improvement). This demonstrates that using semantic frames of the sentences as well as their dependency structure can be effective in identifying container relations. However, F1 score of 0.506 shows that there is still plenty of room for improvement on this task. Error analysis showed that many of the false negatives relate to the inter-sentence relations. Our approach is designed for capturing only intra-sentence container relations. Similarly, some other false negatives were due to the dates that were not syntactically part of the sentence. An example is: “{June 14, 2010}: His first [colonoscopy] was positive for [polyp]”. In this example, {June 14, 2010} is the anchor and [colonoscopy] and [polyp] are the targets. However, the designated date is not any syntactic part of the sentence and consequently, our approach is unable to capture that as the correct anchor of the narrative container.

## 4 Discussion and conclusions

SemEval 2016 task 12 (Clinical TempEval) was focused on temporal information extraction from clinical narratives. We developed and evaluated a system for identifying TIMEX3 and EVENT spans,

| Features | DR Type |       |      |      |       |
|----------|---------|-------|------|------|-------|
|          | All     | After | Bef. | B/O  | Over. |
| Base     | .785    | .725  | .791 | .536 | .820  |
| + Set 1  | .792    | .751  | .796 | .545 | .823  |
| + Set 2  | .803    | .756  | .812 | .538 | .833  |

Table 10: DR Results breakdown by type based on different features on the development set. Base features are defined in Table 2, Set 1 and 2 features are defined in Table 3.

TIMEX3 and EVENT attributes, document-time relations, and narrative container relations. Our system employed machine learning classification scheme for all the tasks based on various sets of syntactic, lexical, and semantic features. In all tasks, we showed improvement over the baseline and, in all but one case (CR-Precision) we placed above the median of all participants (The official ranking of the systems were not announced at the time of writing).

While we showed the effectiveness of diverse set of features along with supervised classifiers, we also illustrated that incorporating manually crafted extraction rules improves results. However, manual rules should be constrained as some rules interfere with the learning algorithm and negatively affect the results. The strongest rules were those based on consistent patterns, such as dates in the standard format (e.g. MM-DD-YYYY). On the other hand, while some other rules improved the recall, they led to much lower precision and F1 score. For example, a rule that matches the word “time” as TIMEX3 span, improved our TS recall considerably but at the expense of overall precision and therefore was not included in the final submission.

For narrative containment relations, we showed that semantic frames and dependency structure of the sentence are helpful in identifying the relations. However, our approach is limited to intra-sentence relations and we are not detecting relations that are cross-sentences. In future work, we aim to expand our approach to detect inter-sentence container relationships.

## Abstract

The 2016 Clinical TempEval continued the 2015 shared task on temporal information extraction with a new evaluation test set. Our team, UtahBMI, participated in all sub-tasks using machine learning approaches with ClearTK (LIBLINEAR), CRF++ and CRF-suite packages. Our experiments show that CRF-based classifiers yield, in general, higher recall for multi-word spans, while SVM-based classifiers are better at predicting correct attributes of TIMEX3. In addition, we show that an ensemble-based approach for TIMEX3 could yield improved results. Our team achieved competitive results in each subtask with an F1 75.4% for TIMEX3, F1 89.2% for EVENT, F1 84.4% for event relations with document time (DocTimeRel), and F1 51.1% for narrative container (CONTAINS) relations.

## 1 Introduction

Extracting temporal information from unstructured clinical narratives is an important step towards the accurate construction of a patient timeline over the course of clinical care (Savova et al., 2009), identifying and tracking patterns of care that are crucial for decision making (Augusto, 2005; Wang et al., 2008) and identifying cases or cohorts with temporal criteria for medical research (Raghavan et al., 2014). In the medical domain, more emphasis has been placed on utilizing temporal information from structured databases (Combi et al., 2010). However, recent developments in Medical Natural Language Processing (NLP) research has stimulated work in ex-

tracting information from unstructured clinical text (Meystre et al., 2008; Velupillai et al., 2015a) and facilitated future directions to extracting temporal information (Zhou and Hripcsak, 2007).

The i2b2 series of NLP challenges focused in 2012 on extracting events (problems, treatments and tests), time expressions (date, duration, time and frequency) and temporal relations (before, after, overlap) from a set of annotated discharge summaries. The best performing systems used supervised machine learning approaches, except for time expression identification and normalization where rule-based followed by hybrid approaches were most successful (Sun et al., 2013b; Sun et al., 2013a).

In 2015, the SemEval challenge included a Clinical TempEval task (Bethard et al., 2015) with similar objectives to the 2012 i2b2 challenge. The TimeML event and temporal expressions specification language (Pustejovsky et al., 2010) was adapted to define events, time expressions and relation annotations suitable for the clinical domain (Styler et al., 2014). The THYME (Temporal Histories of Your Medical Event) corpus is used in the Clinical TempEval challenge. The annotations in this corpus introduce the use of narrative containers concept (Pustejovsky and Stubbs, 2011) to reduce the complexity of finding temporal relations between every possible pair, and allow rapid discovery through automatic inferences. Each event and time expression is, when possible, assigned a narrative container that defines their temporal span. Groups of events and times within a narrative container can then be linked as one unit with other containers; eliminating the need to explicitly link every pair of events and times.

The additional pairs can be derived easily from minimal links between pairs within different narrative containers.

We present in this paper the methods used and results obtained from experiments with SVM-based linear classifiers and CRF-based sequential classifiers for the Clinical TempEval task. We complement the paper with a discussion and insights that potentially could help future efforts in this domain.

## 2 Methods

### 2.1 Task & Materials

The 2016 Clinical TempEval challenge included 6 subtasks: TIMEX3 1) span detection and 2) attribute classification, EVENT 3) span detection and 4) attribute classification, 5) relation between each event and document creation time classification (known as DocTimeRel), and narrative container or 6) CONTAINS relations between pairs of events and times classification. Our team participated in both phases provided in the challenge (phase 1: plain text only of the test set and phase 2: reference annotations for TIMEX3 and EVENTS including attributes were given for the relation classification subtasks) For a detailed description of the subtasks and evaluation metrics we refer the reader to (Bethard et al., 2015; Bethard et al., 2016).

The THYME corpus used in this task consists of treatment and pathology notes for colon cancer patients from the Mayo clinic. Three datasets were provided: *train* (=293 documents), *dev* (=147) and *test* (=151). We used the *dev* set to benchmark different approaches during system development and as a guideline to manually select the best performing features. All final models used for predictions were trained using the combined *train+dev* datasets. The *test* set was used for the final evaluation. Each subtask was addressed separately using a machine learning classifier and groups of almost similar features with slight changes such as surrounding context window sizes. cTAKES (Savova et al., 2010) was used to pre-process each clinical note to generate morphological, lexical and syntactic-level annotations, which were used as features for training the classifiers. The ClearTK machine learning package (Bethard et al., 2014) was used to build Support Vector Machine (SVM) LIBLINEAR (Fan

et al., 2008) classifiers, while CRFsuite (Okazaki, 2007) and CRF++ (Kudo, 2005) were used to build Conditional Random Field (CRF) sequential classifiers. Both cTAKES and ClearTK utilize the Apache Unstructured Information Management Applications (UIMA) framework (Ferrucci and Lally, 2004) which makes it easy to integrate modules from both applications and pipeline output from cTAKES to ClearTK using the XML Metadata Interchange (XMI) format.

### 2.2 Input Preparation/Feature Extraction

Each clinical note in the corpus was previously segmented into sections with a [start section id=...] and [end section id=...] markers that were easy to identify and annotate using regular expressions. Therefore, we built a UIMA module to segment each clinical note into section boundaries; each annotated with their respective section ID. cTAKES clinical pipeline (version 3.2.2) was used to extract lexical and syntactic features. These include sentence boundaries, tokens, lemmas, part-of-speech tags, syntactic chunk tags (e.g. Verb Phrase-VP, Noun Phrase-NP), token type as defined by cTAKES (see figure 1), as well as dependency parse and semantic role labels used for relation classification. Furthermore, ClearTK feature extractors were used to generate word shape features (e.g. capital, lower, numeric), character patterns and character N-gram features for the linear classifiers. The CRFsuite package comes with built-in feature extractor functions for word shapes, character patterns and N-gram which were used for the TIMEX3, EVENT and DocTimeRel CRF classifiers. Table 1 outlines the features used in each subtask.

For the CRF packages, the features had to be transformed into a flat, tab-separated structure with columns of tokens and associated features each placed in one line. Sentences are designated by empty lines following a sequence of lines of tokens (see Figure 1 for an example).

### 2.3 SVM-based Approach

The LIBLINEAR package within ClearTK was used to train all linear classifiers with default settings ( $C=1.0$ ;  $s=1$ ;  $\text{Loss}=\text{dual L2-regularized}$ ) except for TIMEX3 (grid search performed on the training set indicated a better value for  $C=0.5$ ). We re-used

| Feature Type                           | CRFsuite |        |            | CRF++      | LIBLINEAR |        |            |          |
|--|----------|--------|------------|------------|-----------|--------|------------|----------|
|  | TIMEX3   | EVENT  | DocTimeRel | DocTimeRel | TIMEX3    | EVENT  | DocTimeRel | CONTAINS |

| Dilated | dilat | JJ  | I-NP  | WordToken   | 20112      | ... |

**Figure 1:** Example of the flat input used for the CRF approaches: features in columns separated by tabs.

the approach taken in the 2015 Clinical TempEval (Velupillai et al., 2015c) for TIMEX3, EVENT and DocTimeRel subtasks, with minor changes in the used features. For TIMEX3, one separate classifier was created for each class (e.g., DATE, TIME). For EVENT, one classifier was created for detecting the text span, and one separate classifier for each attribute (i.e., MODALITY, DEGREE, POLARITY and TYPE). In addition, we added a classifier in this pipeline, for event relations with the document time (DocTimeRel). The main feature additions in this year’s challenge were a section ID feature for all classifiers; and a binary feature—whether or not a token was classified as temporal expression of an adapted version of HeidelTime (Strötgen and Gertz, 2010)—for the TIMEX3 subtask.

For the narrative container (CONTAINS) relations subtask, we trained four models to predict relations between pairs of 1) event-event and 2) event-time within a sentence; and 3) event-event and 4) event-time across consecutive sentences. This approach has been previously shown to be most effective in predicting temporal relations (Xu et al., 2013). The candidate pairs were selected<sup>1</sup> using

the following strategy: All possible combinations of pairs between events and events-times within a sentence were generated for training and classification. For event-event pairs across consecutive sentences; only the first and last event from the current sentence were paired with the first and last from next (or subsequent) sentence. For event-time pairs across sentences; each time phrase in the current sentence is paired with the first and last events from the preceding and following sentences. This approach suffers from the limitation of allowing many examples with the negative class (i.e., pairs without a relation) to be selected; and hence causes class imbalance that may affect classifier training. (Tang et al., 2013) demonstrated that using heuristics to select candidates that are more likely to be part of a relation could produce superior results for temporal relation classification. Another possible remedy is to introduce scaling parameters to adjust the weight of each class during training, such that data samples from the positive class get more weight while the negative class samples get less weight (Lin et al., 2015). Due to time constraints, we were unable to experiment with either of these approaches.

## 2.4 CRF-based Approach

For the sequential classification, we used the CRF-suite for TIMEX3, EVENT and DocTimeRel subtasks in phase 1, and CRF++ for the DocTimeRel subtask in phase 2. All CRF trained models used default settings ( $C=1.0$ ; algorithm=L-BFGS). During phase 1, we employed a cascaded approach: we trained CRFsuite models to 1) predict textual spans of TIMEX3 and EVENT tokens separately; 2) pre-

<sup>1</sup>cTAKES Temporal module was very useful in facilitating experiments for the TLINK relations.

|                     | span         |              |              | span+class   |              |              |
|---------------------|--------------|--------------|--------------|--------------|--------------|--------------|
|                     | P            | R            | F1           | P            | R            | F1           |
| MAX                 | 0.840        | 0.758        | 0.795        | 0.815        | 0.735        | 0.772        |
| CRFsuite            | 0.798        | 0.714        | 0.754        | 0.771        | 0.690        | 0.729        |
| LIBLINEAR           | <b>0.810</b> | 0.690        | 0.745        | <b>0.792</b> | 0.674        | 0.728        |
| CRFsuite+LIBLINEAR  | 0.761        | <b>0.769</b> | <b>0.765</b> | 0.733        | <b>0.741</b> | <b>0.737</b> |
| memorize (Baseline) | 0.774        | 0.428        | 0.551        | 0.746        | 0.413        | 0.532        |

**Table 2:** TIMEX3 subtask results on the test set.

dict TIMEX3 and EVENT attributes using the predictions in step 1), and 3) predict DocTimeRel and CONTAINS relations using the predictions in steps 1-2. The prediction labels were encoded using the standard IOB2 format of **Inside**, **Begin**, and **Outside**. For instance, prediction labels for the phrase “see him this afternoon .” will be encoded as “O O B-TIME I-TIME O” where “this afternoon” is a TIMEX3 expression in this context. CRF classifiers are probabilistic graphical models that take into account a previous window of prediction labels and assign the most likely sequence of labels based on estimates obtained from the training data. Therefore, they usually perform better in tasks that require assigning labels to sequential data. This is particularly true for the TIMEX3 subtask where the majority of time phrases span multiple tokens.

### 3 Results

The performance we obtained for the various subtasks on the test set are shown in Tables 2, 3, 4. We also include the results from two baseline systems (**memorize** — for EVENT, TIMEX3 and DocTimeRel, and **closest** — for CONTAINS relations) provided by the workshop organizers, as well as the maximum score achieved in each subtask from all submissions (Bethard et al., 2016). Note that for the narrative container subtask, we report the official score and corrected score we obtained after discovering and correcting a bug affecting the LIBLINEAR models that prevented predictions of event-time relations.

CRF achieved a better performance (F1 %75.4) than the linear classifier (F1 %74.5) when detecting TIMEX3 spans because of higher recall (R %71.4). The LIBLINEAR model resulted in higher precision (P %81). Our initial analysis indicates that this is partly due to many CRF predictions overlapping with the reference annotations rather than matching exactly. When using a strict match evaluation approach, these overlaps are counted as false

positives. For example, the CRF approach generated TIMEX3 labels for expressions like “at the time” and “in the past” while the reference standard included TIMEX3 annotations for only “the time” and “past”, respectively. Combining the predictions from both models (by taking the union set of outputs and discarding duplicated predictions) allowed for improved performance (F1 %76.5) suggesting that an ensemble-based strategy could yield superior results for this subtask. Additional analysis will be needed to understand which class of TIMEX3 phrases each model is better at predicting and apply a more sophisticated ensemble method such as weighted average.

The results for the EVENT subtasks were almost identical between the two approaches (CRF or LIBLINEAR), except when classifying the *modality* and *type* attributes where CRF performed better. Combining the predictions from both models did not allow for any performance improvements. Note also that the baseline results for this subtask are very high.

For the DocTimeRel subtask, the CRFsuite model reached an F1 of %74.5 in phase 1, while the CRF++ model reached an F1 of %84.4 in phase 2; allowing for significant improvement over the performance of the LIBLINEAR model (F1 %81.8). For the CONTAINS relations classification subtask, the LIBLINEAR models achieved an F1 of %42.2 in phase 1 when using CRF predictions of TIMEX3 and EVENT; and F1 of %51.1 in phase 2. Note that for phase 2 we also included the prediction of DocTimeRel relations from CRF as an input feature to the LIBLINEAR models.

### 4 Discussion

Several important issues need to be addressed for future improvement in this task or other similar tasks. We outline some of these issues below, along with an analysis from the reference standard annotations and the system prediction errors.

The CRF-based classifiers detected TIMEX3 mentions with higher accuracy. As mentioned previously, many of these mentions were overlapping with the reference standard annotations. Our output included 352 false positive errors when using a strict match evaluation. Among these errors, about

|                     | span  |       |       | span+modality |       |       | span+degree |       |       | span+polarity |       |       | span+type |       |       |
|---------------------|-------|-------|-------|---------------|-------|-------|-------------|-------|-------|---------------|-------|-------|-----------|-------|-------|

**Table 4:** Relation classification results on the test set.

<sup>†</sup>Indicates official scores before bug correction.

228 were overlapping (but not matching perfectly) with reference annotations, and the remaining 124 errors were due to other reasons. If counting these overlapping errors as true positives instead of false positives, as in a partial match evaluation, significant accuracy improvements could be observed (P: 0.929, R: 0.833, F1: 0.878)<sup>2</sup>. Contributions from last year’s TempEval task have pointed out the issue of TIMEX3 annotations inconsistency in the reference standard (Tissot et al., 2015). After examining the 228 overlapping false positive errors further, we noticed through empirical analysis that many were due to either missing or added prepositions (e.g., ‘at’, ‘in’, ‘for’, ‘about’) and determiners (‘a’, ‘the’). Further examination revealed that, as pointed out by the previous authors, there is an inconsistent trend in the reference standard annotations. For example, the reference standard contains the following TIMEX3 phrases (underlined words indicate words not annotated in the reference standard): “in the past”, “in the last three days”, “for many years”, “for two years”, “at this time”, “at this time”, “about 27 years ago” and “about 30 years ago”. These irregularities will make it difficult for any machine learning model to generalize well beyond the given dataset and most likely will indicate overfitting for higher performance models (Velupil-

lai et al., 2015b). The reported inter-annotator agreement for TIMEX3 span annotations of F1 77.4% (Bethard et al., 2015) further supports these assumptions. Therefore, future work should focus on creative ways to deal with this inconsistency and enable more generalizable solutions. Apart from the overlapping errors due to reference standard inconsistencies; other types of errors may indicate room for future improvement. We believe that training multiple classifiers and combining the outputs using ensemble-based approach could yield superior results as manifested from combining predictions of CRF and LIBLINEAR models.

For the DocTimeRel subtask, the CRF-based classification approach also allowed for significant improvements, particularly in phase 2. Table 5 shows the confusion matrix and evaluation scores obtained on the dev set for each category of DocTimeRel relation using CRF++ model when trained on the training set. The final scores achieved (R 83.3%) on the dev set, are comparable to the scores achieved (R 84.3%) on the test set. This allows us to make consistent conclusions about classifier performance on one set (dev) that can be expected to apply on the other set (test). The lowest accuracy (R 48.6%) was observed with the BEFORE/OVERLAP category. A possible explanation for this lower accuracy is the small number of training samples available in this category (2160 instances in the training set out of 38885). The confusion matrix shows that this category gets almost a balanced error rate between the BEFORE (297) and OVERLAP (271) categories. In addition, the highest number of misclassified instances occur in OVERLAP (972) and BEFORE (858) categories where one category is confused for the other. Future work should focus on improving classification in the BEFORE and OVERLAP categories.

The performance achieved using LIBLINEAR models in the CONTAINS relations subtask (F1 42.2%–51.1%) is a significant improvement over last year’s attempt using a CRF model (F1 12.3%–

<sup>2</sup>This score was obtained using the --overlap option from the official evaluation script.

**Table 5:** Confusion matrix and scores for each category of DocTimeRel relation obtained on the dev set using CRF++ classifier.

26.0%) (Velupillai et al., 2015c). We think that studying different strategies for candidate pair selection or experimenting with different class weights to reduce effects of negative class predictions could allow for improvement in this subtask. In addition, although we used two separate models to predict relations between event pairs within and between consecutive sentences, we restricted the way we chose candidates across sentences (first and last from current sentence are paired with first and last from next sentence). This restriction was used to avoid an increase in the number of pairs without a relation (i.e., negative class pairs); in addition to the increased computational runtime penalty. However, this means that any candidate pairs spanning across many sentences will be missed by our classifier. This is especially true for some event and time phrases that are usually at the beginning of a sentence (mostly introducing a section header) and act as narrative containers for many events in the next few sentences. For instance, our classifier missed the ‘HISTORY’ narrative container appearing as part of the section header “PAST MEDICAL HISTORY”, which is usually a relation source for many events discussed within the section. One example from the dev set shows that the ‘HISTORY’ event CONTAINS following events (e.g., medical conditions in a numbered list) spanning from the next first sentence down to the eleventh sentence. Future work could focus on using carefully hand-crafted rules to capture these pairs to increase recall. We think that the most successful approach for this subtask could use hybrid approaches combining rules and machine learning classifiers to improve recall and retain high precision, respectively.

## 5 Conclusion

Temporal information extraction and reasoning from clinical text remains a challenging task. Our analysis

of different machine learning approaches have been informative, and resulted in competitive results for the 2016 Clinical TempEval subtasks. We plan to develop hybrid and ensemble-based approaches in the future to further improve performance on this, and other clinical corpora.

## Acknowledgments

We would like to thank the Mayo clinic and the 2016 Clinical TempEval challenge organizers for providing access to the clinical corpus, and arranging NLP shared task.

## Abstract

This paper describes our approach to participate on SemEval2016 Task12: Clinical TempEval. Our system was based on IBEnt, a framework to identify chemical entities and their relations in text using machine learning techniques. This system has two modules, one to identify chemical entities, and other to identify the pairs of entities that represent a chemical interaction in the same text. In this work we adapted both IBEnt modules to extract temporal expressions, event expressions and relations, by creating new CRF classifiers, lists and rules. The top result of our system was in phase2 for the identification of narrative container relations where it obtained the maximum score of precision (0.823) from all participants.

## 1 Introduction

In this paper we present our approach to participate on SemEval 2016 Task12: Clinical TempEval (Bethard et al., 2016) challenge. In phase1, participants had only access to the raw text, and they were asked to identify and classify time expressions (TIMEX3), event expressions (EVENT) and relations between expressions (RELATION), and in phase2 participants had access to the raw text and the manual EVENT and TIMEX3 annotations, and they were asked to identify only RELATION annotations. Our team participated in TS (identify the span of TIMEX3 expressions), ES (identify the span of EVENT expressions) and CR (identify narrative container RELATION) subtasks in phase1, and in

phase2 we participated in the CR subtask. Our system was based on IBEnt (Lamurias et al., 2015), a framework that identifies chemical entities and their relations in text using machine learning techniques. Although IBEnt has been designed to extract chemical entities, we wanted to find out its potential to deal with other type of expressions. IBEnt has two modules: module one, an improvement of the tool developed by (Grego and Couto, 2013), recognizes chemical entities based on the Stanford NER software (Finkel et al., 2005) to train Conditional Random Field (CRF) classifiers using labelled data as input; module two identifies the pairs of entities that represent a chemical interaction in a given text based on machine learning techniques and domain knowledge. In particular, this latter module uses a non-linear kernel, the Shallow Language kernel (Giuliano et al., 2006) taking into account both the global and local context of each entity to determine if they are interacting or not. The Shallow Language Kernel uses the word, lemma, POS and tag of each token to train a classifier. One instance was generated for each candidate pair, whose elements were identified with a specific tag. In our system we modified both modules in order to extract the relevant expressions and relations. We used module one to extract the span of TIMEX3 and EVENT expressions, and module two to extract the RELATION between expressions. For each subtask we modify IBEnt differently. To extract TIMEX3 expression, the features of the CRF classifier were changed, as well as some specific rules and lists. To extract EVENT expressions we modified the features of the CRF classifier and we added some rules. For TIMEX3 and EVENT

expressions we used n-gram features, lemma, context and word shape. Identifying the RELATION between expressions required a more complex scheme, with the training of four CRF classifiers and the creations of specific rules, addressed to find relations between near entities. For RELATION we used as features the word, lemma, POS and NER tag. Thus, the aim of our system was to identify the span of temporal expressions (TIMEX3) and clinical events (EVENT), and find relations between them (RELATION).

## 2 Methods

To train our system we used the data set provided by Clinical TempEval organization, with 439 raw text clinical notes from Mayo Clinics and the respective manual annotations, and 153 raw text clinical notes to test the system. Some adaptations were made to IBEnt framework with the intent of identifying TIMEX3 and EVENT expressions. The manual annotated data set was divided into train and development sets. We used the train set to train the CRF classifiers and the development set to evaluate and tune the performance. First, as a pre-processing step, the raw text was split into sentences using the Genia Sentence Splitter (Sætre et al., 2007). Each sentence was then processed by Stanford CoreNLP to obtain basic synthetic information to be used by the algorithms.

For TIMEX3 expressions extraction, Stanford NER already had a library for recognizing and normalizing TIMEX3 expressions, named SUTime. The problem with SUTime was that it does not recognize temporal expressions related with clinical terms, such as "postoperative". To solve this inconvenience, our team created a manual list, with approximately 200 temporal clinical terms, such as "post-op", "pre-surgery" and "peritreatment", using different combinations of words, based on temporal medical concepts from Unified Medical Language System (UMLS) (Bodenreider, 2004). To complement this list, we trained a CRF classifier with the manual annotations and we created post-processing rules to improve the results. These rules were to exclude sections that were not supposed to be annotated, such as patient medication, allergies and education; to divide dates the CRF classifier was an-

notating together, for example "10-06-2010 10-06-2011" thus the system could consider this as two separated entities instead of just one entity; and to exclude invalid characters, such as quotation marks, commas and parenthesis. These rules were heuristically created, based in the observation of the clinical notes raw text.

For EVENT expressions extraction we trained a CRF classifier with the training set provided. We also created rules to solve problems the classifier was not able to identify and fix. One of the rules was about the number of words an event can have (we considered that an event had just one word, which is nearly always the case). For example, "tumor demonstrated" should be considered by the system as two entities. The other rule was to exclude expressions with numbers, once the CRF classifier was annotating, for example, "T4" and "N2" as EVENT expressions.

Regarding RELATION extraction, our approach was slightly different from the ones used to extract TIMEX3 and EVENT. For this subtask, we trained four different CRF classifiers, according with the relation type: EVENT EVENT; EVENT TIMEX3; TIMEX3 TIMEX3 and TIMEX3 EVENT. Each candidate pair was considered if the two entities appear in the same or adjacent sentences. A couple of rules were also created to find relations in the raw text. First rule: if there is a TIMEX3 expression and in the next four words there is an EVENT expression, the system points a relation between both expressions (TIMEX3 and EVENT). The second rule is about the patients history: every TIMEX3 or EVENT below the EVENT HISTORY will have a relation with it. These rules were determined empirically in order to reduce the number of potential relations, since any two entities mentioned in the same document could constitute a relation.

## 3 Results submission

The original submitted results for phase1 had a bug. Entities, which should always have different IDs, had the same ID for EVENT and RELATION. Thus, the evaluation script provided by the organization (Chen and Styler, 2013) was unable to evaluate our system. To fix this problem, we sent the same results again but with the corrected IDs. For both

phase1 and phase2, we submitted two runs. Table1 shows the differences in our system between runs for each subtask. For TIMEX3 expressions, Phase1 Run1 (P1R1) was submitted only with the annotations obtained with the manual list of temporal concepts, without any expression obtained with the CRF classifier. On the other hand, Phase1 Run2 (P1R2) was submitted with the annotations obtained with the CRF classifier and the manual list of temporal concepts previously explained in Methods section. P1R1 and P1R2 for EVENT expressions just differ in the Stanford NER features used to train the CRF classifier, for example, MaxNGramLeng, maxLeft and useTypeSeqs. Regarding RELATION, in phase1 the main difference between runs was the input used, i.e., for this phase we used the TIMEX3 and EVENT expressions extracted from the raw text using our system. We submitted the RELATION annotated with the classifiers and with the rules (see Methods section). Phase2 submission had a greater difference between each run. Beside the fact the input was the manual annotations for TIMEX3 and EVENT provided by the organization, for Phase2 Run1 (P2R1) we submitted the RELATION obtained with either the CRF classifiers or rules, and for Phase2 Run2 (P2R2) we submitted the relations obtained with both the CRF classifiers and rules.

## 4 Results and Discussion

In this section we exhibit the results of ULISBOA for the participating subtasks and we discuss these results. In Table 2 we present ULISBOA results for both phases 1 and 2, and the maximum scores obtained in the competition for each subtask.

### 4.1 TS identifying the spans of time expressions(TIMEX3)

For TIMEX3 expressions extraction there is a major difference in the results of P1R1 and P1R2. For this subtask we intended to modify Stanford NER features, focusing P1R1 for a better recall and P1R2 for a better precision. Instead, and due to a misunderstanding, P1R1 was submitted only with the TIMEX3 annotations obtained through the manual list of temporal concepts, which justifies the low recall. However, after a deeper analysis of this problem, we concluded that precision should be higher, once it was assumed that all the terms in the list are always a TIMEX3 expression. With a posterior revision of the list (after the deadline of submission), we tested it again. Terms included in the list, like “at this time” and “at that time”, were removed and we added all terms that were already in the list with the first letter in uppercase, with this obtaining a higher precision (0.933). This test suggest that the temporal list we have created is a good complement to our system. For P1R2, the score achieved is near the maximum for precision (-0.064), recall (-0.066) and F1-measure (-0.063). There are some words our system did not annotate as TIMEX3 expression, for example, “time” and “date”. We also observed that there was some ambiguity on the annotations regarding the spans of expressions with more than one words. For example, there were cases where “at this time” was annotated, and others where only “this time” was annotated. These inconsistencies made it more difficult to train a CRF classifier and to generate a list of TIMEX3 expressions. Another issue was about our manual list of temporal concepts, which did not consider uppercases words, so the system did not annotate terms such as “Intraop” as TIMEX3.

### 4.2 ES identifying the spans of event expressions(EVENT)

P1R1 and P1R2 scores were similar in EVENT expressions extraction, with a difference between runs of 0.002 for precision, 0.006 for recall and 0.004 for F1-measure. For both runs we used different Stanford NER features, not achieving significant differences in results. However, P1R1 was the closest to the maximum score, especially regarding to precision (-0.034). Once this differences are not statisti-

|                               |            | TIMEX3       |              |              | EVENT        |              |              | RELATIONS    |              |              |
|-------------------------------|------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|--------------|

| <b>Phase1<br/>with bugfix</b> | Run1(P1R1) | 0.623        | 0.065        | 0.118        | 0.881        | 0.745        | 0.807        | 0.122        | 0.009        | 0.017        |
|                               | Run2(P1R2) | 0.776        | 0.692        | 0.732        | 0.879        | 0.739        | 0.803        | 0.108        | 0.009        | 0.017        |
|                               | Max        | <b>0.840</b> | <b>0.758</b> | <b>0.795</b> | <b>0.915</b> | <b>0.891</b> | <b>0.903</b> | <b>0.531</b> | <b>0.471</b> | <b>0.479</b> |
| <b>Phase2</b>                 | Run1(P2R1) | -            | -            | -            | -            | -            | -            | 0.273        | 0.255        | 0.264        |
|                               | Run2(P2R2) | -            | -            | -            | -            | -            | -            | <b>0.823</b> | 0.056        | 0.105        |
|                               | Max        | -            | -            | -            | -            | -            | -            | <b>0.823</b> | <b>0.564</b> | <b>0.573</b> |

**Table 2:** ULISBOA results for phase1 (TIMEX3, EVENT and RELATION) and phase2 (RELATION). P=precision; R=Recall; F1=F1-measure; Max=maximum score obtained in the challenge.

cally significant, we are going to focus our discussion in P1R1. For this subtask, we trained a CRF classifier and combined the results with the rules explained in Methods sections. We did not use any ontology or dictionary which explains why some basic terms were not annotated (False Negatives), such as “scan” and “normal”, or which were incorrectly annotated (False Positives), such as “CT-scan” and “plan”. Our system achieved a score of 0.80 to F1-measure in the aforementioned subtask, i.e., a considerable part of the expressions was correctly classified as EVENT. However, classifying an expression as EVENT depends on its surrounding context. In the previous example, “scan”, as the action of doing an exam, should be annotated as an EVENT, and ”CT-scan”, as X-Ray Computed Tomography machine, should not be annotated. Thus, there is an increased demand to develop new semantic techniques, such as semantic similarity, to complement our system (Couto and Pinto, 2013). Another problem was about the rule that considers the EVENT only as one word, because instead of separate the entity in two different entities, this rule excluded these entities from the results, so we were losing one entity and lowering the recall.

#### 4.3 CR identifying narrative container relations(RELATION)

For Clinical TempEval phase1, our system RELATION results were much lower than the maximum scores, for both P1R1 (precision -0.409; recall -0.471; F1-measure -0.462) and P1R2 (precision -0.423; recall -0.471; F1-measure -0.462). The variances in the system between each run in phase1 were only the input, TIMEX3 and EVENT expressions extracted from the raw text with our system.

In phase2, our results were improved when com-

pared with phase1 (see Table2). For example, in phase1, the same clinical note had 3 RELATIONS identified, compared with 109 RELATIONS identified in phase2. A better recall was obtained in phase2, for both runs. For P2R1 we considered relations identified either by the classifiers or rules, which is why we got a better recall for this run. For P2R2, we considered relations identified both by the classifiers and rules, i.e., we only accepted relations as positive if the same relation was identified by both the classifier and the rules. For example, in the sentence “the oncologist today would attempt to quantify”, in P2R1 the relation between “today” and “quantify” was detected by the rules, but not by the classifier, showing in the final results as a false positive. In P2R2 this did not happen, being this relation excluded from final results because only the rules had detected it. In P2R2 our system achieved a maximum score of 0.823 for precision. However, the recall was lower than P2R1, since we limited the number of relations to be considered. Thus, we can affirm that our system in P2R2 found less relations, but with much higher precision.

## 5 Conclusions and Future Work

In SemEval Clinical TempEval we participated in three of the six subtasks: TS (TIMEX3 span extraction), ES (EVENT span extraction) and CR (RELATION extraction). Our system, based on machine learning and rules, achieved the maximum precision score for RELATIONS in Phase2. However, more work is necessary to understand how we can improve the recall without a significant decrease in precision. Despite the fact that we had limited time to work for this challenge, our scores for TIMEX3 and EVENT expressions extraction were acceptable and near the maximum scores achieved for other

systems. For future work, we intend to correct errors already found and test the system again, and for EVENT expressions we want to test several ontologies, such as SNOMED-CT (Cornet and de Keizer, 2008), to improve our results. Due to the ambiguity of clinical notes, we must understand the real impact manual rules have in final results, so we may have the opportunity to create a greater number and more accurate rules in order to be applied in a larger number of cases. One technique that can be used is distant learning (Mintz et al., 2009). This technique uses a knowledge base, such as an ontology, to automatically generate training data, requiring less manual effort. Another approach is to extend our domain knowledge about the problem in hand by for example collecting and exploring semantic web medical resources (Machado et al., 2015). Furthermore, we want to create an open source framework for our system, after we make it stable. Next SemEval Clinical TempEval edition, we hope to participate in the remaining subtasks and to improve our results, especially for RELATION, where much work remains to be done.

## Abstract

We propose a deep neural network based natural language processing system for clinical information (such as time information, event spans, and their attributes) extraction from raw clinical notes and pathology reports. Our approach uses the context words and their part-of-speech tags and shape information as features. We utilize the temporal (1D) convolution neural network to learn the hidden feature representations. In prediction step, we use the Multilayer Perceptron (MLP) to predict event spans. The empirical evaluation demonstrates that our approach significantly outperforms baseline methods.

## 1 Introduction

In past several years, there has been much interest in applying neural network based deep learning techniques to solve many natural language processing (NLP) tasks. From low-level tasks such as language modeling, POS tagging, named entity recognition, and semantic role labeling (Collobert et al., 2011; Mikolov et al., 2013), to high-level tasks such as machine translation, information retrieval, semantic analysis (Kalchbrenner and Blunsom, 2013; Socher et al., 2011a; Tai et al., 2015) and sentence relation modeling tasks such as paraphrase identification and question answering (Socher et al., 2011b; Iyyer et al., 2014; Yin and Schutze, 2015). Deep representation learning has demonstrated its importance for

To whom all correspondence should be addressed. This work was partially supported by NSF-IIS 1117965, NSF-IIS 1302675, NSF-IIS 1344152, NSF-DBI 1356628, NIH R01 AG049371.

these tasks. All the tasks get performance improvement via learning either word level representations or sentence level representations.

In this work, we introduce the deep representation learning technologies to the electronic medical record research. Specifically, we focus on clinical information extraction, using clinical notes and pathology reports from the Mayo Clinic. Our system is designed to identify event expressions consisting of the following components:

- The spans (character offsets) of the expression in the raw text
- Contextual Modality: ACTUAL, HYPOTHETICAL, HEDGED or GENERIC
- Degree: MOST, LITTLE or N/A
- Polarity: POS or NEG
- Type: ASPECTUAL, EVIDENTIAL or N/A

The input of our system consists of raw clinical notes or pathology reports. The following is an example:

*April 23, 2014: The patient did not have any postoperative bleeding so we will resume chemotherapy with a larger bolus on Friday even if there is slight nausea.*

The output annotations over the text capture the key information such as event mentions and attributes. Table 1 illustrates the output of clinical information extraction in details.

To solve this task, the major challenge is how to precisely identify the spans (character offsets) of

| Clinical Note   | Event Mention | Event Attribute |                       |  |
|---|---------------|-----------------|-----------------------|--|
| April 23, 2014:<br>The patient did not have any postoperative bleeding so we will resume chemotherapy with a larger bolus on Friday even if there is slight nausea. | bleeding      | type=N/A        | polarity=NEG          |  |
|   |               | degree=N/A      | modality=ACTUAL       |  |
|   | resume        | type=ASPECTUAL  | polarity=POS          |  |
|   |               | degree: N/A     | modality=ACTUAL       |  |
|   | chemotherapy  | type=ASPECTUAL  | polarity=POS          |  |
|   |               | degree=N/A      | modality=ACTUAL       |  |
|   | bolus         | type=ASPECTUAL  | polarity=POS          |  |
|   |               | degree=N/A      | modality=ACTUAL       |  |
|   | nausea        | type=ASPECTUAL  | polarity=POS          |  |
|   |               | degree=N/A      | modality=HYPOTHETICAL |  |

**Table 1:** An example of information extraction from clinical note.

the event expressions from raw clinical notes. Traditional machine learning approaches usually build a supervised classifier with features generated by the Apache clinical Text Analysis and Knowledge Extraction System (cTAKES)<sup>1</sup>. For example, BluLab system (Velupillai et al., 2015) extracted morphological (lemma), lexical (token), and syntactic (part-of-speech) features encoded from cTAKES. Although using the domain specific information extraction tools can improve the performance, learning how to use this software well for clinical domain feature engineering is still very time-consuming. In short, a simple and effective method that only leverages basic NLP modules and achieves high extraction performance is desired for regular users.

To address this challenge, we propose a deep neural networks based method, especially convolution neural network (Collobert et al., 2011), to learn hidden feature representations directly from raw clinical notes. More specifically, one method first extracts a window of surrounding words for the candidate word. Then, we attach each word with their part-of-speech tag and shape information as extra features. After that, our system deploys a temporal convolution neural network to learn hidden feature representations. Finally, our system uses Multilayer Perceptron (MLP) to predict event spans. Note that we use the same model to predict event attributes.

## 2 Constructing High Quality Training Dataset

The major advantage of our system is that we only leverage NLTK<sup>2</sup> tokenization and a POS tagger to preprocess our training dataset. When implementing our neural network based clinical information extraction system, we found it is not easy to construct high quality training data due to the noisy format of clinical notes. Choosing the proper tokenizer is quite important for span identification. After conducting experiments, we found that “RegexpTokenizer” can match our needs. This tokenizer can generate spans for each token via sophisticated regular expression such as:

```
nltk.tokenize.RegexpTokenizer
(" \w+|\$\[ \d\.\]+\| \$+ ")
```

We then use “PerceptronTagger” as our part-of-speech tagger due to its fast tagging speed. Note that when extracting context words, please make sure you deploy the same tokenization module instead of just splitting strings by space.

## 3 Neural Network Classifier

Event span identification is the task of extracting character offsets of the expression in raw clinical notes. This subtask is quite important due to the fact that the event span identification accuracy will affect the accuracy of attribute identification. We first run our neural network classifier to identify event spans. Then, given each span, our system tries to identify attribute values.

### 3.1 Temporal Convolutional Neural Network

The way we use temporal convolution neural network for event span and attribute classification is similar with the approach proposed by (Collobert et al., 2011). Generally speaking, we consider a word as represented by  $K$  discrete features  $w \in D^1 \times \dots \times D^K$ , where  $D^K$  is the dictionary for the  $k^{th}$  feature. In our scenario, we just use three features such as token mention, pos tag, and word shape. Note that word shape features are used to represent the abstract letter pattern of the word by mapping lower-case letters to “x”, upper-case to “X”, numbers to “d”, and retaining punctuation. We associate to each feature a lookup table. Given a word, a feature vector is then obtained by concatenating all lookup table outputs. Then a clinical snippet is transformed into a word embedding matrix. The matrix can be fed to further 1-dimension convolutional neural network and max pooling layers. Below we will briefly introduce core concepts of Convolutional Neural Network (CNN).

#### Temporal Convolution

Temporal Convolution applies one-dimensional convolution over the input sequence. The one-dimensional convolution is an operation between a vector of weights  $\mathbf{m} \in \mathbb{R}^m$  and a vector of inputs viewed as a sequence  $\mathbf{x} \in \mathbb{R}^n$ . The vector  $\mathbf{m}$  is the *filter* of the convolution. Concretely, we think of  $\mathbf{x}$  as the input sentence and  $\mathbf{x}_i \in \mathbb{R}$  as a single feature value associated with the  $i$ -th word in the sentence. The idea behind the one-dimensional convolution is to take the dot product of the vector  $\mathbf{m}$  with each  $m$ -gram in the sentence  $\mathbf{x}$  to obtain another sequence  $\mathbf{c}$ :

$$\mathbf{c}_j = \mathbf{m}^T \mathbf{x}_{j-m+1:j}. \quad (1)$$

Usually,  $\mathbf{x}_i$  is not a single value, but a  $d$ -dimensional word vector so that  $\mathbf{x} \in \mathbb{R}^{d \times n}$ . There exist two types of 1d convolution operations. One was introduced by (Waibel et al., 1989) and also known as Time Delay Neural Networks (TDNNs). The other one was introduced by (Collobert et al., 2011). In TDNN, weights  $\mathbf{m} \in \mathbb{R}^{d \times m}$  form a matrix. Each row of  $\mathbf{m}$  is convolved with the corresponding row of  $\mathbf{x}$ . In (Collobert et al., 2011) architecture, a sequence of length  $n$  is represented as:

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \dots \oplus \mathbf{x}_n, \quad (2)$$

where  $\oplus$  is the concatenation operation. In general, let  $\mathbf{x}_{i:i+j}$  refer to the concatenation of words  $\mathbf{x}_i, \mathbf{x}_{i+1}, \dots, \mathbf{x}_{i+j}$ . A convolution operation involves a filter  $\mathbf{w} \in \mathbb{R}^{hk}$ , which is applied to a window of  $h$  words to produce the new feature. For example, a feature  $c_i$  is generated from a window of words  $\mathbf{x}_{i:i+h-1}$  by:

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b), \quad (3)$$

where  $b \in \mathbb{R}$  is a bias term and  $f$  is a non-linear function such as the hyperbolic tangent. This filter is applied to each possible window of words in the sequence  $\{\mathbf{x}_{1:h}, \mathbf{x}_{2:h+1}, \dots, \mathbf{x}_{n-h+1:n}\}$  to produce the feature map:

$$\mathbf{c} = [c_1, c_2, \dots, c_{n-h+1}], \quad (4)$$

where  $\mathbf{c} \in \mathbb{R}^{n-h+1}$ .

We also employ dropout on the penultimate layer with a constraint on  $\ell_2$ -norms of the weight vector. Dropout prevents co-adaptation of hidden units by randomly dropping out a proportion  $p$  of the hidden units during forward-backpropagation. That is, given the penultimate layer  $\mathbf{z} = [\hat{c}_1, \dots, \hat{c}_m]$ , instead of using:

$$y = \mathbf{w} \cdot \mathbf{z} + b \quad (5)$$

for output unit  $y$  in forward propagation, dropout uses:

$$y = \mathbf{w} \cdot (\mathbf{z} \circ \mathbf{r}) + b, \quad (6)$$

where  $\circ$  is the element-wise multiplication operator and  $\mathbf{r} \in \mathbb{R}^m$  is a masking vector of Bernoulli random variables with probability  $p$  of being 1. Gradients are backpropagated only through the unmasked units. At test step, the learned weight vectors are scaled by  $p$  such that  $\hat{\mathbf{w}} = p\mathbf{w}$ , and  $\hat{\mathbf{w}}$  is used to score unseen sentences. We additionally constrain  $\ell_2$ -norms of the weight vectors by re-scaling  $\mathbf{w}$  to have  $\|\mathbf{w}\|_2 = s$  whenever  $\|\mathbf{w}\|_2 > s$  after a gradient descent step.

## 4 Experimental Results

### 4.1 Dataset

We use the Clinical TempEval corpus<sup>3</sup> as the evaluation dataset. This corpus was based on a set of

<sup>3</sup><http://alt.qcri.org/semeval2016/task12/index.php?id=data>

| Category  | Train | Dev   | Test  |
|-----------|-------|-------|-------|
| Documents | 293   | 147   | 151   |
| Events    | 38872 | 20973 | 18989 |

**Table 2:** Number of documents, event expressions in the training, development and testing portions of the THYME data

600 clinical notes and pathology reports from cancer patients at the Mayo Clinic. These notes were manually de-identified by the Mayo Clinic to replace names, locations, *etc.* with generic placeholders, but time expression were not altered. The notes were then manually annotated with times, events, and temporal relations in clinical notes. These annotations include time expression types, event attributes, and an increased focus on temporal relations. The event, time, and temporal relation annotations were distributed separately from the text using the Anaphora standoff format. Table 2 shows the number of documents, event expressions in the training, development and testing portions of the 2016 THYME data.

## 4.2 Evaluation Metrics

All of the tasks were evaluated using the standard metrics of precision (P), recall (R), and  $F_1$ :

$$\begin{aligned} P &= \frac{|S \cap H|}{|S|} \\ R &= \frac{|S \cap H|}{|H|} \\ F_1 &= \frac{2 \cdot P \cdot R}{P + R} \end{aligned} \quad (7)$$

where  $S$  is the set of items predicted by the system and  $H$  is the set of items manually annotated by the humans. Applying these metrics of the tasks only requires a definition of what is considered an “item” for each task. For evaluating the spans of event expressions, items were tuples of character offsets. Thus, system only received credit for identifying events with exactly the same character offsets as the manually annotated ones. For evaluating the attributes of event expression types, items were tuples of (begin, end, value) where begin and end are character offsets and value is the value that was given to the relevant attribute. Thus, systems only received credit for an event attribute if they both found

an event with correct character offsets and then assigned the correct value for that attribute (Bethard et al., 2015).

## 4.3 Hyperparameters and Training Details

### Objective Function

We want to maximize the likelihood of the correct class. This is equivalent to minimizing the negative log-likelihood (NLL). More specifically, the label  $\hat{y}$  given the inputs  $x_h$  is predicted by a softmax classifier that takes the hidden state  $h_j$  as input:

$$\begin{aligned} \hat{p}_\theta(y|x_h) &= \text{softmax}(W \cdot x_h + b) \\ \hat{y} &= \underset{y}{\text{argmax}} \hat{p}_\theta(y|x_h) \end{aligned} \quad (8)$$

After that, the objective function is the negative log-likelihood of the true class labels  $y^k$ :

$$J(\theta) = -\frac{1}{m} \sum_{k=1}^m \log \hat{p}_\theta(y^k|x_h^k) + \frac{\lambda}{2} \|\theta\|_2^2, \quad (9)$$

where  $m$  is the number of training examples and the superscript  $k$  indicates the  $k$ -th example.

### Hyperparameters

We use Lasagne<sup>4</sup> deep learning framework. We first initialize our word representations using publicly available 300-dimensional Glove word vectors<sup>5</sup>. We deploy CNN model with kernel width of 2, a filter size of 300, sequence length is  $2 * windows\_size + 1$ , number filters is  $seqlen - kw + 1$ , stride is 1, pool size is  $seqlen - filter\_size + 1$ , cnn activation function is tangent, MLP activation function is sigmoid. MLP hidden dimension is 50. We initialize CNN weights using a uniform distribution. Finally, by stacking a softmax function on top, we can get normalized log-probabilities. Training is done through stochastic gradient descent over shuffled mini-batches with the AdaGrad update rule (Duchi et al., 2011). The learning rate is set to 0.05. The mini-batch size is 100. The model parameters were regularized with a per-minibatch L2 regularization strength of  $10^{-4}$ .

<sup>5</sup><http://nlp.stanford.edu/projects/glove/>

#### 4.4 Results and Discussions

Table 3 shows results on the event expression tasks. Our initial submits RUN 4 and 5 outperformed the memorization baseline on every metric on every task. The precision of event span identification is close to the max report. However, our system got lower recall. The reason of lower recall values is that the word2vec may not cover more domain specific words. Table 4 shows results on the phase 2 subtask.

| Methods       | DocTimeRel |       |       |
|---------------|------------|-------|-------|

#### 5 Conclusions

In this paper, we introduced a new clinical information extraction system that only leverages deep neural networks to identify event spans and their attributes from raw clinical notes. We trained deep neural networks based classifiers to extract clinical event spans. Our method attached each word to their part-of-speech tag and shape information as extra features. We then hire temporal convolution neural network to learn hidden feature representations. The entire experimental results demonstrate that our approach consistently outperforms the existing baseline methods on standard evaluation datasets.

Our research proved that we can get competitive results without the help of a domain specific feature extraction toolkit, such as cTAKES. Also we only leverage basic natural language processing modules such as tokenization and part-of-speech tagging. With the help of deep representation learning, we can dramatically reduce the cost of clinical information extraction system development. Due to the recall values are still low, we will consider use domain specific tools to enhance feature engineering.

# Brumblefly at SemEval-2016 Task 12: Recurrent Neural Networks vs. Joint Inference for Clinical Temporal Information Extraction

Mobilize Center  
jason-fries@stanford.edu

## Abstract

We submitted two systems to the SemEval-2016 Task 12: Clinical TempEval challenge, participating in Phase 1, where we identified text spans of time and event expressions in clinical notes and Phase 2, where we predicted a relation between an event and its parent document creation time.

For temporal entity extraction, we find that a joint inference-based approach using structured prediction outperforms a vanilla recurrent neural network that incorporates word embeddings trained on a variety of large clinical document sets. For document creation time relations, we find that a combination of date canonicalization and distant supervision rules for predicting relations on both events and time expressions improves classification, though gains are limited, likely due to the small scale of training data.

## 1 Introduction

This work discusses two information extraction systems for identifying temporal information in clinical text, submitted to SemEval-2016 Task 12 : Clinical TempEval (Bethard et al., 2016). We participated in tasks from both phases: (1) identifying text spans of time and event mentions; and (2) predicting relations between clinical events and document creation time.

Temporal information extraction is the task of constructing a timeline or ordering of all events in a given document. In the clinical domain, this is a key requirement for medical reasoning systems as well as longitudinal research into the progression of

disease. While timestamps and the structured nature of the electronic medical record (EMR) directly capture some aspects of time, a large amount of information on the progression of disease is found in the unstructured text component of the EMR where temporal structure is less obvious.

We examine a deep-learning approach to sequence labeling using a vanilla *recurrent neural network* (RNN) with word embeddings, as well as a joint inference, structured prediction approach using Stanford’s knowledge base construction framework DeepDive (Zhang, 2015). Our DeepDive application outperformed the RNN and scored similarly to 2015’s best-in-class extraction systems, even though it only used a small set of context window and dictionary features. Extraction performance, however lagged this year’s best system submission. For document creation time relations, we again use DeepDive. Our system examined a simple temporal distant supervision rule for labeling time expressions and linking them to nearby event mentions via inference rules. Overall system performance was better than this year’s median submission, but again fell short of the best system.

## 2 Methods and Materials

Phase 1 of the challenge required parsing clinical documents to identify TIMEX3 and EVENT temporal entity mentions in text. TIMEX3 entities are expressions of time, ranging from concrete dates to phrases describing intervals like “the last few months.” EVENT entities are broadly defined as anything relevant to a patient’s clinical timeline, e.g., diagnoses, illnesses, procedures. Entity mentions

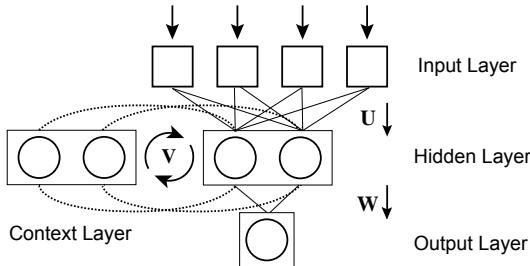

are tagged using a document collection of clinic and pathology notes from the Mayo Clinic called the THYME (Temporal History of Your Medical Events) corpus (Styler IV et al., 2014).

We treat Phase 1 as a sequence labeling task and examine several models for labeling entities. We discuss our submitted tagger which uses a vanilla RNN<sup>1</sup> and compare its performance to a DeepDive-based system, which lets us encode domain knowledge and sequence structure into a probabilistic graphic model.

For Phase 2, we are given all test set entities and asked to identify the temporal relationship between an EVENT mention and corresponding document creation time. This relation is represented as a classification problem, assigning event attributes from the label set {BEFORE, OVERLAP, BEFORE/OVERLAP, AFTER}. We use DeepDive to define several inference rules for leveraging neighboring pairs of EVENT and TIMEX3 mentions to better reason about temporal labels.

## 2.1 Recurrent Neural Networks

### 2.1.1 Overview

**Figure 1:** Simple Recurrent Neural Network.  $\mathbf{U}$  is the input  $\times$  hidden layer weight matrix.  $\mathbf{V}$  is the context layer  $\times$  hidden layer weight matrix, and  $\mathbf{W}$  is the output weight matrix. Dotted lines indicate recurrent edge weights.

Vanilla (or Elman-type) RNNs are recursive neural networks with a linear chain structure (Elman, 1990). RNNs are similar to classical feedforward neural networks, except that they incorporate an additional hidden context layer that forms a time-lagged, recurrent connection (a directed cycle) to the

<sup>1</sup>There was a bug in our original RNN submission that dramatically lowered recall. We report the original and corrected test set scores in order to better characterize the contributions of this work.

primary hidden layer. In the canonical RNN design, the output of the hidden layer at time step  $t - 1$  is retained in the context layer and fed back into the hidden layer at  $t$ ; this enables the RNN to explicitly model some aspects of sequence history. (see Figure 1).

Each word in our vocabulary is represented as an  $n$ -dimensional vector in a lookup table of  $|vocab| \times n$  parameters (i.e., our learned embedding matrix). Input features then consist of a concatenation of these embeddings to represent a context window surrounding our target word. The output layer then emits a probability distribution in the dimension of the candidate label set. The lookup table is shared across all input instances and updated during training.

Formally our RNN definition follows (Mesnil et al., 2013):

$$h(t) = f(\mathbf{U}x(t) + \mathbf{V}h(t - 1))$$

where  $x(t)$  is our concatenated context window of word embeddings,  $h(t)$  is our hidden layer,  $\mathbf{U}$  is the input-to-hidden layer matrix,  $\mathbf{V}$  is the hidden layer-to-context layer matrix, and  $f(x)$  is the activation function (logistic in this work).

$$f(x) = \frac{1}{1+e^{-x}}$$

The output layer  $y(t)$  consists of a softmax activation function  $g(x)$

$$y(t) = g(\mathbf{W}h(t)) \quad g(x_i) = \frac{e^{x_i}}{\sum_k e^{x_k}}$$

where  $\mathbf{W}$  is the output layer matrix. Training is done using batch gradient descent using one sentence per batch. Our RNN implementation is based on code available as part of Theano v0.7 (Bastien et al., 2012).

### 2.1.2 Word Embeddings

For baseline RNN models, all embedding parameters are initialized randomly in the range [-1.0, 1.0]. For all other word-based models, embedding vectors are initialized or *pre-trained* with parameters trained on different clinical corpora. Pre-training generally improves classification performance over random initialization and provides a mechanism to leverage large collections of unlabeled data for use in semi-supervised learning (Erhan et al., 2010).

We create word embeddings using two collections of clinical documents: the MIMIC-III database

| Corpus    | Note Type        | Tokens | Vocab |
|-----------|------------------|--------|-------|
| MIMIC-III | Mixed (15 types) | 758M   | 260K  |
| UIHC-ALL  | Mixed (41 types) | 6.5B   | 899K  |
| UIHC-CN   | Clinic Notes     | 2.3B   | 378K  |
| UIHC-PN   | Progress Notes   | 1.8B   | 378K  |

**Table 1:** Summary statistics for embedding corpora.

containing 2.4M notes from critical care patients at Beth Israel Deaconess Medical Center (Saeed et al., 2011); and the University of Iowa Hospitals and Clinics (UIHC) corpus, containing 15M predominantly inpatient notes (see Table 1). All word embeddings in this document are trained with word2vec (Mikolov et al., 2013) using the Skip-gram model, trained with a 10 token window size. We generated 100 and 300 dimensional embeddings based on prior work tuning representation sizes in clinical domains (Fries, 2015).

### 2.1.3 RNN Taggers

We train RNN models for three tasks in Phase 1: a character-level RNN for tokenization; and two word-level RNNs for POS tagging and entity labeling. Word-level RNNs are pre-trained with the embeddings described above, while character-level RNNs are randomly initialized. All words are normalized by lowercasing tokens and replacing digits with N, e.g., 01-Apr-2016 becomes NN-apr-NNNN to improve generalizability and restrict vocabulary size. Characters are left as unnormalized input. In the test data set, unknown words/characters are represented using the special token <UNK>. All hyperparameters were selected using a randomized grid search.<sup>2</sup>

**Tokenization:** Word tokenization and sentence boundary detection are done simultaneously using a character-level RNN. Each character is assigned a tag from 3 classes: WORD (W) if a character is a member of a token that does not end a sentence; END (E) for a token that does end a sentence, and whitespace O. We use IOB2 tagging to encode the range of token spans.

Models are trained using THYME syntactic annotations from colon and brain cancer notes. Training

data consists of all sentences, padded with 5 characters from the left and right neighboring sentences. Each character is represented by a 16-dimensional embedding (from an alphabet of 90 characters) and an 11 character context window. The final prediction task input is one, long character sequence per-document. We found that the tokenizer consistently made errors conflating E and W classes (e.g., B-W, I-E, I-E) so after tagging, we enforce an additional consistency constraint on B-\* and I-\* tags so that contiguous BEGIN/INSIDE spans share the same class.

**Part-of-speech Tagging:** We trained a POS tagger using THYME syntactic annotations. A model using 100-dimensional UIHC-CN embeddings (clinic notes) and a context window of  $\pm 2$  words performed best on held out test data, with an accuracy of 97.67% and  $F_1 = 0.973$ .

**TIMEX3 and EVENT Span Tagging:** We train separate models for each entity type, testing different pre-training schemes using 100 and 300-dimensional embeddings trained on our large, unlabeled clinical corpora. Both tasks use context windows of  $\pm 2$  words (i.e., concatenated input of 5 n-d word embeddings) and a learning rate of 0.01. We use 80 hidden units for 100-dimensional embeddings models and 256 units for 300-dimensional models. Output tags are in the IOB2 tagging format.

## 2.2 DeepDive

DeepDive developers build domain knowledge into applications using a combination of *distant supervision rules*, which use heuristics to generate noisy training examples, and inference rules which use *factors* to define relationships between random variables. This design pattern allows us to quickly encode domain knowledge into a probabilistic graphical model and do joint inference over a large space of random variables.

For example, we want to capture the relationship between EVENT entities and their closest TIMEX3 mentions in text since that provides some information about when the EVENT occurred relative to document creation time. TIMEX3s lack a class DocRelTime, but we can use a distant supervision rule to generate a noisy label that we then leverage to predict neighboring EVENT labels. We also know that the set of all EVENT/TIMEX3 mentions

<sup>2</sup>RNN parameter space: hidden units: [48 - 384]; L/R context window [2 - 6]; learning rate: (0.001, 0.01, 0.1, 0.25). Character-level RNN parameters: dim: (16, 32); sentence padding [0 - 5].

within a given note section, such as patient history, provides discriminative information that should be shared across labels in that section. DeepDive lets us easily define these structures by linking random variables (in this case all entity class labels) with factors, directly encoding domain knowledge into our learning algorithm.

### 2.2.1 TIMEX3 and EVENT Spans

**Phase 1:** Our baseline tagger consists of three inference rules: logistic regression, conditional random fields (CRF), and skip-chain CRF (Sutton and McCallum, 2006). In CRFs, factor edges link adjoining words in a linear chain structure, capturing label dependencies between neighboring words. Skip-chain CRFs generalize this idea to include skip edges, which can connect non-neighboring words. For example, we can link labels for all identical words in a given window of sentences. We use DeepDive’s feature library, ddlib, to generate common textual features like context windows and dictionary membership. We explored combinations of left/right windows of 2 neighboring words and POS tags, letter case, and entity dictionaries for all vocabulary identified by the challenge’s baseline memorization rule, i.e., all phrases that are labeled as true entities  $\geq 50\%$  of the time in the training set.

**Feature Ablation Tests** We evaluate 3 feature set combinations to determine how each contributes predictive power to our system.

**Run 1:** dictionary features, letter case

**Run 2:** dictionary features, letter case, context window ( $\pm 2$  normalized words)

**Run 3:** dictionary features, letter case, context window ( $\pm 2$  normalized words), POS tags

### 2.2.2 Document Creation Time Relations

**Phase 2:** In order to predict the relationship between an event and the creation time of its parent document, we assign a DocRelTime random variable to every TIMEX3 and EVENT mention. For EVENTS, these values are provided by the training data, for TIMEX3s we have to compute class labels. Around 42% of TIMEX3 mentions are simple dates (“12/29/08”, “October 16”, etc.) and can be naively canonicalized to a universal timestamp. This is done using regular expressions to identify common date patterns and heuristics to deal with incomplete dates.

The missing year in “October 16”, for example, can be filled in using the nearest preceding date mention; if that isn’t available we use the document creation year. These mentions are then assigned a class using the parent document’s DocTime value and any revision timestamps. Other TIMEX3 mentions are more ambiguous so we use a distant supervision approach. Phrases like “currently” and “today’s” tend to occur near EVENTS that overlap the current document creation time, while “ago” or “X-years” indicate past events. These dominant temporal associations can be learned from training data and then used to label TIMEX3s. Finally, we define a logistic regression rule to predict entity DocRelTime values as well as specify a linear skip-chain factor over EVENT mentions and their nearest TIMEX3 neighbor, encoding the baseline system heuristic directly as an inference rule.

## 3 Results

### 3.1 Phase 1

Word tokenization performance was high,  $F_1=0.993$  while sentence boundary detection was lower with  $F_1 = 0.938$  (document micro average  $F_1 = 0.985$ ). Tokenization errors were largely confined to splitting numbers and hyphenated words (“ex-smoker” vs. “ex - smoker”) which has minimal impact on upstream sequence labeling. Sentence boundary errors were largely missed terminal words, creating longer sentences, which is preferable to short, less informative sequences in terms of impact on RNN mini-batches.

Tables 2 and 3 contain results for all sequence labeling models. For TIMEX3 spans, the best RNN ensemble model performed poorly compared to the winning system (0.706 vs. 0.795). DeepDive runs 2-3 performed as well as 2015’s best system, but also fell short of the top system (0.730 vs. 0.795). EVENT spans were easier to tag and RNN models compared favorably with DeepDive, the former scoring higher recall and the latter higher precision. Both approaches scored below this year’s best system (0.885 vs. 0.903).

### 3.2 Phase 2

Finally, Table 4 contains our DocRelTime relation extraction. Our simple distant supervision rule leads

| Method                        | Span         |              |                |

**Table 4:** Phase 2: EVENT Document Creation Time Relation extraction measures (baseline precision/recall scores not provided).

models (DeepDive runs 2-3) which isn't surprising considering the small amount of training data available compared to typical deep-learning contexts. There was a statistically significant improvement for RNNs pre-trained with clinical text word2vec embeddings, reflecting the consensus that embeddings capture some syntactic and semantic information that must otherwise be manually encoded as features. Performance was virtually the same across all embedding types, independent of corpus size, note type, etc. While embeddings trained on more data perform better in semantic tasks like synonym detection, its unclear if that representational strength is important here. Similar performance might also just reflect the general ubiquity with which temporal vocabulary occurs in all clinical note contexts. Alternatively, vanilla RNNs rarely achieve state-of-the-art performance in sequence labeling tasks due to well-known issues surrounding the vanishing or exploding gradient effect (Pascanu et al., 2012). More sophisticated recurrent architectures with gated units such as Long Short-Term Memory (LSTM), (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (Chung et al., 2014) or recursive structures like Tree-LSTM (Tai et al., 2015) have shown strong representational power in other sequence labeling tasks. Such approaches might perform better in this setting.

DeepDive's feature generator libraries let us easily create a large space of binary features and then let regularization address overfitting. In our extraction system, just using a context window of  $\pm 2$  words and dictionaries representing the baseline memorization rules was enough to achieve median system performance. POS tag features had no statistically significant impact on performance in either EVENT/TIMEX3 extraction.

For classifying an EVENT’s document creation time relation, our DeepDive application essentially implements the joint inference version of the baseline memorization rule, leveraging entity proximity to increase predictive performance. A simple distant supervision rule that canonicalizes TIMEX3 timestamps and predicts nearby EVENT’s lead to a slight performance boost, suggesting that using a larger collection of unlabeled note data could lead to further increases.

While our systems did not achieve current state-of-the-art performance, DeepDive matched last year’s top submission for TIMEX3 and EVENT tagging with very little upfront engineering – around a week of dedicated development time. One of the primary goals of this work was to avoid an over-engineered extraction pipeline, instead relying on feature generation libraries or deep learning approaches to model underlying structure. Both systems explored in this work were successful to some extent, though future work remains in order to close the performance gap between these approaches and current state-of-the-art systems.

# KULeuven-LIIR at SemEval 2016 Task 12: Detecting Narrative Containment in Clinical Records

Artuur Leeuwenberg and Marie-Francine Moens

Department of Computer Science  
KU Leuven, Belgium

{tuur.leeuwenberg, sien.moens}@cs.kuleuven.be

## Abstract

In this paper, we describe the KULeuven-LIIR system at the Clinical TempEval 2016 Shared Task for the narrative container relation sub-task (CR). Our approach is based on the cTAKES Temporal system (Lin et al., 2015). We explored extending this system with different features. Moreover, we provide an error analysis of the submitted system, and report on some additional experiments done after submission.

## 1 Introduction

We describe the KULeuven-LIIR submissions for the Clinical TempEval 2016 shared task (Bethard et al., 2016). Our motivation for this first participation is to gain insight into the task, and the data, as a basis for future work. We participated in the narrative container relation (CR) task. In the CR task narrative containment relations between events, and events and temporal expressions are to be extracted. Two examples of such relations are given in Sentence 1.

- (1) A *colonoscopy* on *27 September 2008* revealed a circumferential *lesion*.

The relations that are to be extracted are

- CONTAINS(*27 September 2008*, *colonoscopy*)
- CONTAINS(*colonoscopy*, *lesion*)

In the shared task, the clinical records on colon cancer from the THYME corpus are used (Styler IV et al., 2014). We participated in phase 2 evaluation,

which means that manually annotated EVENT and TIMEX3 spans with their attributes are provided as part of the input. We submitted two runs that are both based on the cTAKES-Temporal system (Lin et al., 2015). For the first run, we used cTAKES-Temporal with a set of already provided features. We further explain the cTAKES-Temporal system and the features that we used in Section 2. For the second run, we added new features, that are based on an error analysis of a small sample from the results of running the first system on the development set. These additional features are described in Section 3. Moreover, we describe a more elaborate error analysis of the second system in Section 4, and some experiments that we performed with the aim to handle these errors in Section 5.

## 2 The cTAKES Temporal System (run 1)

The first version of the temporal module in cTAKES<sup>1</sup>, an extensive open source information extraction system for clinical free-texts (Savova et al., 2010), is described by (Lin et al., 2015). We used the currently available version in our experiments. The current version of cTAKES Temporal consists of two SVM classifiers to detect containment. One for containment between events (EE), and one for containment between temporal expressions and events (TE), each using different features, as the nature of the two types of relations is quite different. The features we used for each classifier are described in Table 2, and will be explained further in the next paragraph. Note that with entity we refer to either an EVENT or TIMEX3 expression, which can con-

<sup>1</sup>[ctakes.apache.org/](http://ctakes.apache.org/)

sist of several tokens (words, numbers, punctuation etc.). The search space, or the entity-pairs that the system considers are all EE and TE pairs in each sentence or line, in each document for their respective classifier (the EE SVM, or the ET SVM).

As in the THYME corpus only the heads of events are annotated, cTAKES-Temporal expands these heads to their full phrase (e.g., the annotated head *cancer* expands to *ascending colon cancer*). Afterwards it creates extra training data by not only considering the pairs of entity phrases, but also the sub-phrases (e.g., *cancer*, *colon cancer*, and *ascending colon cancer*).

The precision, recall, and F-measure that our first submission scored on the test set is reported in Table 5. What can be noticed from the top-part of Table 5 is that the cTAKES Temporal system (run 1) gives reasonable results, scoring  $\sim 9\%$  higher than the median F-measure of all systems evaluated in Clinical TempEval 2016, and  $\sim 4\%$  short compared to the best system.

## 2.1 Features

The features used in run 1 correspond to those described by (Lin et al., 2015), and feature extraction is included within the (open source) cTAKES Temporal module. In this module, tokenization is done following the Penn Treebank rules (Mott et al., 2009). Sentence boundaries, parts-of-speech, chunks, and constituency parses (for finding heads) are obtained using the corresponding cTAKES modules. Dependency paths are extracted using the ClearNLP dependency parser model in cTAKES. UMLS types are extracted by means of direct token or chunk matches, and by creation of lexical variants using the UMLS Lexical Variant Generation package<sup>2</sup>.

## 3 Additional Features (run 2)

Our motivations for the additional features come from analyzing a small sample of errors (small due to time constraints at the moment of submission) of the first system on the development set, from which we concluded that especially long distance and sometimes also short distance relations characterized by prepositions (especially *of* and *with*) were not found by the system. An example of

<sup>2</sup><https://www.nlm.nih.gov/research/umls>

such a relation missed by the system is *CONTAINS*(*colonoscopy*, *polypectomy*) in the fragment given in Figure 3.

The first added feature is a modified version of the dependency path (MDP). We include part of speech tags in the path for nouns, personal pronouns, numbers, adjectives and determiners. For other parts of speech we include the words themselves. In the original dependency path feature of cTAKES Temporal, only parts of speech are included. The second

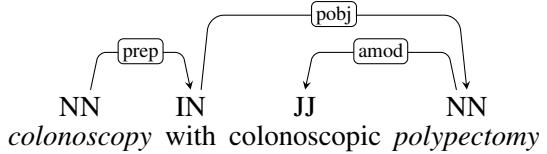

Figure 1: Sentence fragment, with its POS, and dependencies.

feature consists of the sequence in-between the two entities (IBS), i.e., the words in-between connected by an underscore. We replace the same categories as for the MDP by their respective POS in the sequence. The modified dependency path, and the in-between sequence (IBS) feature for the small fragment in Figure 3, where we consider *colonoscopy*, and *polypectomy* are:

MDP: <NN>prep<with>pobj<NN>

IBS: with\_JJ

The precision, recall, and F-measure on the test set for the second run are shown in Table 5. Adding these features resulted only in a tiny increase in both precision and recall (0.001). From this we conclude that our error sample might not have been representative enough for the rest of the corpus, or that the features do not cover the errors made. Also, there is probably overlap between the MDP feature and the existing dependency path feature, and between the IBS feature and the existing Tokens feature explaining why adding the MDP and IBS features do not help much.

## 4 Error Analysis

### 4.1 Error Categories

We also ran the system of the second run on the development set of the THYME corpus (but now only trained on the train set) and analyzed its errors with

| Feature                  | Description   | Extraction   |
|--------------------------|---|--|
| 1. Tokens                | String features for the tokens within each entity, the entity’s first and last token, and the tokens in-between the two entities. | cTAKES-Temporal module, with Penn Treebank tokenization rules (Mott et al., 2009)        |
| 2. POS                   | String features for the parts of speech of the tokens of both entities.   | cTAKES’ POS tagger   |
| 3. Event Attributes      | String features for each event modality, polarity, and event type of both entities.   | Part of the input (phase 2 evaluation)   |
| 4. UMLS                  | Boolean flags for the semantic UMLS type of each entity, and as a paired feature (type <sub>1</sub> -type <sub>2</sub> ).         | cTAKES-Temporal module, with UMLS Lexical Variant Generation                             |
| 5. Dependency Path       | The dependency path between the entities, comprised of edge-labels, and POS tags.   | cTAKES dependency parser (clinical ClearNLP model)                                       |
| 6. Overlapped Head       | Consists of a string feature for each overlapping head word, and numerical features for the count and ratio of overlapping words. | cTAKES Temporal module, where heads are found by means of the cTAKES Constituency Parses |
| 7. Nearest Flag          | Boolean flag on if two entities are the closest candidates of each other.   | cTAKES Temporal module   |
| 8. Conjunction Flag      | Boolean flag for conjunctions in-between the entities only <i>CC</i> , <i>COMMA</i> , or <i>IN</i> POS tags are considered.       | cTAKES Temporal module (using cTAKES’s POS tagger)                                       |
| 9. Special Word Relation | Boolean feature for special phrase types in-between the entities (e.g., <i>starts out</i> : STARTING).                            | Manually constructed list by (Lin et al., 2015)  |
| 10. Temporal Attributes  | String features for EVENT modality, and TIMEX3 class.   | Part of the input (phase 2 evaluation)   |

**Table 1:** Feature descriptions for the EVENT-EVENT classifier, using features 1, 2, 3, 4, 5, 6 and the TIMEX3-EVENT classifier, using features 1, 3, 5, 7, 8, 9, 10.

| category     | count | percentage |
|--------------|-------|------------|
| Correct      | 22    | 44%        |
| Questionable | 10    | 20%        |
| Negation     | 5     | 10%        |
| Other        | 13    | 26%        |

**Table 2:** Categories of **false positives** for the run 2 system on the THYME development set.

regard to predicting the correct CONTAINER relations. Around 69% of the errors were false negatives, and around 31% false positives. We then randomly sampled 50 errors of both types and categorized them ( $\sim 1.5\%$  of false negatives, and  $\sim 3.3\%$  of false positives). For the false positives, we found four frequent categories: (1) predictions that we judge to be *correct* positive predictions, (2) predictions that we judge the correctness to be *questionable*, (3) incorrect predictions caused by an unprocessed *negation*.

In Table 2 the statistics of the categories are shown. What can be noticed is that many of the false positives are questionable or correct. This indicates that the actual precision of the system might be higher. On the other hand, the consistent errors

that the system makes result from ignoring negations or negating verbs (e.g., *to quit*). The errors in the category ‘other’ had various causes, such as wrong tokenization, mistakes in event annotation, or sometimes the cause was unclear.

A bigger, and maybe more interesting, source for improvement are the false negatives, i.e., the relations missed by the system. Here we found the following major (non-mutually exclusive) categories: (1) *cross-sentence* relations, (2) *unknown tokens (UNKS)* are tokens that appear in the dev-set as argument of the relation, but not in the train-set. Categories (1) and (2) appear to be a common source of false negatives. Another frequent error category is (3) the relation *crosses a newline*<sup>3</sup>, (4) the relation is part of a data *table*, as shown in Figure 2, (5) one of the arguments of the relation is part of a within-sentence enumeration (usually comma-separated), (6) some false negatives we judge to be *correctly* predicted as negative. The proportions of these categories are shown in Table 3. In our notion of UNK errors, we exclude unseen dates (e.g.,

<sup>3</sup>Note that sentence boundaries are given by the sentence boundary detection, and new lines by the newline token ('\n').

| category           | count | percentage |
|--------------------|-------|------------|
| Cross-sentence     | 13    | 26%        |
| UNKs (excl. dates) | 13    | 26%        |
| Cross-newline      | 11    | 22%        |
| Table              | 9     | 18%        |
| Enumeration        | 6     | 12%        |
| Correct            | 4     | 8%         |
| Other              | 10    | 20%        |

**Table 3:** Categories of **false negatives** for the run 2 system on the THYME development set.

February 2, 2008) as they include digits, resulting in many (rather predictable) UNK tokens.

## 4.2 Examples of Errors

The UNK tokens from the false negatives seem a mix of more domain specific and general terms. More domain-specific terms are *CK5-6*, *seepage*, *mesh*, and *Mumps*. The more general are *outline*, *QUALITY*, *function*, and *question*. The cross-newline and table error categories have some overlap. An example of the cross-newline category is shown in Figure 2, where the missed relation in our random sample is  $\text{CONTAINS}(HISTORY, \text{affected})$ . But also the containment between *HISTORY* and *Polio*, *Obesity*, *equivalency*, *hyperlipidemia*, *Hypertension*, *PVD*, *stenosis*, and *disease* are missed by the system. A table-error would look similar, but with test measurement reports, such as for example patient height, weight, or body mass index.

PAST MEDICAL HISTORY  
 1) Polio at age 15. RUE affected.  
 2) Obesity.  
 3) CAD equivalency with hyperlipidemia ...  
 4) Hypertension, well-controlled.  
 5) PVD of left leg. Stable and asymptomatic.  
 6) Moderate aortic stenosis.  
 7) Non-alcoholic fatty liver disease.

**Figure 2:** An example of the cross-newline error category, where the  $\text{CONTAINS}(HISTORY, \text{affected})$  relation is missed by the system (and many more).

The enumeration error category contains within sentence enumerations. An example sentence is given in sentence (2).

- (2) We have discussed the *characteristics* of the cancer, including the type of malignancy, size,

grade, lymph node *status*, and stage of the cancer.

Here,  $\text{CONTAINS}(\text{characteristics}, \text{status})$  is the missed error in our sample. One reason for this type of errors might be that the currently used dependency parser chains the parts of such enumerations, resulting in a long dependency path between the two entities, which is less likely to occur frequently in the training data.

## 4.3 Token Frequency

We also looked at token diversity in the training set for event-event containment, and time-event containment. What can be noticed from Table 4 is that there are slightly more EE container relations, than TE container relations. It is also striking that the source (first argument of the containment relation, i.e., the container) of the TE relations have a relatively low average token frequency, and a high percentage of UNKs, compared to the source of the EE relations. The explanation for this is that for the TE pairs the source category (TIMEX3) of tokens includes dates, containing numbers, causing big token diversity (each date is a new token). To get a better idea of token diversity without considering each number as a different token we conflated the digits in TE source tokens (e.g., *February 2, 2008* becomes *February 5, 5555*). In-between the brackets the percentage of UNKs is shown, after digit conflation of these tokens. Furthermore, the source of both the TE and the EE relations, i.e., the container, seems to be less diverse compared to the target, i.e., the event that is contained. We conclude that this is because of the relatively low vocabulary size of this category, and low percentage of UNKs, i.e., there are less different containers (container EVENT or TIMEX3 expressions) than containees (contained EVENTS).

## 5 Out-of-Competition Experiments

We conducted two sets of experiments, one set to address the UNK-related errors, and one to address the cross-newline errors.

To tackle the UNK token category, without adding extra resources, we experimented with adding subword features, in particular character 3-grams of the entities. We also experimented with adding word embeddings to the event-event SVM. We trained

|                  | Event-Event |        | Time-Event  |        |
|------------------|-------------|--------|-------------|--------|
|                  | source      | target | source      | target |
| train-tokens     | 5931        | 5931   | 5093        | 5093   |
| train-vocabulary | 637         | 1417   | 1268 (839)  | 1198   |
| avg. token-freq. | 9.3         | 4.2    | 4.0 (6.0)   | 4.3    |
| UNK percentage   | 0.10        | 0.18   | 0.43 (0.17) | 0.15   |

**Table 4:** Token-frequency statistics. The ‘source’ of the containment relation refers to the container, and target to the containee. For TE sources we also calculated statistics after digit conflation, shown in-between brackets.

the embeddings on 10 million words of crawled web data from the oncology/colon cancer domain<sup>4</sup> plus the THYME training data. To construct the word vectors we used the continuous bag-of-words (CBOW), and Skip-gram model (SG) by (Mikolov et al., 2013). The vectors are of dimension 250, and were trained using the default settings in the word2vec toolkit<sup>5</sup>. What can be noticed from Table 5 is that adding these features did not significantly improve the F-measure.

| System   | P            | R            | F            |
|--|--------------|--------------|--------------|
| clinical tempeval 2016 – median                              | 0.589        | 0.345        | 0.449        |
| clinical tempeval 2016 – best                                | <b>0.823</b> | <b>0.564</b> | <b>0.573</b> |
| run 1  | 0.714        | 0.428        | 0.536        |
| run 2  | 0.715        | 0.429        | 0.536        |
| run 2 + character 3-grams                                    | 0.706        | 0.428        | 0.533        |
| run 2 + CBOW <sup>EE</sup>                                   | 0.701        | 0.438        | 0.539        |
| run 2 + SG <sup>EE</sup>                                     | 0.708        | 0.433        | 0.537        |
| run 2 + newline extension                                    | <b>0.714</b> | 0.441        | 0.545        |
| run 2 + newline ext. + CBOW <sup>EE</sup>                    | 0.706        | 0.452        | 0.551        |
| run 2 + newline ext. + CBOW <sup>EE</sup> + SG <sup>EE</sup> | 0.705        | <b>0.452</b> | <b>0.551</b> |

**Table 5:** THYME test set performance of different system settings. The lower part of the table comes from experiments done out-of-competition.

With the goal to handle errors caused by separation by a newline, we extended the search space by adding candidate pairs (either EE, or ET) that were separated by a new line, but for which the end of the line consisted of a comma, or colon symbol. This increased recall (by 2%), and thus F-measure slightly as well (by 1%). This small increase in performance does not match with the relative size of the cross-newline error category, so there is still much room for improvement.

<sup>5</sup>code.google.com/archive/p/word2vec/

## 6 Conclusions & Future Work

In this paper we described the first participation of KULeuven-LIIR in the Clinical TempEval Shared Task 2016 (Bethard et al., 2016). Our motivation to participate was to gain insight into the CONTAINER relation extraction task, and the data for future research. We started from the cTAKES-Temporal system (Lin et al., 2015) and experimented with adding various features. From our experiments we conclude that adding the modified dependency path feature, or in-between sequence features does not improve the performance of the system. Furthermore, from our cTAKES Temporal module, we noticed that cross-sentence relations, cross-newline relations, and UNKs are an important source of error. Also, false negatives seem a bigger problem than false positives. To tackle the problem of UNKs, we experimented with adding word embeddings, trained on in-domain web crawled text, as a feature, and adding a character n-gram feature. These features did not seem to contribute significantly. For future research it could be interesting to explore alternative methods to deal with UNKs. To tackle the cross-newline mistakes the system made, we extended the scope of the candidate pair creation across new lines, which improved recall on the test set slightly, but still leaves much room for improvement.

## Acknowledgments

The authors would like to thank the reviewers for their constructive comments which helped us improve the paper. Also, we would like to thank the Mayo Clinic for permission to use the THYME corpus. This work was funded by the KU Leuven C22/15/16 project ”MAchine Reading of patient recordS (MARS)”, and by the IWT-SBO 150056 project ”ACquiring CrUcial Medical information Using LAnguage TEchnology” (ACCUMULATE).

## Abstract

In this paper, we describe the system developed for our participation in the Clinical TempEval task of SemEval 2016 (task 12). Our team focused on the subtasks of span and attribute identification from raw text and proposed a system that integrates both statistical and linguistic approaches. Our system is based on Conditional Random Fields with high-precision linguistic features.

## 1 Introduction

Extracting and linking temporal and medical information from medical documents is a highly useful task for many clinical applications and plays an important role in health care assessment and patient safety (Sun et al., 2013). Since 2007, the SemEval competition includes a temporal information extraction task which is now transposed onto the medical domain.

This year, the twelfth task included six subtasks that are described in (Bethard et al., 2016). Our team focused on the first four of these (Phase 1 submission), i.e. identification of entity spans and attribute values from raw text<sup>1</sup>.

We present an approach combining linguistic rules and machine learning methods. The tools presented here were initially developed for French to extract information (temporal expressions, Named Entities, etc.) from newspaper corpora, a text genre which is quite different from medical documents.

<sup>1</sup>For the event attributes, only the “polarity” attribute is handled by our system.

This challenge was thus a good opportunity for us to evaluate the scalability of our tools for both a language other than French and a new text genre.

## 2 Data

We received three different sets of medical documents: two for the development of our system, and one for testing purposes. The documents are clinical notes and pathology reports. The *Train* dataset comprises 297 clinical reports. The *Dev* dataset, used for testing our developments, contains 150 reports. Finally, the *Test* dataset, available only for the evaluation of our model, includes 153 documents.

All the documents are manually de-identified by the Mayo Clinic and annotated according to an extension of the ISO-TimeML standard (Pustejovsky et al., 2010): the THYME Annotation Guidelines, developed for the THYME project (Styler et al., 2014).

## 3 Methodology

The originality of our approach comes from the simultaneous consideration of both terminological and linguistic resources which feed a statistical model based on the Conditional Random Fields paradigm (Lafferty et al., 2001).

In our opinion, this strategy allowed us to take full advantage of the precision inherent to symbolic approaches while enabling us to benefit from the flexibility of supervised statistical modeling methods. Such a hybrid methodology has proven useful in previous research dealing with part-of-speech tagging (Constant and Sigogne, 2011).

### 3.1 Statistical analysis

Models such as Conditional Random Fields (CRF) are able to learn quickly and effectively from a large amount of observed data represented by features that are identified during the preprocessing step. Such systems typically use a set of language-independent and generic features, such as the prefix of the token or the characters that compose each token (letters, digits, hyphens, etc.).

Such a model has many advantages, the most important being its sequentiality, i.e. the fact that the CRF takes into account the context of an observation. But this approach also has its limitations. First, it is language- and domain-independent. Consequently, some generic features can be irrelevant for the concerned language or domain. Likewise, a standard CRF learns from its training corpus. Consequently, its knowledge is proportional to the variety of the corpus: if a word, a pattern, a structure is not in the corpus, the model will not recognise it and this might generate errors. In the case of textual data, this may also result in limited (lexical) coverage over unseen data.

To address the weaknesses of CRF learning, we used the CRF presented in (Watrin et al., 2014), which allows us to leverage external linguistic knowledge and resources, that will be presented in the next section. We looked at the span and attribute identification task as a sequence labelling task: a single model tags each token into the documents as being or not a relevant entity and the assigned tags capture the spans and the type of the recognised entities. The possible entity tags follow the pattern  $\langle TYPE \rangle + \langle ATTRIBUTE \rangle$ , so our tagset contains tags such as TIMEX3+DATE, TIMEX3+DURATION or EVENT+NEG. The O tag is assigned to tokens outside of any entity. In short, the sequence labelling tagging allows us to identify in a single run the boundaries, the type and the attribute of an entity.

The CRF model is developed with the CRFsuite package (Okazaki, 2007). Regarding its parameterisation, we used the default parameters proposed by the library (graphical model: first-order Markov CRF with dyad features; training algorithm: L-BFGS; see the library documentation for more information). The set of features remains unchanged against our original model (Watrin et al., 2014) and

| Feature       | explanation                    |
|---------------|--------------------------------|
| Lexical item  | token to be labeled            |
| lowercase     | token in lowercase             |
| hasHyphen     | does the token contain hyphen? |
| hasDigit      | does the token contain digits? |
| allUpperCase  | is the token uppercase only?   |
| shape         | token in a Xxx form            |
| prefix( $n$ ) | $n$ first letters of the token |
| suffix( $n$ ) | $n$ last letters of the token  |

Table 1: Language-independent features

| Feature                | explanation  |
|------------------------|--|
| pos                    | token part-of-speech tag   |
| containsFeature( $x$ ) | does the token belong to the semantic class $x$ ?                |
| sac                    | semantic class ambiguity<br>(all possible classes for the token) |

Table 2: Lexical features

is reproduced in Table 1 and 2. As we will show in section 3.2, we tuned the  $containsFeature(x)$  feature according to the particularities of medical language.

### 3.2 Language resources

We combine two kinds of language-dependent resources: terminological and linguistic resources.

**Terminological resources** The language used in medical health records is characterized by a specific terminology. As this challenge focuses on English texts, we were able to reuse the numerous existing terminologies that are distributed throughout the *Unified Medical Language System* (UMLS). The UMLS brings together more than 150 vocabularies covering various aspects of healthcare (ICD-9-CM, ICD-10-CM, SNOMED-CT, MeSH, etc.) which were compiled into a dictionary of nearly 6 million terms. These entries were automatically classified into five generic categories, i.e. *procedures*, *diagnoses*, *anatomical terms*, *organisms* and *other* by simplifying the categories system of the UMLS. These categories were used as additional features for learning. As a word can be ambiguous, each category is considered as a separate feature in the CRF.

The training corpus being quite limited in size, these resources are necessary to overcome the problem of data sparseness as far as the medical terminology is concerned. As the UMLS already has an extensive coverage, we limited ourselves to importing its terminological components without any further linguistic processing, i.e. splitting into smaller units, stemming, etc. However, it has been shown that terminological components are only partially representative of the medical language in use (De Meyere et al., 2015). For example, terms

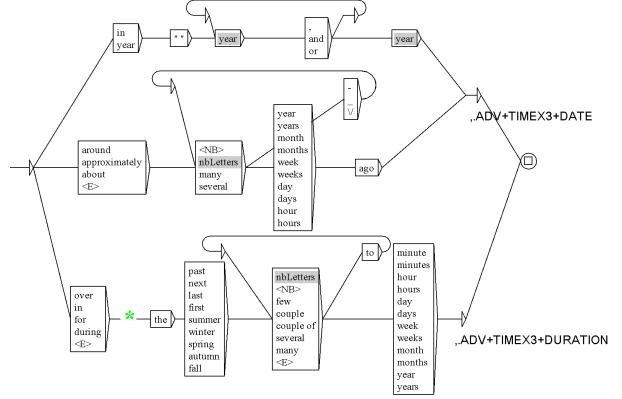

in the UMLS can be affected by syntagmatic and paradigmatic variation to varying degrees (e.g. *incomplete bladder emptying = the emptying function of the bladder is incomplete*) or may be too precise or complex to actually be used in electronic health records (e.g. *Histologically confirmed intracranial glioblastoma multiforme (GBM) or gliosarcoma*). The use of approximate string matching, generation of lexical variants and cleaning up of the dictionary would certainly improve the performance for this step and have a beneficial influence on the subsequent processes. We will discuss some points of further improvement in section 4.

**Linguistic resources** Besides terminological resources, we also developed linguistic rules for the detection of negated sequences (e.g. *Patient does not show any signs of dehydration*) and temporal expressions (e.g. *In 2006 and 2009*). These two types of information can be expressed in a large variety of ways and may be split into more than one part. We therefore formalized our rules into local grammars as implemented by the text processing framework Unitex (Paumier, 2003).

Concretely, these graphs model generic patterns that are manually constructed to extract relevant sequences. Figure 1 represents an example of graphs for the extraction of time points (e.g. *in 1998 and 2001, three years ago*, etc.) and duration (e.g. *during the last few weeks*). Grey boxes represent subgraphs that model days of the month, month names (and possible abbreviations), years, etc. Such grammars (or transducers) are able to capture complex entities and to consider the linguistic context of sequences. For instance, a duration expression is often preceded by a preposition such as *over*, *during* or *for*. The Unitex grammars allow us to specify this requirement more easily than with regular expressions<sup>2</sup>.

We designed two graphs for the detection of negation markers that occur either on the left (e.g. *His work-up ruled out an acute coronary event*) or on the right (e.g. *Genetic testing has not yet been per-*

<sup>2</sup>The star in Figure 1 indicates the end of the left context, meaning that this part of the grammar is used for computing matches but is not extracted (i.e. a preposition such as *over* must precede the article *the* but will not be included in the TIMEX3+DURATION entity).

**Figure 1:** Example of Unitex transducer for the extraction of TIMEX3+DATE and TIMEX3+DURATION expressions

| Events                 | P     | R     | F1    |
|------------------------|-------|-------|-------|
| <b>Max</b>             | 0.915 | 0.891 | 0.903 |
| <b>ES:&lt;span&gt;</b> | 0.892 | 0.878 | 0.885 |
| <b>Median</b>          | 0.887 | 0.846 | 0.874 |
| <b>Max</b>             | 0.900 | 0.875 | 0.887 |
| <b>EA:Polarity</b>     | 0.870 | 0.857 | 0.864 |
| <b>Median</b>          | 0.868 | 0.813 | 0.839 |

**Table 3:** Results for the EVENT subtasks

*formed*) of a medical entity and five graphs identifying each TIMEX3 attribute. Each transducer produces a lexically relevant output that is integrated as features into our CRF model.

## 4 Results

In this section, we present our results on the final test data. We trained two different models: one was trained on the “Train” subcorpus, the other one on the “Train” and “Dev” datasets. We expected better results with the second model, given the larger training corpus. As the performance gain was quite limited between the two models, we do not mention here the performances of the first model.

In order to provide some context to these results, we also report the median and maximum results. Table 3 shows results for the EVENT tasks (ES, EA:polarity) and results for the TIMEX3 tasks (TS, TA) are reported in Table 4.

There are many more EVENT entities than TIMEX3 entities in the whole corpus (Train, Dev and Test). Consequently, we assume that if a class is more represented in the training corpus, the per-

| <b>Timex3</b>          | <b>P</b> | <b>R</b> | <b>F1</b> |
|------------------------|----------|----------|-----------|
| <b>Max</b>             | 0.840    | 0.758    | 0.795     |
| <b>TS:&lt;span&gt;</b> | 0.777    | 0.564    | 0.653     |
| <b>Median</b>          | 0.779    | 0.539    | 0.637     |
| <b>Max</b>             | 0.815    | 0.735    | 0.772     |
| <b>TA:Class</b>        | 0.752    | 0.545    | 0.632     |
| <b>Median</b>          | 0.755    | 0.499    | 0.618     |

| <b>TA:set</b>        | 0.742    | 0.441    | 0.554     |

**Table 5:** Detailed results for TIMEX3 attributes

formances obtained on this class tend to be better: as we observed, the performances obtained for the EVENT class are higher than the ones for the TIMEX3 class.

In Table 5, we detail our results for each of the TIMEX3 attributes. Our system obtained very good results for the PREPOSTEXP attribute, probably because the lexical variation in this class is quite limited. By contrast, the results for the TIME and QUANTIFIER attributes remain low: this is partially explained by their low representation in the training corpus – the lowest among all the TIMEX3 attributes.

## 5 Discussion

A careful error analysis of 20% of the test corpus enabled us to pinpoint strategies for further improvement. We only considered TIMEX3 entities for this analysis. We identified four main types of issues that we can easily fix. We report the proportions of the various types of errors in Table 6.

**Positional errors** First, we noticed that some “easy” temporal expressions such as *Spring 2010* or *September 14, 2010* are not tagged by our system, even if they are detected by our linguistic rules and are thus inserted into the CRF’s matrix of features. In a significant number of cases, the expressions are at the beginning of the sentence. The tuning of the tagger according to a specific type of documents (newspapers) may partially explain these er-

| <b>Error type</b>       | <b>Percent</b> |
|-------------------------|----------------|
| Positional errors       | 14.6%          |
| Improvable resources    | 13.5%          |
| Graph inconsistency     | 5.3%           |
| Corpora inconsistencies | 49.1%          |
| Other                   | 17.5%          |

**Table 6:** Error analysis (TIMEX3)

rors, and weighting the CRF’s features would be a simple way of addressing this issue. Indeed, these weights could favour some features instead of others. For instance, if we apply a greater weight onto the feature reporting the linguistic information given by the grammars, this feature will have a greater influence than the feature “position in the sentence” and the errors explained in this paragraph will be reduced.

**Improvable linguistic resources** Secondly, our system missed some entities because they are neither in the training corpus nor in our linguistic resources, for e.g. *in childhood* (TIMEX3+DATE), *QID* (TIMEX3+SET) and *short number* (TIMEX3+QUANTIFIER). One issue highlighted here is that our lexical coverage is still too narrow, and we thus need to further expand our linguistic resources. On the one hand, the Unitex grammars for TIMEX3 entities need to be extended in order to detect more – and more complex – expressions. For this purpose, a more detailed linguistic study of a medical corpus in English is needed. On the other hand, it would be beneficial to preprocess our terminological resources so that they would better reflect authentic medical texts. Some processes may consist in cleaning up UMLS entries with phrasings typical of classificatory systems (e.g. *not otherwise specified*), splitting long terms into smaller units and generation of lexical variants (e.g. *varices of the esophagus* → *esophageal varices*)<sup>3</sup>.

**Graph inconsistency** Thirdly, some linguistic rules do not fit with the annotation scheme used in the reference corpora. Our DATE grammar, for example, is able to detect a date followed by a time (e.g. *September 2, 2010 at 18:45*) and associates the

<sup>3</sup>In this error class, we only quantified the errors due to the lack of completeness of our graphs, while the terminological resources are used for EVENT identification.

tag DATE to the whole sequence. However, it appeared that such sequences are actually split into a DATE entity and a TIME entity in the corpus. Fortunately, such minor problems can easily be corrected.

**Corpora inconsistency** We also noted repeated inconsistencies in the corpora that were provided. This is not surprising as the corpus was manually annotated and obtaining a satisfactory inter-annotator agreement can be complicated for such a task, due to the fastidious and time-consuming nature of manual annotation in general; for details, see the TimeBank Documentation (Pustejovsky et al., 2006). However, we believe that some inconsistencies tend to lower our results and we will discuss two of them.

The first one concerns incoherent annotation between the training and the test corpora and accounts for about 30% of the total error rate. For example, some sequences are tagged in the training corpus but not in the test corpus: consider the sequence *recently-diagnosed*, where the adverb *recently* was tagged as a DATE about 15 times in the training corpus, but is never annotated in the test corpus. This has an influence on our results as our system extracts all these kinds of sequences.

This class also includes errors rather due to a difference in perspectives. It seems that the human annotators have tried to capture relevant but maximally succinct entities. Indeed, few annotated sequences contain more than 2 words for the EVENT class, 3 for the TIMEX3 class. On the contrary, our rules are designed to recognize the longest sequences possible. As a consequence, they always capture modifiers like *approximately* or *at least* when occurring before a SET entity, i.e. *approximately 4 times a day* or *at least 3 months ago*. Such a delimitation is actually considered as incorrect during the evaluation procedure.

The second type of inconsistencies concerns the annotation of prepositions and determiners and also affects all the corpora; these errors represent about 20% of the total error rate. During the development phase, we noted that the boundaries of two identical entities are sometimes different because the preposition and/or the determiner is not always considered. For example, we observed three different annotations in the data for the sequence “at the same time”, namely, *at the same time*, *the same time*

and *same time*. We made the same observation for other prepositions introducing temporal expressions, i.e. *for*, *over* (DURATION) and *in*, which were inconsistently annotated. For consistency, we adjusted our system to include the determiner in the entity, but not the preposition. Since the evaluation only considered as correct entities with the same offsets as those of the manually annotated entities, such a variation among the reference annotations inevitably had a negative impact on our score.

Nonetheless, we think that establishing a common definition of the temporal adverbial before the annotation phase is needed. Indeed, the preposition is structurally and semantically important for the adverbial (Gross, 1990): *in September*, for example, has a DATE attribute, but *since September* is a DURATION expression. Moreover, adopting this adverbial configuration would address issues at higher levels of linguistic analysis. Thus, such a definition step seems to be really important.

Finally, the *Other* category contains occasional errors. For instance, the sequence *in less than 6-weeks* is tagged as a DATE in the reference corpus, but as a DURATION by our system: this tag is incorrect given the semantic context of the expression. We consider these cases as learning errors due to a lack of occurrences of such constructions. One way to minimize this problem would be to increase the number of texts used for training.

## 6 Conclusion

This paper presents a hybrid approach for medical and temporal information extraction. Our objective was to evaluate the scalability of tools that have been previously developed to process French news articles. Our methodology relies on a single CRF model enriched by linguistic knowledge, and has been slightly adapted. We reused the terminological component of the UMLS and designed high-precision linguistic rules that feed the statistical model. The results are encouraging given the time constraints, but could definitely be improved using different strategies, some of which are detailed regarding major classes of errors.

## Abstract

The 2016 Clinical TempEval challenge addresses temporal information extraction from clinical notes. The challenge is composed of six sub-tasks, each of which is to identify: (1) event mention spans, (2) time expression spans, (3) event attributes, (4) time attributes, (5) events' temporal relations to the document creation times (DocTimeRel), and (6) narrative container relations among events and times. In this article, we present an end-to-end system that addresses all six sub-tasks. Our system achieved the best performance for all six sub-tasks when plain texts were given as input. It also performed best for narrative container relation identification when gold standard event/time annotations were given.

## 1 Introduction

Temporality is crucial in understanding the course of clinical events from a patient's electronic health records. Since a large part of the information on temporality resides in narrative clinical notes, automatic extraction of temporal information from clinical notes using natural language processing (NLP) techniques has received much attention. Over the years, research community challenges on clinical temporal information extraction have been organized; i.e., the 2012 Informatics for Integrating Biology and the Bedside (i2b2) challenge (Sun et al., 2013), the 2013/2014 CLEF/ShARe challenge (Mowery et al., 2014), and the 2015 Clinical TempEval challenge (Savova et al., 2015). These challenges provide annotated corpora on temporal entities and relations, which facilitate comparisons

of multiple systems and expedite the development of clinical temporal information extraction methodologies.

The 2016 Clinical TempEval challenge is the most recent community challenge that addresses temporal information extraction from clinical notes. Following the 2015 Clinical TempEval challenge, the 2016 challenge consists of six sub-tasks, each of which is to identify: (1) spans of event mentions, (2) spans of time expressions, (3) attributes of events, (4) attribute of times, (5) events' temporal relations to the document creation times (DocTimeRel), and (6) narrative container relations among events and times (TLINK:Contains). 440 annotated clinical notes from Mayo Clinic, or the THYME corpus (Styler IV et al., 2014), were provided as the training data set, and 153 plain text clinical notes were provided as the test set. The participating systems were evaluated through two phases. In phase 1, the systems were evaluated on their results for all six sub-tasks given plain texts as inputs. In phase 2, system predictions on DocTimeRel and TLINK:Contains were evaluated given the gold-standard event annotations (EVENT) and time annotations (TIMEX3).

In this article, we describe a comprehensive system that addresses all six sub-tasks. We designed the system by adapting state-of-the-art techniques from previous work on named entity recognition (Tang et al., 2013a; Jiang et al., 2011) and temporal relation identification (Tang et al., 2013b; Lin et al., 2015) in the medical domain. Our end-to-end system achieved top performance for all six sub-tasks in the phase 1 and the TLINK:Contains identification task in the phase 2 stages of the challenge.

## 2 Methods

Our temporal information extraction system consists of four modules: the first module identifies the spans of event mentions and time expressions along with their types; the second module identifies attributes of events and times; the third module predicts DocTimeRel; and the last module identifies TLINK:Contains among events and times. The output results from previous modules are utilized by the latter modules. We describe those modules in detail in the following sections.

Please note that we utilized the following tools to construct our system: 1) CLAMP toolkit (<http://clinicalnlptool.com/index.php>) for tokenization, 2) OpenNLP toolkit (<http://opennlp.sourceforge.net/>) for Part-Of-Speech (POS) tagging and constituency parsing, and 3) ClearNLP toolkit (<https://code.google.com/p/clearnlp/>) for dependency parsing. We utilized wrappers provided by cTAKES (Savova et al., 2010).

### 2.1 Event mentions and temporal expressions recognition

As the first step, our system identifies the spans of event mentions and time expressions along with their types.

According to our observations of the corpus, different types of event mentions and time expressions may show characteristics different from one another. For instance, events with EVIDENTIAL type are usually represented with verbs such as ‘showed’, ‘reported’, ‘confirms’, in contrast to the events with N/A type that are usually represented with medical terms such as ‘nausea’, ‘chemotherapy’ or ‘colonoscopy’. Similarly, times with DATE type appear more often with the preposition ‘on’, while times with DURATION type appear more often with ‘during’ or ‘since’. Such variations in the characteristics may limit the system’s performance, if one tries to identify event mentions or time expressions of all types at once and then identify their types. Therefore, our system identifies the spans of events and times as well as their types simultaneously.

An HMM-SVM sequence tagger (Joachims et al., 2009) is employed to tag each token in the clin-

ical notes as either O (outside of an event mention), B-type (beginning of an event mention of *type*), or I-type (inside of an event mention of *type*), where *type* can be any of the three event types defined by the Clinical TempEval challenge (i.e, N/A, ASPECTUAL, and EVIDENTIAL). Another HMM-SVM tagger is used in a similar manner to identify spans and types of time expressions.

We use various features that have been successfully used for many entity recognition tasks in the clinical domain (Tang et al., 2013b; Lin et al., 2015). In addition, we incorporate the results of SUTime (Stanford temporal tagger) (Chang and Manning, 2012) into our system as a feature. SUTime is a rule-based tagger that identifies time expressions as defined by the TimeML (Mani and Pustejovsky, 2004). The features used are as follows:

**Lexical features:** n-gram (uni-, bi-, and tri-) of nearby words (window size of +/- 2), character n-gram (bi- and tri-) of each word, prefix and suffix of each word (up to three characters), and orthographic forms of each word (obtained by normalizing numbers, uppercase letters, and lowercase letters to '#', 'A', and 'a', respectively, and by regular expression matching)

**Syntactic features:** POS n-gram (uni-, bi-, and tri-) of nearby words (window size of +/- 2)

**Discourse level features:** sentence length, sentence type (e.g., whether the sentence ends with a colon or starts with an enumeration mark such as ‘1.’), and section information

**Word representation features:** features derived from Brown clustering (Brown et al., 1992), random indexing (Lund and Burgess, 1996) and word embedding (Tang et al., 2014) (trained on MiPACQ (Albright et al., 2013) and MIMIC II (Saeed et al., 2011) corpora)

**Features from external resources:** dictionary matching results using customized dictionaries of medical/temporal terms, and the temporal expression prediction results from SUTime (TIMEX3 only).

### 2.2 Event attribute identification

Given spans and types of event mentions, our system further identifies three attributes of the events,

i.e., *modality*, *degree*, and *polarity*. We trained three SVM classifiers for each of the three attributes using LIBLINEAR SVM package (Fan et al., 2008). We used features similar to those described in Section 2.1, where the features are extracted from a window size of +/- 5 tokens around each event mention. Additionally, we used the attribute-specific features (described below) for event attribute identification.

**Attribute-specific features:** existence of conditionality/possibility keywords (e.g., ‘if’, ‘unless’, ‘could’, and ‘likely’) in the window size of +/-5 tokens

### 2.3 DocTimeRel identification

Our system identifies DocTimeRel of each event mention in a manner similar to which it identifies event attributes. An SVM classifier was trained using the LIBLINEAR package, where the features are extracted from the window of +/- 5 tokens around each event mention. In addition to the set of features similar to the ones described in Section 2.1, the following features are used:

**DocTimeRel-specific features:** tense information of the verbs in the same sentence, event attributes, and information on time expressions in the same sentence (token/POS of time expressions before/after the event mention, token/POS of words between the closest time expression and the event mention)

### 2.4 TLINK:Contains identification

We divide the task of narrative container relation identification into six sub-problems based on two criteria: (1) whether the target narrative container relation is between two events or between an event and a time and (2) whether the two event/time mentions are within one sentence, within two adjacent sentences, or across more than two sentences. For each sub-problem, we trained an SVM classifier that identifies whether an ordered pair of two events/times (or a *candidate pair*) forms a TLINK of Contains type, using the LINLINEAR SVM package.

Before training the classifiers, we apply the following steps in order to take into account the data distribution characteristics. First, in the gold standard dataset, a large number of implicit temporal re-

lations are left unannotated intentionally. Since providing implicit relations as negative instances to the SVM learners may harm the learning process, we extended the gold standard set of TLINK:Contains to its transitive closure, and used the extended set as the positive instances for training. The transitive closure was generated by applying Floyd-Warshall algorithm (Floyd, 1962) on the gold standard TLINK set based on the transitivity of the TLINK:Contains relation (i.e, A contains B  $\wedge$  B contains C  $\rightarrow$  A contains C).

Second, since any two events/times can be a candidate pair to train a classifier, the number of candidate pairs becomes huge with small portion of positive instances among them. This may not be ideal for training a classifier. In order to reduce the number of prospective negative instances, we filtered out some of the candidate pairs that are highly unlikely to form a TLINK:Contains relation based on the THYME corpus annotation guideline<sup>1</sup>. We removed a candidate pair either 1) when the two event/time mentions are not in the same section, or 2) when one event has ACTUAL modality while the other has HYPOTHETICAL modality, or 3) when one event has BEFORE DocTimRel while the other has AFTER DocTimeRel. For candidate pairs whose event/time mentions are across more than two sentences, we further filtered out the pairs based on heuristic rules, in order to keep only the candidate pairs that are highly likely to form a TLINK:Contains relation. We kept a candidate pair only when an event/time among the two events/times is mentioned in a section header that includes the keywords ‘history’ or ‘evaluation’ or in a section header that ends with a time expression.

We also applied cost-sensitive learning in order to counterbalance the effect of dominating number of negative instances. To each class, we assigned weight that is inversely proportional to the class frequency, adjusting the penalty factor in SVM training (Ben-Hur and Weston, 2009). For instance, if there were 20 positive pairs among 100 candidate pairs, we would assign the weight 5 (100/20) to the positive class and the weight 1.25 (100/80) to the negative class.

---

| sub-task | P            | R            | F            |
|----------|--------------|--------------|--------------|
| ES (t)   | 0.915        | 0.891        | 0.903        |
| TS (t)   | 0.840        | 0.758        | 0.795        |
| ES (s)   | <b>0.915</b> | <b>0.891</b> | <b>0.903</b> |
| TS (s)   | 0.836        | 0.757        | <b>0.795</b> |
| ES (m)   | 0.887        | 0.846        | 0.874        |
| TS (m)   | 0.779        | 0.539        | 0.637        |

**Table 1:** Test set results on EVENT span (ES) and TIMEX3 span (TS) identification. Bold faces signify the cases where our system showed the top performance.

The features used for the six classifiers are as follows. Note that an event mention was expanded to its covering noun phrase before the feature extraction:

**Common features:** event/time attributes, token and

POS features on event/time mentions (as provided by cTAKES), punctuation between event/time mentions, other event/time mentions within the same sentence as the two event/time mentions, number of other event/time mentions between the two event/time mentions, tense of the verbs in the same sentence, section information, sentence type (the same as in Section 2.1), and word embedding representations of the head words of event/time mentions

**Features for single-sentence cases:** dependency path linking the two event/time mentions (as provided by cTAKES)

**Features for multi-sentence cases:** line distance between the two event/time mentions, and tokens that are common to the two event/time mentions

### 3 Results

In this section, we present our system’s performance on test set along with the top and the median results from the challenge. Table 1, 2, and 3 show the results on event/time span identification, event/time attribute identification, and DocTImeRel and TLINK:Contains identification, respectively. In the tables, (t) and (m) stand for the top and median results of the 2016 challenge, while (s) stands for our system’s results. Our system showed top F1 scores for event/time span, for event/time attribute, for DocTimeRel (phase 1 only), and for TLINLK:Contains identification.

**Table 3:** Test set results on DocTimeRel (DR) and TLINK:Contains (CR) identification. (a) phase 1 results. (b) phase 2 results. Bold faces signify the cases where our system showed the top performance.

| DocTimeRel value | # EVENTS (%) | Acc.  |
|------------------|--------------|-------|
| AFTER            | 2073 (10.9%) | 81.3% |
| OVERLAP          | 8983 (47.3%) | 90.1% |
| BEFORE           | 6984 (36.8%) | 79.9% |
| BEFORE/OVERLAP   | 952 (5.0%)   | 51.5% |

**Table 4:** DocTimeRel identification accuracy on each DocTimeRel value. # EVENTS represents the number of event annotations from the gold standard with the specified DocTimeRel value in the test set.

## 4 Conclusion and discussion

In this article, we describe a system that shows the top performance in the 2016 Clinical TempEval challenge. We adapted the state-of-the-art techniques for entity recognition and temporal relation identification in the clinical domain, and show that those techniques are effective for the Clinical TempEval challenge as well.

For time expression identification, we found some error cases in which the system’s prediction differs with the gold standard annotation only on the inclusion or exclusion of a preposition. For example, while a DURATION type time is annotated for the phrase “for the past 40 years” in the gold set, our system predicted a DURATION for the phrase “the past 40 years” omitting the preposition ‘for’ from the gold standard annotation.

Table 4 shows the DocTimeRel identification accuracy on each DocTimeRel value. Accuracy on the value OVERLAP is the highest, which might come from the abundance of the training data. Surprisingly, the classifier worked better for the value AFTER than the value BEFORE, even though there were three times more events with BEFORE DocTimeRel than those with AFTER. We conjecture that explicit keywords that indicate the future tense such as “will” and “potential” played key roles in identifying AFTER DocTimeRel.

Table 5 shows the 10-fold cross validation results of the six classifiers for TLINK:Contains identification. Temporal relations between an event and a time were predicted more accurately than the relations between two events. Classifiers for pairs across more than two sentences showed the best F1 scores, due to the heuristic filtering steps in which we kept only the candidate pairs that are highly likely to form a narrative container relation.

| sub-problem    | F     |
|----------------|-------|
| EVENT-EVENT-1  | 66.9% |
| EVENT-EVENT-2  | 69.1% |
| EVENT-EVENT-3  | 76.2% |
| EVENT-TIMEX3-1 | 79.9% |
| EVENT-TIMEX3-2 | 76.3% |
| EVENT-TIMEX3-3 | 84.3% |

**Table 5:** F1 scores of the six classifiers for TLINK:Contains identification (10-fold cross validation on the training set). EVENT-EVENT and EVENT-TIMEX represent the sub-problems regarding the candidate pairs between two events, and the sub-problems regarding the pairs between an event and a time, respectively. The suffixes ‘-1’, ‘-2’ and ‘-3’ indicate that the pairs should be within one sentence, within two adjacent sentences, and across more than two sentences, respectively.

We plan to further improve our system to show higher performance based on the observations above.

## Acknowledgments

We would like to thank the Mayo Clinic for permission to use the THYME corpus. This study was supported in part by NIGMS grant 1 R01 GM103859.

# NUIG-UNLP at SemEval-2016 Task 13: A Simple Word Embedding-based Approach for Taxonomy Extraction

Joel Pocostales

Insight Centre for Data Analytics

National University of Ireland, Galway

name.surname@insight-centre.org

## Abstract

This paper describes the NUIG-UNLP system submitted to SemEval-2016, Task 13. We implement a semi-supervised method that extracts hypernym candidates for the terms provided in the test list. The main assumption of our system is that hypernyms may be induced by adding a vector offset to the corresponding hyponym word embedding. The vector offset is obtained as the average offset between 200 pairs of hyponym-hypernym in the same vector space. Our approach ranked second on connectivity (c.c.) and categorisation (i.i.) for the English taxonomy construction, and fifth on the overall ranking. Despite of these modest results, our system achieved comparable evaluations scores with the other participants.

## 1 Introduction

Hyponyms and hypernyms (sometimes called subordinate and superordinate terms, respectively) describe a type of relation which, in general, can be defined in terms of asymmetric entailment: given the hyponym of feline, cat, and its hypernym, feline, we can state that all cats are felines, but not that all felines are cats.

Likewise, the relations that hyponyms and hypernyms signal can also be characterized as a *isa* relation between a hyponym  $X$  and hypernym  $Y$ : for nouns,  $X$  is a Kind of  $Y$  or  $X$  is a type of  $Y$  (Saint-Dizier and Viegas, 1995). These particular *type / kind-of* relations form the backbone of the construction of Lexical Taxonomies and Ontologies (Buitehaar et al., 2004; Navigli et al., 2011), and those

in turn plays a essential role in many Natural Language Processing applications: Question Answering, Textual Entailment, Natural Language Inference, or Text Summarization (Bordea et al., 2015).

In this regard, despite the fact that taxonomy construction can be addressed from a diversity of approaches, the lexico-syntactic patterns-based are still the most widely used. Nevertheless, in the last years some vector space-based approaches have emerged for learning semantic hierarchies (Saxe et al., 2013; Khashabi, 2013; Fu et al., 2014; Rei and Briscoe, 2014; Tan et al., 2015; Nayak, 2015). In the next sections we will mainly turn our attention to this type of approaches.

### 1.1 Task Definition

The five participating teams in SemEval-2016 Task 13 were provided with six datasets in four languages (English, Dutch, French and Italian)<sup>1</sup>. The datasets can be divided in three domains (science, environment and food). Additionally, this year the TExEval-2 task has a focus in four subtasks related to taxonomy construction:

1. Taxonomy construction
2. Hypernym identification
3. Multilingual taxonomy construction
4. Multilingual hypernym identification

However, due to lack of time, we decided to address only the English monolingual subtasks.

<sup>1</sup>The corresponding system description papers can be found in Cleuziou and Moreno (2016), Panchenko et al. (2016) and Tan (2016).

The key idea behind TExEval tasks is the creation and evaluation of systems capable of automatically extracting hierarchical relations from text and then constructing taxonomies. Following (Fu et al., 2014), ideally, the construction of those hierarchies can be seen as a directed acyclic graph *DAG* with a finite set of nodes (words) and edges representing the *asymmetric* and *transitive* hyponym-hypernym relations. This is formally defined by Fu et al. (2014) as follows:

- $\forall x, y \in L : x \xrightarrow{H} y \Rightarrow \neg(y \xrightarrow{H} x)$
- $\forall x, y, z \in L : (x \xrightarrow{H} z \wedge z \xrightarrow{H} y) \Rightarrow x \xrightarrow{H} y$

where in our case  $x$ ,  $y$  and  $z$  denote the terms in the domain list  $L_d \in L$ , and the hyponym-hypernym relation is represented by  $\xrightarrow{H}$ . Therefore, the aim of the task was to return a list of pairs  $x \xrightarrow{H} y$  for each term in the six different domains  $L_d$ .

## 2 Experimental Setup

We describe in this section our taxonomy extraction system.

### 2.1 Training Data

Since TExEval-2 organizers did not provide any specific corpus for the task, we used the latest Wikipedia dump<sup>2</sup>. We preprocessed it using the WikiExtractor tool<sup>3</sup>, which generates a plain text from a Wikipedia database dump discarding markup tags and any other element different than text, such as tables, references, lists and images. On the other hand, in order to generate a single word embedding for each entry in the test list, we underscore all the entries containing open compound words:

```
civil engineering ⇒
civil_engineering
```

### 2.2 Word Embeddings Generation

We use the log-bilinear model GloVe (Pennington et al., 2014) trained over the above-mentioned Wikipedia corpus to generate vector space representations of words. Following the analogy task results presented in their paper and some pre-experimental

<sup>2</sup>We used the English snapshot of 17-Nov-2015

<sup>3</sup><https://github.com/attardi/wikiextractor>

test, we set a windows size of 10 and 300 dimensions word embeddings. The number of iterations of the model was set to 20.

### 2.3 Offset Model

Mikolov et al. (2013) and subsequently Levy and Goldberg (2014) demonstrated that word embeddings generated by neural nets (and also other traditional distributional methods) preserve some syntactic and semantic information. Some of this encoded information, such as relational similarities between pairs of words, can be recovered by simple vector offsets between the vector embeddings of each word. Thus, as Mikolov et al. (2013) and Levy and Goldberg (2014) showed, given two pairs of words that share a relation,  $a : a^*, b : b^*$ , the relation between those two words can be represented by their vector offset, as follows:

$$a^* - a \approx b^* - b \quad (1)$$

Therefore, the vector of the word  $b^*$  should be similar to the proxy vector  $y'$

$$y' = b - a + a^* \quad (2)$$

where  $y'$ , ideally, corresponds to the vector representation of  $b^*$ . Since  $y'$  will rarely match the exact position of the word  $b^*$ , different similarity measures may be applied to find the most similar word to  $y'$ . In this paper we will focus only in Cosine similarity (4) and Euclidean distance (5):

$$\cos(b^*, y) = \frac{b^* \cdot y'}{\|b^*\| \|y'\|} \quad (3)$$

maximizing the function:

$$\arg \max_{b^* \in V} (\cos(b^*, y')) \quad (4)$$

where  $V$  is the vocabulary.

And given the Euclidean distance formula, subsequently we obtain the following function:

$$d(b^*, y') = \|b^* - y'\|^2 \Rightarrow \arg \min_{b^* \in V} \|b^* - y'\|^2 \quad (5)$$

## 2.4 Offset Model for Hypernym-Hyponym Relation

Mikolov et al. (2013) and Levy and Golberg (2014) have only tested the vector offset method for simple symmetric relations such a capital-country, gender inflections, adjective-to-adverbs, etc. However, as Rei and Briscoe (2014) pointed out, hypernym-hyponyms relations are conceivable much more difficult to represent by simple vector offsets, as their relations rarely are symmetric.

Rei and Briscoe (2014) in their paper first assess how word embeddings perform in hypernym-hyponym detection and generation, and second, propose a new directional similarity measure (WeightedCosine) based on two new properties to detecting these relations.

In our submitted system, though, we finally decided not to implement this new measure due to lack of time.

## 2.5 Offset Model for the Hypernym-Hyponym Relation

We first generate a random list of 200 pairs of hypernym-hyponyms. This training list was extracted from the trial data provided in Bordea et al. (2015) and WordNet (Miller, 1995; Fellbaum, 1998) covering different domains.

Using the Gensim library<sup>4</sup> (Řehůřek and Sojka, 2010) we compute the vector offset as the average offset of all the pairs generated in the above-mentioned training data (Mikolov et al., 2013; Nayak, 2015):

$$v_{offset} = \frac{1}{n} \sum_{i=1}^n (v_{hyper(i)} - v_{hypo(i)}) \quad (6)$$

where  $n = 200$ , as the number of pairs of hypernym-hyponym in our training data.

Once the  $v_{offset}$  has been obtained, we add it to the target terms in the test list:

$$y' \approx v_{term} + v_{offset} \quad (7)$$

where we assume that the addition of the vectors  $v_{offset}$  and  $v_{term}$  projects  $y'$  close enough to the hidden hypernym representation  $b^*$ . Thus, we apply either the measure similarity (4) or (5) and we rank

---

<sup>4</sup><http://radimrehurek.com/gensim/>

either the top 10 or 5 candidates, discarding those terms not included in the test list. We also implement a substring inclusion approach based on regexp (Nevill-Manning et al., 1999) so that

$$\begin{aligned} \text{civil engineering} &\xrightarrow{H} \text{engineering} \\ \text{social psychology} &\xrightarrow{H} \text{psychology} \end{aligned}$$

In other words, given an open compound word such *civil engineering*, we assume that the second term *engineering* is the most likely hypernym of *civil engineering*.

## 3 Evaluation Metrics

In this section we present the results obtained in the second task on Taxonomy Extraction Evaluation as part of SemEval-2016. The metrics correspond to the structural analysis and the comparison against the Gold Standard effectuated by Bordea et al. (2016). The best results among all the systems appear in a bold font (note that Euclidean 5 and Cosine 5 have been excluded as they were not submitted on time).

### 3.1 Results

Table 1 shows the structural analysis of our system and the corresponding results when compared to Gold Standard. We were only able to submit the first system (Euclidean 10), and we had to exclude the food domains due to time limitations. However, we will also present here metrics beyond the official system submission, i.e, Euclidean 5 and Cosine 5 covering all domains provided on the test data.

The hyphen (-) is used in cases when the number of cycles could not be computed due to hardware limitations. This outcome should be interpreted as negative, as the presence of cycles goes against Directed Acyclic Graph (DAG) definition.

As per the structural analysis, the main goal is to evaluate the number of correct nodes and edges in comparison with the Gold Standard. Thus, the quantifying metrics in the left block ( $|V|$  ... i.n.) cannot really be considered aside of the Golden Standard evaluation. Therefore, in this section we will mainly focus on the qualifying metrics instead of the quantifying ones.

We observe that, likely, due to the restrictions imposed in our algorithm not allowing hypernym can-

Table 2: Precision, Recall and F-Score for Euclidean Distance 10, 5 and Cosine 5

didates out of the test list, there are no significant differences between Euclidean top 10 and 5.

We also note that the number of cycles was considerably higher on the euclidean approaches, in fact, exceeding the computer memory capacities for some domains, namely, Science, Science\_WordNet (see the surprisingly high figure for Euclidean 5, Science\_WN). On the other hand, unlike our initial assumptions, the cosine approach did not perform much better than the Euclidean ones. Our system obtained comparable recall values with the other systems, at the expenses, though, of the precision. Therefore, the results achieved by our systems are in general modest, especially taking into consideration that our algorithm also included a substring inclusion module (as described in section 2.5).

### 3.2 Conclusion and Discussion

Although there is still room for improvement in our system, we conclude that the diversity involved in the complex hypernym-hyponym relations cannot easily be captured by a simple vector offset mean. As direction for future work, it might be worth considering domain specific vectors as well as incrementing the number of training pairs for the vector offset mean.

Our system ranked second on connectivity (c.c.) and categorisation (i.i.) for the English taxonomy construction, and fifth on the overall ranking (see Bordea et al. (2016) for further details on the evaluation metrics).

## Abstract

This paper describes our submission to the SemEval-2016 Taxonomy Extraction Evaluation (TExEval-2) Task. We examine the endocentric nature of hyponyms and propose a simple rule-based method to identify hypernyms at high precision. For the food domain, we extract lists of terms from the Wikipedia lists of lists by using the name of each list as the endocentric head and treating all terms in the extracted tables as the hyponym of the endocentric head.

Our submission achieved competitive results in taxonomy construction and ranked top in hypernym identification when evaluated against gold standard taxonomies and also in manual evaluation of novel relations not covered by the gold standard taxonomies.

## 1 Introduction

Semantic taxonomies provide structured world knowledge to Artificial Intelligence (AI) and Natural Language Processing (NLP) systems. Traditional broad-coverage taxonomies such as CYC (Lenat, 1995), SUMO (Pease et al., 2002; Miller, 1995), YAGO (Suchanek et al., 2007) and Freebase (Bollacker et al., 2008) have been manually created or curated with much effort.

With the rapid technological evolution, it is more feasible to construct a domain-specific taxonomy that caters to domain or company specific terminology (Lefever, 2015). This motivated the move towards unsupervised approaches to taxonomy extraction (Berland and Charniak, 1999; Lin and Pantel,

2001; Snow et al., 2006) and specifically focused towards particular domains (Velardi et al., 2013; Bordea et al., 2015).

The aim of the Taxonomy Extraction Evaluation (TExEval) task is to automatically find lexical relations between pairs of terms within several specified domains. Previously, we have developed a hypernym extraction system using word embeddings by exploiting the frequent occurrence of the ‘*X is a Y*’ pattern in encyclopedic text (Tan et al., 2015).

We have achieved competitive results in SemEval-2015 and as a follow up to our study, we would like to explore the endocentric nature of hyponyms that contributed substantially to the system performance in the previous TExEval task.

Below, we will briefly (i) describe related work on different approaches to taxonomy induction, (ii) explain the linguistic phenomenon of endocentricity, (iii) present our endocentric hypo-hypernym identification system and the results of our submission to the TExEval-2 task in SemEval-2016.

## 2 Related Work

The hierarchical structure of domain concepts is made of hypo-hypernymy relations between terms. Different approaches have been proposed to induce these relations automatically ranging from pattern/rule-based approaches (Hearst, 1992; Girju, 2003; Kozareva et al., 2008; Ceesay and Hou, 2015) to clustering and frequency based approaches (Lin, 1998; Caraballo, 2001; Pantel and Ravichandran, 2004; Grefenstette, 2015), classification approaches (Snow et al., 2004; Ritter et al., 2009; Espinosa Anke et al., 2015) and graph-based ap-

proaches (Kozareva and Hovy, 2010; Navigli et al., 2011; Fountain and Lapata, 2012; Tuan et al., 2014; Cleuziou et al., 2015).

More recently, there is a resurgence of vector space or distributional approaches (Van Der Plas, 2005; Lenci and Benotto, 2012; Santus et al., 2014) primarily because of the renaissance of deep learning and neural networks.

Semantic knowledge can be thought of as a vector space where each word is presented by a point and the proximity between words in this space quantifies their semantic association. The vector space is usually constructed from the distribution of words across contexts such that similar meanings tend to be found close to each other within the vector space (Mitchell and Lapata, 2010).

With the present advancement in neural nets and word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Levy et al., 2014; Shazeer et al., 2016), neural space models are gaining popularity in taxonomy induction and relation extraction tasks (Saxe et al., 2013; Fu et al., 2014; Tan et al., 2015).

### 3 Endocentricity

Early research in theoretical linguistics discussed the idea of *endocentric* vs. *exocentric* constructions (Brugmann, 1886; Aleksandrov, 1886; Brockelmann, 1908; Bloomfield, 1983).

A grammatical construction is *endocentric* when it fulfills the same linguistic function as one of its part(s). For instance, the word *goldfish* is an endocentric compound noun as syntactically it functions as a noun just as its component part *fish* and semantically the compound denotes a type of *fish*.

Conversely, when a grammatical construction made of two or more parts is *exocentric*, no part component carries the linguistic function or meaning assigned to the complex construction. Intuitively, we would expect that there are many endocentric hyponyms in a taxonomy where part of the term conveys its main meaning and usually that part of term would be its hypernym.

The endo/exocentricity feature of a lexical term assumes that the term can be split into two or more parts. For example, *fish* is a single noun that cannot be split, thus it cannot be endo- or exocentric.

While experimenting with ways to weight a term

for information retrieval, Jones (1979) observed that compound nouns often follow the head-modifier principle where the meaning of the term can be conveyed by part(s) of the compound. Approaching endocentricity from a different angle, Nichols et al. (2005) identified the semantic head(s) of a term as its hypernym using the lowest scoping element of the Robust Minimal Recursion Semantics (RMRS) (Copestake et al., 2005) structure of the dictionary definition of the term.

In the first TExEval task in SemEval-2015, both Lefever (2015) and Tan et al. (2015)<sup>1</sup> independently developed string-based systems that exploit the endocentric nature of hyponyms.

In our submission to the TExEval-2 task (Bordea et al., 2016), we seek to answer the question of exactly “*how many hyponyms within a taxonomy are endocentric?*”. Additionally, we exploit the endocentric nature of the hyponyms to extend the taxonomy by crawling and cleaning Wikipedia’s *List of Lists of Lists*.<sup>2</sup> Often these lists of terms are found in Wikipedia marked up as tables or in bullet forms.

### 4 Identifying Endocentric Parts

The main implementation of the rule-based identifier<sup>3</sup> checks *if a term T1 is a substring of another term T2 and if so, assign T1 as a hypernym of T2*. Examples of hypo-hypernym pairs captured by this rule includes are (*psycholinguistics*, *linguistics*), (*kobe beef*, *beef*), (*sauce gribiche*, *sauce*).

Our implementation is simpler than the three part morpho-syntactic analyzer component of the multi-modular taxonomy constructor in Lefever (2015). She implemented rules for three different syntactic constructions which check for suffixes and treat single-word terms and multi-word terms differently while our implementation is agnostic to the single and multi-word distinction.

In addition to the first rule, *if a term contains the “of” preposition, we swap the assignment and check that T2 starts with T1 then assign T2 as a hypernym of T1*. Examples of hypo-hypernym pairs

<sup>1</sup><https://github.com/alvations/USAAR-SemEval-2015/tree/master/task17-USAAR-WLV>

<sup>2</sup>[https://en.wikipedia.org/wiki/List\\_of\\_lists\\_of\\_lists](https://en.wikipedia.org/wiki/List_of_lists_of_lists)

<sup>3</sup>Our open-source implementation can be found at <https://github.com/alvations/Endocentricity>

captured by this swap rule are (*elixir of life*, *elixir*), (*sociology of education*, *sociology*).

To improve the precision of the identifier, we set a threshold of a minimum character length of three when identifying a term as a hypernym.

## 5 Extending a Taxonomy with Wikipedia List of Lists of Lists

The Wikipedia List of Lists of Lists (LOLOL) is a crowdsourced list of lists of terms. We adapted the customized crawler<sup>4</sup> (Tan et al., 2014; Tan and Ordan, 2015) to crawl for tables or bullet points in the Wikipedia subpages of the LOLOL for the food domain. We started the crawl from these seed pages under the bullet point of [https://en.wikipedia.org/wiki/List\\_of\\_lists\\_of\\_lists#Food\\_and\\_drink](https://en.wikipedia.org/wiki/List_of_lists_of_lists#Food_and_drink).

When the crawler lands on each List of Lists (LOL) page, it will *treat the URL suffix as the hypernym* and *find words in the bullet points or tables that contain endocentric hyponyms*.

If an endocentric hyponym exists, it will extract either (i) all the terms in bold font if the LOL page is bulleted or (ii) all terms in the first column if the LOL page is in table form. The choice of the first column is based on the fact that often LOL tables are bi-column, one containing the terms and the other the gloss or/and description of the term.

### 5.1 Limitations of LOLOL Trawler

There are a number of issues with this *trawling* (*crawl+clean*) approach to extend the taxonomy.

**LOL pages are not standardized:** The way the crawler cleans the bullets or tables on each LOL page is not standardized because there is no constraint put on the format of the Wikipedia’s LOL page. Our trawler only managed to crawl and clean less than 30 LOL pages when extracting the new terms for the food domain.

**LOL pages are inceptive:** The depth of how nested the LOLs are is undefined. Our trawler can start with a *List\_of\_foods* page and it leads to the *List\_of\_breads* page and then the *List\_of\_American\_breads* page and it contin-

<sup>4</sup>It was built for crawling translations and diachronic texts in previous SemEval tasks

ues. For sanity, we had to break our trawler at the second page depth and return to the main LOLOL page to move on to the next LOL that we have not previously trawled.

## 6 Results

Table 1 presents the overview results of our submissions to the TExEval-2 task. Only the results for the food domain contains the hypo-hypernym pairs extracted by our trawler. The rest of the domains comprise of the outputs solely generated by our endocentric hypo-hypernym identifier.

Although it is counter-intuitive to think that endocentric hypo-hypernym pairs can be wrong, this example aptly demonstrates the limitation: (*honey bunches of oats*, *honey*). In this case, neither ‘*honey bunches of oats*’ can be a hypernym of ‘*honey*’ nor vice versa.

When compared against the gold standard taxonomies, our submission achieved the highest precision in the environment, food (WordNet), science (Eurovoc) and science (WordNet) domains.

As for the Food domain, we expected the fall in precision due to the additional terms that we introduced from the Wikipedia LOLOL outside of the gold standard taxonomy. Thus, we are also unable to determine the true “correctness” of these terms (indicated by the dash in Table 1).

Looking at the proportion of the number of hypo-hypernym pairs that our system correctly identified, we can approximate that *15-25% of the hypernyms in a taxonomy can be easily identified through their endocentric hyponyms* by taking the ratio of #Correct / #Terms.

However, the proportions presented in Table 1 exclude the correct hypo-hypernym pairs that are identified but are not currently in the gold-standard taxonomy. Table 2 presents the results of the manual evaluation for the precision of 100 randomly selected hypo-hypernym pairs that are not in the gold standard taxonomy. Our system achieved top precision in all domains other than science (Eurovoc).

If we consider the precision scores from Table 2 as the precision of the remaining identified but not correct hypo-hypernym pairs in Table 1, we would be able to add to the 15-25% hypononym endocentricity in taxonomies. However, the aggregation of

|                      | R | 0.2655          | <b>0.3805</b> | 0.1881        |

**Table 3:** Comparison of String-based Methods

Comparing against the TExEval-2 organizers baseline string-based method and the TAXI lexico-syntactic substring approach (Panchenko and Biemann, 2016) for the WordNet taxonomies, our system achieved highest precision but underperformed in recall as shown in Table 3.

Since our main implementation of our hypernym identifier is language independent, in retrospect, we can easily remove the swap rule that is attached to the English ‘of’ and apply the identifier to other languages in the TExEval-2 task.

## 6.1 Other Participating Systems

Table 2 presents a summary of the results of novel hypo-hypernym pairs identified by the participating systems in TExEval-2. A detailed overview of the results of TExEval-2 is presented in Bordea et al. (2016).

JUNLP relied on substrings and relations extracted from BabelNet (Navigli and Ponzetto, 2012) to identify hyper-hyponym pairs. Although it is sensible to approach the task using an existing ontology, their system achieved relatively low precision on the manual evaluation of novel hyper-hyponym pairs. The NUIG-UNLP team extended previous work on vector space approaches to taxonomy induction by comparing the similarity between the dense word embeddings of the hyponyms and their candidate hypernyms. They system achieved high recall but attained low precision (Pocostales, 2016).

Similar to our endocentric-based approach, the TAXI team extended the substring-based approach by filtering the hypernym candidates based on corpora statistics of lexico-syntactic patterns. Additionally, they applied pruning methods to improve the

ontological structure which resulted in high Fowlkes and Mallows (F&M) Measure (Panchenko and Biemann, 2016). QASSIT used lexical patterns to extract hypernym candidates and applied the pre-topological space graph optimization technique that is based on genetic algorithm to achieve the desired taxonomy structure (Cleuziou and Moreno, 2016).

TAXI and QASSIT ranked first and second in the taxonomy construction criterion of the TExEval task. Both teams used graph pruning techniques to improve the taxonomy structure and implicitly improve the F&M scores<sup>5</sup> of their taxonomy. Although our endocentricity based hypo-hypernym extraction system ranked first in hypernym identification of TExEval task, we ranked third in taxonomy construction with an overall F&M score of 0.0013.

## 7 Conclusion

In this paper, we have described our submission to the Taxonomy Extraction Evaluation (TExEval-2) Task for SemEval-2016. We have empirically shown that 15-25% of the hypernyms in a taxonomy can be easily identified through their endocentric hyponyms and we briefly discuss the intuitions and limitations of the approach.

We have achieved competitive results in taxonomy construction and achieved top precision score for hypernym identification in most domains involved in the task.

## Acknowledgments

The research leading to these results has received funding from the People Programme (Marie Curie Actions) of the European Union’s Seventh Framework Programme FP7/2007-2013/ under REA grant agreement no 317471.

# JUNLP at SemEval-2016 Task 13: A Language Independent Approach for Hypernym Identification

Promita Maitra and Dipankar Das

Department of Computer Science Engineering, Jadavpur University  
Kolkata, India

promita.maitra@gmail.com and dipankar.dipnil2005@gmail.com

## Abstract

This paper describes our approach to build a language-independent hypernym extraction system, based on two modules for the SemEval-2016 Task 13 on Taxonomy Extraction Evaluation (TExEval-2). This task focuses only on the hypernym-hyponym relation extraction from a list of terms collected from various domains and languages. The first module of our system is built on the state-of-the-art system using BabelNet while the second one deals with the parts found within terms and which are useful to establish a hierarchical relation among them. Our system performed well in terms of *recall* in most of the domains irrespective of the languages; however, the precision scores indicate a scope of improvement. In case of overall ranking, our present system stands fourth in monolingual (i.e. English) evaluation and second in multilingual (i.e. Dutch, Italian, French) setup.

## 1 Introduction

The rapid growth in terms of digitalized texts in the recent years (specially, in the fields including scientific, clinical, enterprise, legal, and personal information management) has made the management of textual information increasingly important. In order to fulfill the need of having more structured data, ontologies, taxonomy or hierarchical relations between ontological concepts are considered as useful tools for content organization, navigation, and retrieval, as well as to provide valuable input for semantically intensive tasks such as question answering and textual entailment. This task specifically focuses on the

identification of hypernym-hyponym relation among terms in four different languages (English, Dutch, Italian and French) and different domains. Typically, taxonomy construction has three basic steps: entity or concept identification, discover different relations among different entities and taxonomy construction. The challenge organizers have made it easy by already providing us with a list of extracted entities (also called concepts/terms) for each of the domains in each of the languages. Our approach was to build a system that fits a multilingual setup and significantly reduces the computational time and complexity by taking existing resources into consideration.

The rest of the paper is organized as follows: Section 2 describes the task at hand in brief along with the main challenges. Section 3 gives a brief overview of the work already done in this field. Section 4 contains the details of the modules we have used to address the problem. Section 5 presents the analysis of results and finally, the conclusion and future scopes are discussed in Section 6.

## 2 Problem Description

SemEval-2016 Task 13: Taxonomy Extraction Evaluation (TExEval-2) has its main focus on hypernym-hyponym relation extraction from given lists of terms collected from multiple domains like Food, Environment and Science (Bordea et al., 2016). This year, the task organizers have extended the problem setup to address the multilingual structure. Along with English, there were terms in French, Dutch and Italian as well for all the domains. For this particular task, we did not have to go through the complexities of entity identification from a text

as the lists of terms were already given.

- i. One of the main challenges was that we were not provided with any annotated or plaintext corpus that we can use as training. However, the organizers suggested that it would be helpful if we explore the Wikipedia dump for the same.
- ii. Second big challenge was to develop a system that will work for languages we do not understand. Ontology development being such a task where some basic domain knowledge is inevitable, this multilingual setup was indeed a great concern for us.
- iii. We were specifically asked not to use the resources we most frequently use in this kind of tasks as they were used to construct the gold standard. The list of the resources that were prohibited is:
  - hypernym-hyponym relations from the WordNet<sup>1</sup>,
  - skos:broader and skos:narrower relations from EuroVoc<sup>2</sup>,
  - the Google product taxonomy<sup>3</sup>,
  - the Taxonomy of fields and their subfields provided for the National Academies of Sciences, Engineering, and Medicine<sup>4</sup>.

However, in contrast, we were free to add more terms if needed to the term lists that were provided by the organizers.

### 3 Related Work

Hypernym detection from text is one of the most popular hierarchical relation extraction tasks in ontology learning for which research work dates back to at least 1984 (Calzolari, 1984). Hypernym can be described as a linguistic term for a word whose meaning includes the meanings of other words, which are known as hyponyms. For instance, *flower* is a hypernym of *daisy* and *rose*. On the other hand,

*daisy* and *rose* are some of the hyponyms of *flower*. In simple words, this relation deals with identifying the concepts and finding the particular superclass they fit in. Manually constructing these kind of relations from text is a time-consuming and labour-intensive procedure. Hence, the researchers felt the need to make this process automatic. The methods proposed can broadly be categorized into two: supervised and unsupervised. While the unsupervised methods can identify and extract semantic relations from plain text without the need of any pre-annotated text corpora, the supervised methods often find it difficult to find an annotated corpora in similar domain. A major part of the previous researches on automatic semantic classification of words was developed based on the method first proposed by Hearst, that the presence of certain lexico-syntactic patterns can indicate a particular semantic relationship between two noun phrases (Hearst, 1992). This paper introduced six basic lexical patterns. This rule based approach was further extended in subsequent works bringing out more valid patterns, either handcrafted or learned from training corpus for semantic relation extraction (Berland and Charniak, 1999) (Kozareva et al., 2008) (Widdows and Dorow, 2002). Pattern based results are effective and reliable, scores high on precision measure. However, these methods suffer in terms of recall. Later, a few distributional approaches were proposed by different authors making use of the large corpora present in (Guido Boella, 2014) (Navigli and Velardi, 2010). Machine learning based methods make use of features like term co-occurrence, semantic similarity or other syntactic information from text collection. Precision of these machine learning based approaches is lower compared to pattern based approach. The simple morpho-syntactic approach also proved to yield a decent result (Lefever, 2015) (Sang et al., 2011). In recent years, several researches are being carried out to extract semantic relations from texts in other languages.

### 4 System Description

In the present challenge, we had to keep three main points in mind. We wanted to make a single system appropriate for a multilingual setup (Dutch, French, Italian and English). However, it became

<sup>1</sup><https://wordnet.princeton.edu/>

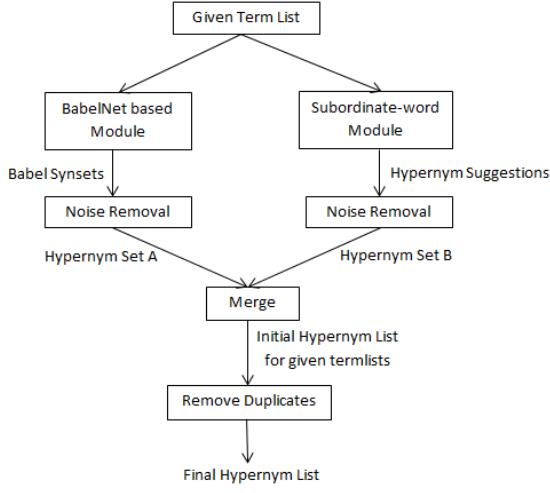

<sup>2</sup><http://eurovoc.europa.eu/>

<sup>3</sup><https://www.google.com/basepages/producttype/taxonomy.en-US.txt>

<sup>4</sup>[http://sites.nationalacademies.org/PGA/Resdoc/PGA\\_044522](http://sites.nationalacademies.org/PGA/Resdoc/PGA_044522)

more difficult as we were not allowed to use any of the widely used resources like WordNet, EuroVoc, Google Product Taxonomy etc. Building a taxonomy which would provide structured information about semantic relations between words is an extremely slow and labor-intensive process. Therefore, we kept our focus on building a system which would be simple and significantly light in terms of computation time.

**Figure 1:** Basic system diagram

Our system has two main modules, as shown in Figure 1:

- i. Extracting semantic relations from BabelNet.
- ii. Analyzing the terms to find a subterm suitable to become a hypernym.

#### 4.1 BabelNet Based Module

BabelNet<sup>5</sup> is an open source resource containing both multilingual dictionary with lexicographic and encyclopedic coverage of terms, and a network of concepts and named entities connected in a very large network of semantic relations, called Babel synsets (Navigli and Ponzetto, 2012). Each of the Babel synsets represents a given meaning and contains all the synonyms which express that meaning in a range of different languages. BabelNet 3.5 covers 272 languages, which also include our task related languages like English, French, Dutch and Italian.

<sup>5</sup><http://babelnet.org/>

Finding out semantic relations from the entire Wikipedia dump with a pattern based approach proved to be quite a long process and computationally expensive as there can be numerous types of valid patterns that can hold a hypernym-hyponym relation. On the other hand, it would take days to initially start with a few patterns and then search for more with a bootstrapping approach. On the other hand, BabelNet already provides a variety of semantic relations for a large number of concepts using knowledge from various resources available including Wikipedia. So, our system execution time gets significantly reduced if we just use the semantic relation set available in BabelNet instead of extending the Wikipedia corpus and analyzing it for the pattern search. Secondly, we wanted to have a system that would fit into the multilingual setup that the task intends to have this year. The facts were that we do not have a satisfactory amount of knowledge required for identifying the valid patterns for hypernym-hyponym relations in languages other than English, and we also do not have an annotated training data to learn those patterns via a bootstrapping method for those languages. Therefore, it was essential for us to have a tool that could automatically extract such knowledge from corpus.

For each term that appears in each domain, we obtain a synset from the BabelNet for hypernym relations found over the Wikipedia articles in different languages. As the task organizers specifically asked not to use resources like WordNet, only the Wikipedia source is taken into account while obtaining hypernym relations, skipping the others like WordNet, VerbNet, Microsoft Terminology etc. This is done to make the system computationally light and reduce the huge time needed to process the Wikipedia articles searching for patterns. We consider the terms for their NOUN POS tag sense, with the language mentioned in the query. We only considered the NOUN POS tags because it was seen from our observation of term lists, that they contain terms which are mostly nouns. We get the synset for each term which contains a lot of noise such as repetitive sense words, out-of-domain senses, senses in different morphological form than the existing terms, etc. We fed the raw synset output to a cleansing module which would give us only the unique in-domain terms in their correct morphological form as

given in the term-list.

We further extended this module to find the synsets of the terms present in the cleansed output in order to obtain the entire hypernym tree for the given term which helps to increase the recall of our system.

#### 4.2 Subordinate-word Module

This module deals with finding appropriate parts of given terms that can possibly be the hypernym of the original term. For example, *Fruit Custard* is a type of *Custard*. Now these subordinate-words which are potential hypernyms can be of the following two types.

- The subordinate-word can itself be an independent term present in the term-list given. For example, if we have both the terms *Biochemistry* and *Chemistry* in the term-list, we can just analyze the term *Biochemistry* and identify *Chemistry* as its possible hypernym.

- There might be multiple terms for which no common part is an independent term but significant overlap exists among those, even more than once. In such cases we have introduced that overlapped part as our new term in the term-list. For example, we have *Chocolate Pudding* and *Vanilla Pudding* as two terms in our list but no entry for *Pudding*. Since we get overlapping in previous two terms with *Pudding*, we can consider *Pudding* as the possible hypernym of *Chocolate Pudding* and *Vanilla Pudding*.

However, the problem is that we were getting some noise in the input due to the stopwords present in the list. For example, University of PlaceA and University of PlaceB will have University and of as the subordinate-word hypernyms. Of cannot be a hypernym to some term. So we remove those subordinate-words which has only stopwords in them. Again, we had to deal with different morphological forms of the same word as hypernyms, for example science and sciences. For such instances, we checked if any one form is the part of our term list. If yes, we keep that form and remove others or we keep the lemmatized form otherwise.

### 5 Analysis of Results

Just as construction of suitable ontology from text, evaluation of an extracted ontology is not a simple

| Language | Precision | Recall | Fscore |
|----------|-----------|--------|--------|
| English  | 0.15      | 0.30   | 0.20   |
| Dutch    | 0.16      | 0.22   | 0.19   |
| French   | 0.17      | 0.25   | 0.20   |
| Italian  | 0.13      | 0.20   | 0.19   |

**Table 1:** Average Precision, Recall, Fscore for Gold standard evaluation across all domains.

task either. For this particular task, structural evaluation was done which includes the presence of cycles, the number of intermediate nodes compared to leaf nodes, and the number of over generic relations with the root node. The output relations were also evaluated against collected gold standards collected from WordNet and other well known, openly available taxonomies using evaluation measures like standard precision, recall and Fscore.

Table 1 shows the average result of our system with respect to the gold standard evaluation for each language taking an average over all the domains. We had our focus on generating a hypernym tree for each term by providing the hypernyms of a term as next input to the system. This resulted in better recall but the precision of our system showed a visible decline compared to the baseline system for all the languages.

Table 2 shows the structural evaluation of the output produced by our system for different domains in English and other languages. The structural measures used for the evaluation are as follows:

- V: number of distinct vertices;
- E: number of distinct edges;
- c.c.: number of connected components;
- i.i.: intermediate nodes =  $V - L$  where  $L$  is the set of leaves
- cycles: YES = the taxonomy contains cycles, NO = the taxonomy is a Directed Acyclic Graph (DAG)
- Cumulative Fowlkes and Mallows Measure (FM): cumulative measure of the similarity of two taxonomies.

As we can see, though we have cycles present in relations of English language, all other language-output is a DAG. We achieved better score in categorization due to high number of distinct vertices, edges and intermediate nodes obtained by our system.

| Measure               | English | Multilingual |
|-----------------------|---------|--------------|
| Cyclicity             | 3       | 0            |
| Structure (FM)        | 0.1498  | 0.0155       |
| Categorisation (i.i.) | 377     | 178.22       |
| Connectivity (c.c.)   | 53.17   | 34.89        |

**Table 2:** Structural Evaluation for English and other languages.

## 6 Conclusion and Future Scope

In this paper we have discussed in brief our approach to address the Taxonomy Extraction and Evaluation task of SemEval 2016. We have kept our focus mainly on keeping the computation time optimal and building a system suitable for multilingual setup. We took a completely unsupervised approach without directly considering a text corpora. Both of our modules need only the terms to be fed as input and generates possible hypernym candidate for each term in a short span of time compared to the huge amount of time and knowledge needed to manually craft the lexico-syntactic pattern/regular expressions in each domain and then analyzing the large corpora for possible matches. The results were good in terms of recall, but the precision score suffered due to our approach of generating as many possible in-domain hypernyms of a term as we can.

We can try to improve our system’s performance by making use of information available with Wikipedia dump other than the article texts such as infobox properties, redirect links, article titles, categories or other meta-information available. Also, provided a training set, we believe a bag-of-word model constructed within a specific context window can yield better overall results.

## Abstract

This paper presents our participation to the SemEval “Task 13: Taxonomy Extraction Evaluation (TExEval-2)” (Bordea et al., 2016). This year, we propose the combination of recent semantic vectors representation into a methodology for semisupervised and auto-supervised acquisition of lexical taxonomies from raw texts. In our proposal, first similarities between concepts are calculated using semantic vectors, then a pretopological space is defined from which a preliminary structure is constructed. Finally, a genetic algorithm is used to optimize two different functions, the quality of the added relationships in the taxonomy and the quality of the structure. Experiments show that our proposal has a competitive performance when compared with the other participants achieving the second position in the general rank.

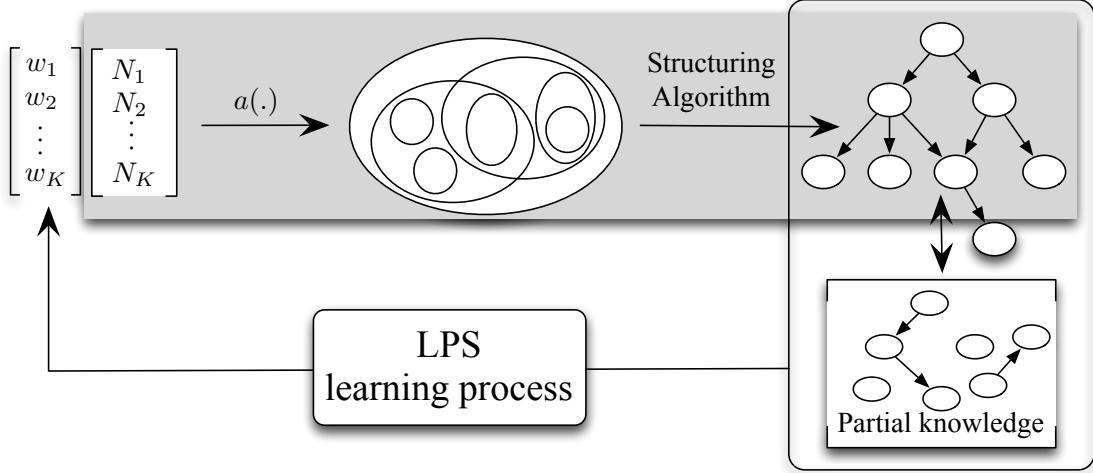

## 1 Introduction

The task of automatic taxonomy extraction consists in the generation of hierarchical relations between pairs of terms from a given initial set of terms. In this paper, we describe the second participation of QASSIT team to the “Taxonomy Extraction Evaluation (TExEval)” task. In this opportunity, we were interested in re-examining our proposed algorithm (Cleuziou and Dias, 2015)(Cleuziou et al., 2015), but with an improved range of information as input. Our algorithm is based on Pretopological Spaces combined with patterns and collocations counts. Patterns are a useful way to capture knowledge from huge corpus (Hearst, 1992), but its per-

formance could be influence by the size of the corpus or the use of a fixed vocabulary. This is a main drawback of the previous version of the algorithm (Cleuziou et al., 2015), the requirement of non-zero mentions in a corpus of the input terms in the specific chosen patterns. For example, to an optimal performance our algorithm requires that the term “computational biology” appears at least once in one of the used patters. However, when searching in wikipedia with the query “*computational biology* is a ...” then we obtain results such as “PLOS Computational Biology is a peer-reviewed computational biology journal”, “The Journal of Computational Biology is a monthly peer-reviewed scientific journal”, “Cancer computational biology is a field that aims to determine the future mutations in” and “Computational biology is a specialized domain that often requires knowledge of computer programming”<sup>1</sup>. The first three results include the desired term as a part of another more specific term (in this case journal titles) and only the last result could be considered as relevant information. Moreover, neither “domain” or “computer programming” are part of the input terms for the taxonomy. This situation makes difficult the direct use of patterns with our algorithm for the taxonomy construction task.

In order to overcome this difficulty, we have re-defined our algorithm to exclusively use as input information gathered from the corpus without the use of specific query patterns. Additionally, we have explored the integration of recent techniques in words representation known as semantic vectors (Mikolov

<sup>1</sup>Only journal titles are obtained when the pattern is replaced by “is an” .

**Figure 1:** The LPS process uses partial knowledge on the expected structure in order to improve the parameterization of the pretopological space.

et al., 2013). This technique allows us to calculate similarities of the input terms if they are present in a corpus, avoiding the requirement of explicit patterns of the previous versions. Additionally, these vectors allow semantic similarity calculation of concepts that are not found together, but that their context does. The remainder of this paper includes a brief description of our pretopological spaces algorithm and their modifications for the integration of semantic vectors (Section 2). Experiments and results are presented in Section 3 and finally, discussion and conclusions are presented in Sections 4 and 5 respectively.

## 2 Pretopological Spaces for Lexical Taxonomy Acquisition

We used the learning pretopological spaces framework (LPS) proposed in our previous participation in the TExEval task and fully described in (Cleuziou and Dias, 2015). The general LPS framework is illustrated in Figure 1, and a brief description is presented below. This algorithm considers as input a set of non-symmetric binary relations  $\{N_1, \dots, N_K\}$  over a set of terms  $E$  and a partial knowledge  $S$  used as true partial information to structure  $E$ ; *LPS* aims to find a *Space*  $w$  which induces a good subsumption propagation function  $a()$  for structuring  $E$ ; the fitness function that guides the learning process is

defined by:

$$Score(w, S) = F_{meas.}(w, S) \times I_{struct.}(w) \quad (1)$$

where  $F$  and  $I$  are two terms quantifying respectively the satisfactions about:

- the matching with the partial knowledge  $S$  and
- a taxonomy structural property expected as output (e.g. a tree-like structure).

The score defined in Equation 1 is used to guide the exploration of the space of solutions through a learning strategy based on a Genetic Algorithm (GA).

### 2.1 Sources used for LPS Taxonomy Acquisition

In our previous algorithm, we have used patterns and collocation measures as piece of information to model the subsumption propagation between terms. In this version, we abandon the use of patterns due the additional extra task it requires to avoid noisy information. However, we introduce another source of information with low manual requirements in order to have a more automatic version of our algorithm. The three main sources of information we use are described below.

First, we have integrated a new robust semantic representation called semantic vectors or word

**Table 1:** Comparative automatic evaluation of the proposed taxonomies.

| Dataset (Domain)      | Measure | Best          | QASSIT        | Rank |
|-----------------------|---------|---------------|---------------|------|
| Environment (Eurovoc) | Fscore  | <b>0.2992</b> | 0.1725        | 4/5  |
|                       | F&M     | 0.2384        | <b>0.4349</b> | 1/5  |
| Science               | Fscore  | <b>0.3669</b> | 0.2165        | 3/5  |
|                       | F&M     | 0.3634        | <b>0.5757</b> | 1/5  |
| Science (Eurovoc)     | Fscore  | <b>0.3118</b> | 0.2431        | 3/5  |
|                       | F&M     | <b>0.3893</b> | <b>0.3893</b> | 1/5  |
| Science (Wordnet)     | Fscore  | <b>0.3776</b> | 0.2384        | 4/5  |
|                       | F&M     | <b>0.2255</b> | <b>0.2255</b> | 1/5  |

embedding (Mikolov et al., 2013). These vectors are extracted using an unsupervised framework from large amounts of text information. The main characteristic of these vectors are their ability to encode semantic similarities in a rather small vector (300 dimensions) for each word or multi-word present in the corpus. In our experiments we have used a set of pre-trained vectors over an open domain collection<sup>2</sup>. We have searched by each corresponding term and assigned only one vector to it. If the term is a composed term and it is not found in the pre-trained set them the sum of vectors related to each word that compose the term is used. Following this strategy near to 95% of the terms have an assigned vector. Similarities between vectors are computed using the cosine similarity.

Second, we have extracted the collocation values between terms, to do so we have used the english subpart of wikipedia.org for frequency counts extraction. For each pair of terms ( $x, y$ ), we retrieve the number of wikipedia pages where both terms occur ( $\text{hits}(x, y)$ ). For example,  $\text{hits}(\text{memory}, \text{politics})$  is retrieved with the following query [“memory” AND “politics”].

Finally, the partial knowledge<sup>3</sup> has been obtained by first extracting a list of candidate subsumption pairs observing suffix matching and then by manually correcting the candidate list and/or adding new pairs of subsumptions with the aim to reach at least two hundreds subsumption relations into  $S$ .

Each of the three previous sources led to a couple of (non-symmetric) binary relations over the set of

terms  $E$ . Finally, sixteen binary relations are given as input of the LPS framework in order to learn a relevant pretopological space.

### 3 Experiments and results

Manual and automatic evaluation were performed using four datasets<sup>4</sup>. Further details could be found in (Bordea et al., 2016). The automatic evaluation is based on the comparison of the proposed taxonomy against the respective gold standard. Several automatic metric were used by the task organizers. However, we have focused on more robust metrics such as  $Fscore = 2(P * R)/(P + R)$  and  $F&M$ . Results for the best<sup>5</sup> participant (Best column) and ours (QASSIT column) are reported in Table 1. Similarly, manual quality evaluation is performed over a random selection of hundred ISA relationships found in the proposed taxonomies. Each of these hundred relationship is binary evaluated as relevant or not. The used metric is  $P_m = |\text{correctISA}|/100$  which calculates the accuracy of the taxonomies. Results for the best participant (Best column) and ours (QASSIT column) are presented in Table 2. In both tables the column *Rank* correspond to the obtained rank when compared with the other participants.

### 4 Discussion

In the general ranking our algorithm achieves the second position over the five participants in the Taxonomy Extraction Evaluation task; full results are

<sup>2</sup>Publicly available at <https://code.google.com/archive/p/word2vec/>.

<sup>3</sup>Note that this is an expensive manual task. In future version we plan to eliminate this stage.

<sup>4</sup>The task include six datasets, however we have participated only in four of them.

<sup>5</sup>Best from the results obtained by (Tan et al., 2016), (Pocostales, 2016), JUNLP and (Panchenko and Biemann, 2016).

**Table 2:** Comparative manual evaluation over 100 randomly selected candidates.

| Dataset (Domain)      | Best        | QASSIT      | Rank |
|-----------------------|-------------|-------------|------|
| Environment (Eurovoc) | <b>0.22</b> | 0.07        | 4/5  |
| Science               | <b>0.71</b> | 0.07        | 4/5  |
| Science (Eurovoc)     | 0.04        | <b>0.05</b> | 1/5  |
| Science (Wordnet)     | <b>0.47</b> | 0.22        | 2/5  |

included in (Bordea et al., 2016), but it can be partially observed in Table 1. Our results outperform other participants in terms of *F&M*, but fails to obtain a similar performance in terms of *Fscore*. Note that the average of the column rank is 2.25 indicating that if only these metrics where considered our position remains the same. Indeed, in the evaluation many others factor were evaluated such as: Cyclicity, Categorisation (i.i.), Connectivity (c.c.) and domains. Our results are also good in all them where we obtain first or second best performance, except for Categorisation (i.i.) where we are the least performing team. Indeed, this can be explained by our choice of these objective functions that are driven by the partial knowledge. Due to the cost required to generate this partial knowledge, the manual annotators tend to relate one concept to many concepts which force some flatness in our taxonomy. However, the  $I_{structure}$  objective criteria tends to force the acquisition of a hierarchical structure. In future experiments we plan to include additional objectives to avoid this situation.

In terms of manual evaluation, we obtain good results only for the *Science (Eurovoc)* dataset where our algorithm get the best performance. One explanation is the random selection of only hundred relationships to evaluate. Note that this sample is small compared with the actual number of terms in each dataset. However, only one of the participants manage to get good results in the manual evaluation. For the *Science dataset*, the ordered results of all participants are: 0.71, 0.14, 0.09, 0.07 and 0.06. Note that our performance, 0.07, is not very far from 3th and 5th position, but clearly far form the first one. This situation is quite similar for the *Environment (Eurovoc)* dataset, where the missing values of Table 2 are 0.02, 0.08 and 0.11. Note that, again, the best performance is clearly far from the other participants. A deeper analysis over the selection of the

sample for manual annotation or a full manual evaluation<sup>6</sup> must be performed to grasp a better understanding of these differences.

## 5 Conclusion

In this paper we presented the participation of the QASSIT team in the “Taxonomy Extraction Evaluation (TExEval-2)” task. Our strategy is based on a semi-supervised pretopological framework that learns a subsumption propagation process over a set of terms described by association measures and semantic vectors as input. Our results achieve the best performances in terms of *F&M* metric over the four datasets. In the general ranking, our algorithm achieved the second position. In terms of the manual evaluation, we obtained the first position for the Science (Eurovoc) dataset, second position for the Science (Wordnet) and fourth position for the remaining two datasets. Results encourage us to continue the exploration of strategies based on the theory of pretopoly and their combination with external resources. However, in future versions of our algorithm we plan to eliminate or automatize the partial knowledge extraction to have a fully automatic taxonomy construction framework.

## Abstract

We present a system for taxonomy construction that reached the first place in all sub-tasks of the SemEval 2016 challenge on Taxonomy Extraction Evaluation. Our simple yet effective approach harvests hypernyms with substring inclusion and Hearst-style lexico-syntactic patterns from domain-specific texts obtained via language model based focused crawling. Extracted taxonomies are evaluated on English, Dutch, French and Italian for three domains each (Food, Environment and Science). Evaluations against a gold standard and by human judgment show that our method outperforms more complex and knowledge-rich approaches on most domains and languages. Furthermore, to adapt the method to a new domain or language, only a small amount of manual labour is needed.

## 1 Introduction

In this paper, we describe TAXI – a taxonomy induction method first presented at the SemEval 2016 challenge on Taxonomy Extraction Evaluation (Bordea et al., 2016). We consider taxonomy induction as a process that should – as much as possible – be driven solely on the basis of raw text processing. While some labeled examples might be utilized to tune the extraction and induction process, we avoid relying on structured lexical resources such as WordNet (Miller, 1995) or BabelNet (Navigli and Ponzetto, 2010). We rather envision a situation where a taxonomy shall be induced in a new domain or a new language for which such resources do not

exist. In this paper, we demonstrate our methodology based on hyponym extraction from substrings and general-domain and domain-specific corpora for four languages and three domains.

## 2 Related Work

The extraction of taxonomic relationships from text is a long-standing challenge in ontology learning, see e.g. Biemann (2005) for a survey. The literature on hyponym extraction offers a high variability of methods, from simple lexical patterns (Hearst, 1992; Oakes, 2005), similar to those used in our method, to complex statistical techniques (Agirre et al., 2000; Ritter et al., 2009).

Snow et al. (2004) use sentences that contain two terms which are known to be hypernyms. They parse sentences and extract patterns from the parse trees. Finally, they train a hyponym classifier based on these features and applied to text corpora.

Yang and Callan (2009) presented a semi-supervised taxonomy induction framework that integrates co-occurrence, syntactic dependencies, lexical-syntactic patterns and other features to learn an ontology metric, calculated in terms of the semantic distance for each pair of terms in a taxonomy. Terms are incrementally clustered on the basis of their ontology metric scores.

Snow et al. (2006) perform incremental construction of taxonomies using a probabilistic model. They combine evidence from multiple supervised classifiers trained on large training datasets of hyponymy and co-hyponymy relations. The taxonomy learning task is defined as the problem of finding the taxonomy that maximizes the probability of individ-

ual relations extracted by the classifiers.

Kozareva and Hovy (2010) start from a set of root terms and use Hearst-like lexico-syntactic patterns to harvest hypernyms from the Web. The extracted hypernym relation graph is subsequently pruned.

Veraldi et al. (2013) proposed a graph-based algorithm to learn a taxonomy from textual definitions, extracted from a corpus and the Web. An optimal branching algorithm is used to induce a taxonomy.

Finally, Bordea et al. (2015) introduced the first shared task on Taxonomy Extraction Evaluation to provide a common ground for evaluation. Six systems participated in the competition. The top system in this challenge used features based on substrings and co-occurrence statistics (Grefenstette, 2015). Lefever et al. (2015) reached the second place gathered hypernyms from patterns, substrings and WordNet. Tan et al. (2015) used word embeddings, reaching the third place.

### 3 Taxonomy Induction Method

Our approach is characterized by scalability and simplicity, assuming that being able to process larger input data is more important than the sophisticated extraction inference. Our approach to taxonomy induction takes as input a set of domain terms and general-domain text corpora and outputs a taxonomy. It consists of four steps. Firstly, we crawl domain-specific corpora based on terminology of the target domain (see Section 3.1). These complement general-purpose corpora, like texts of Wikipedia articles. Secondly, candidate hypernyms are extracted based on substrings and lexico-syntactic patterns (see Section 3.2). Thirdly, the candidates are pruned so that each term has only a few most salient hypernyms (see Section 3.3). The last step performs optimization of the overall taxonomy structure removing cycles and linking disconnected components to the root (see Section 3.4).

#### 3.1 Corpora for Taxonomy Induction

To build domain-specific taxonomies we use both general and domain-specific corpora.

**General Domain Corpora.** We use three general purpose corpora in our approach presented in Table 1: Wikipedia, 59G and CommonCrawl<sup>1</sup>.

|                          | EN         | FR  | NL  | IT  |
|--------------------------|------------|-----|-----|-----|
| Wikipedia                | 11.0       | 3.2 | 1.4 | 3.0 |
| 59G                      | 59.2       | –   | –   | –   |
| CommonCrawl              | 168000.0 ‡ | –   | –   | –   |
| FocusedCrawl Food        | 22.8       | 7.9 | 3.4 | 3.6 |
| FocusedCrawl Environment | 23.9       | 8.9 | 2.0 | 7.1 |
| FocusedCrawl Science     | 8.8        | 5.4 | 6.6 | 5.1 |

**Table 1:** Corpora sizes used in our system in GB, where ‡ is the size of the crawl archive.

The second corpus is a concatenation of the English Wikipedia, Gigaword (Parker et al., 2009), ukWaC (Ferraresi et al., 2008) and a news corpora from the Leipzig Collection (Goldhahn et al., 2012).

**Domain-Specific Corpora.** Lefever (2015) showed the usefulness for taxonomy extraction of domain dependent corpora crawled from the Web using *BootCat* (Baroni and Bernardini, 2004). This method takes terms as input, which are randomly combined into sequences of a pre-defined length, and sent to a Web search engine. The search results, i.e. the returned URLs, compose a domain-dependent corpus. The number of input terms, the number of queries and the amount of desired URLs impact the size of the corpus. With 1,000 web queries and 10 URLs per query, the expected size of the resulting corpus is around 300 MB. While Lefever (2015) shows that such small in-domain corpora can be already useful for taxonomy extraction, we assumed that better results can be obtained if bigger domain-specific corpora are used.

We therefore follow a different approach based on *focused crawling*, where *BootCat* is used only for initialization of seed URLs. We use the provided taxonomy terms as input for the *BootCat* method, generate 1,000 random triples, and use the retrieved URLs as a starting point for further crawling. Focused crawling is an extension to standard web crawling where URLs, expected to point to relevant web documents, are prioritized for download (Chakrabarti et al., 1999).

Remus and Biemann (2016) introduced a focused crawling approach based on language modeling. The idea is that relevant web documents refer to other relevant web documents, where the relevance of a web document is computed by considering a statistical n-gram language model of a small, initially provided, domain-defining corpus. We provide a domain-defining corpus for each category by

<sup>1</sup><https://commoncrawl.org>

using Wikipedia articles, that are directly contained in the matching Wikipedia category. For example, for the the Food domain we used the Wikipedia articles of *Category:Foods* to build a language model of the Food domain. The language models for each domain were created using the 5-gram with the Kneser-Ney (1995) smoothing.

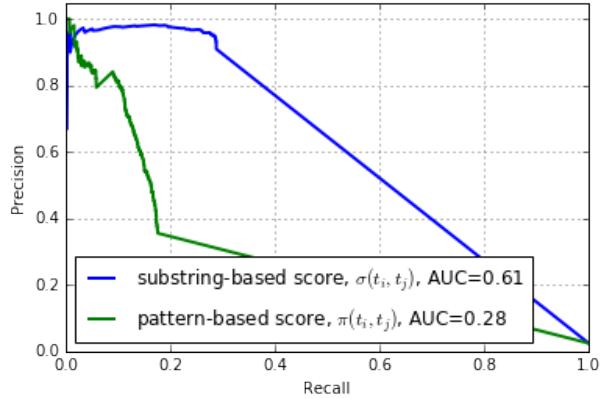

Using this technique, we are able to iteratively follow promising URLs and download web pages until a specified stopping criterion (no more pages with desired perplexity or timeout). Each domain and language was crawled for about one week on a single server machine with 24 cores and 32GB RAM, and harvested between 130 and 800 GB raw content, which results in 2 to 23 GB of unique plain-text sentences (c.f. Table 1). Note, that these sentences might contain cross-domain content.

### 3.2 Candidate Hyponyms via Substrings

A simple yet precise method for hyponym extraction is based on substring matching, c.f. the baseline system in Table 3 and (Lefever, 2015). For instance, “biomedical science” is a “science”, “microbiology” is a “biology” and so on. We calculate the following substring-based hyponymy score  $\sigma(t_i, t_j)$  between a pair of candidate terms  $t_i, t_j$ :

$$\sigma(t_i, t_j) = \begin{cases} \frac{\text{length}(t_j)}{\text{length}(t_i)} & \text{if } m(t_i, t_j) \wedge \neg m(t_j, t_i) \\ 0 & \text{otherwise} \end{cases}$$

Here  $m(t_i, t_j)$  is a function that returns true in case of a match of the term  $t_i$  inside the term  $t_j$ . Such match happens if  $\text{length}(t_i)$  is greater than 3. For English and Dutch, the hyponym  $t_i$  should match in the end of hyponym  $t_j$ , e.g. “natural science” is a “science”. For French and Italian a match of hyponym should be in the beginning of hyponym e.g. “algèbre linéaire” is a “algèbre”, not “linéaire”. The same holds for English and Dutch if a hyponym contains a preposition e.g.: “toast with bacon” is a “toast”, not “bacon” or “brood van gekiemd graan” is “brood”, not “graan”. Finally, if no match is found, we lemmatize terms  $t_i$  and  $t_j$  and retry matching. The precision-recall curve of the substring score calculated on the trial dataset is presented in Figure 1. As one can observe, precision of the substring score is constantly high, reaching 0.91 at the recall level of 0.29 with AUC of 0.61. There-

**Figure 1:** Precision-Recall plots of substring-based and pattern-based features of the TAXI approach measured on the trial dataset.

fore, this score is able to retrieve a significant number of high-quality hyponyms. Yet, only hyponyms of compound words can be retrieved via substrings.

### 3.3 Candidate Hyponyms via Patterns

To extract candidate hyponym relations from texts we used three systems listed below. All of them rely on lexico-syntactic patterns in the fashion of (Hearst, 1992; Klaussner and Zheko, 2011). We used several systems to filter noise via complementary signals. Besides, not all the systems support all the four languages of the SemEval task. Porting of Hearst patterns to a new European language is a straightforward and relatively quick procedure. Yet, due to a dense SemEval schedule, we decided to implement new rules only for two languages not supported by any available system, namely Italian and Dutch and reuse extraction rules for other languages.

**PattaMaika.** This system was used to process English, Italian and Dutch corpora. It implements patterns using UIMA Ruta (Kluegl et al., 2014). First, part-of-speech information is used to assign noun phrase (NP) chunk annotations to nominal phrases. Next, we use patterns to identify hyponym relations between NP chunks. We adapted the 9 English rules to the target languages, resulting in 9 patterns for Italian and 8 patterns for Dutch.

**PatternSim.** This system was used to process English and French corpora. It encodes patterns in the form of finite state transducers implemented

with the Unitex corpus processor.<sup>2</sup> PatternSim relies on 10 English patterns yielding average precision of top 5 extracted semantic relations per word of 0.69 (Panchenko et al., 2012). For French, 9 hypernym extraction patterns are used providing precision at top 5 of 0.63 (Panchenko et al., 2013).

**WebISA.** In addition to *PattaMaika* and *PatternSim*, we used a publicly available database of English hypernym relations extracted from the CommonCrawl corpus (Seitner et al., 2016). We used 108 million hypernym relations with frequency above one. This collection of relations was harvested using a regexp-based implementation of 59 patterns collected from the literature.

**Combination of hypernyms.** Result of the extraction are 18 collections of hypernym relations listed in Table 2. Even the huge *WebISA* collection extracted from tens of terabytes of text does not provide hypernyms for all rare taxonomic terms, such as “ground and whole bean coffee” and “black sesame rice cake”. On the other hand, most of the collections contain many noisy relations. For instance, frequent relations for hypernyms often go in both directions, e.g. “history” is a “science”, but also “science” is a “history”. Therefore, we introduced an asymmetric pattern-based hypernymy score  $\pi(t_i, t_j)$  between terms  $t_i$  and  $t_j$ . It combines information from different hypernym collections to filter noisy extractions. To compute the score, first we normalize extraction counts on the per word basis:  $\pi^k(t_i, t_j) = \frac{freq^k(t_i, t_j)}{\max_j freq^k(t_i, t_j)}$ , where  $freq^k(t_i, t_j)$  is the number of relations extracted between terms  $t_i$  and  $t_j$  by the  $k$ -th extractor. These normalized scores are averaged across all extractors per language-domain pair:  $\bar{\pi}(t_i, t_j) = \frac{1}{|LD|} \sum_{k \in LD} \pi^k(t_i, t_j)$ , where  $LD$  is a set of hypernym collections relevant for a given language-domain pair. For instance, for the language-domain pair ”English-Food”, the  $LD$  contains four collections: general relations extracted by *PatternSim*, *PattaMaika* and *WebISA* plus domain-specific relations extracted by *PatternSim* (see Table 2). Finally, to get the pattern-based score, we subtract averaged scores of two terms in both directions:  $\pi(t_i, t_j) = \bar{\pi}(t_i, t_j) - \bar{\pi}(t_j, t_i)$ . This way, we downrank symmetrical relations like synonyms and co-hyponyms.

<sup>2</sup><http://www-igm.univ-mlv.fr/~unitex>

|             | EN ‡, †, §          | FR‡ | NL†  | IT†  |
|-------------|---------------------|-----|------|------|
| General     | 27.6‡, 4.9†, 118.9§ | 3.2 | 2.22 | 0.13 |
| Food        | 24.1‡               | 3.8 | 0.47 | 0.05 |
| Environment | 26.3‡               | 4.5 | 0.32 | 0.95 |
| Science     | 9.3‡                | 2.7 | 0.97 | 0.05 |

**Table 2:** Number of hypernyms in millions of relations. Systems used to extract respective hypernym collections are denoted with ‡ for *PatternSim*, † for *PattaMaika* and § for *WebISA*.

The precision-recall curve of the pattern-based score on the trial data is presented in Figure 1. This plot is calculated on general corpora as we did not crawl domain specific corpora for the trial dataset domains. As one can see, precision of 0.80 is achieved at recall of 0.15 or less and drops to 0.36 at recall of 0.19. AUC of 0.28 of is less than half of the substring-based score of 0.61. Thus, patterns are a less reliable source of hypernyms than the substrings. Yet, they can capture relations between words with different spelling like “apple” and “fruit”, while the substring-based score need a character overlap, like in “grapefruit” and “fruit”.

### 3.4 Pruning of Hypernyms

Patterns and substrings together yield up to several hundreds of hypernym candidates per term. This step prunes hypernym candidates, ranking them with an unsupervised and supervised combinations of the  $\sigma(t_i, t_j)$  and  $\pi(t_i, t_j)$  scores.

**Unsupervised Pruning.** In this pruning strategy, used for French, Dutch and Italian languages, a term  $t_i$  is a hypernym of term  $t_j$  if their substring score  $\sigma(t_i, t_j)$  is greater than zero or if rank of the term  $t_i$  according to the pattern-based score  $\pi(t_i, t_j)$  equals to one or two. Thus a term  $t_i$  obtains all hypernyms extracted by substrings and up to two hypernyms extracted by patterns.

**Supervised Pruning.** This pruning strategy used for English relies on a supervised classifier trained on the trial dataset (Bordea et al., 2016).<sup>3</sup> This pruning approach uses 3,249 hypernymy relations from the trial taxonomies as positive training samples, e.g. hypernym relation (“biology”, “science”) and 128,183 automatically generated relations as negatives samples coming from two sources: 3,249 in-

<sup>3</sup>We did not submit to SemEval both supervised and unsupervised versions of the system for English as only one run was allowed per language-domain pair.

verted hypernyms, such as (“science”, “biology”) plus 124,934 co-hyponyms from the trial taxonomy, for instance (“biology”, “mathematics”).

The classifier used in the competition had two features that characterize a word pair  $(t_i, t_j)$ , namely substring-, and pattern-based scores  $\sigma(t_i, t_j)$  and  $\pi(t_i, t_j)$ . Note, that the same features were used in the unsupervised approach. We applied an SVM classifier with RBF kernel (Vert et al., 2004), tuning kernel meta-parameters within an internal loop cross-validation procedure.

We tested multiple alternative configurations with extra features, including term frequency, out/in degree of terms in the hypernym graph, term length, expansions of hypernyms based on term clustering and shortest paths in the graph of candidate hypernyms as well as other classifiers including Logistic Regression, Gradient Boosted Trees, and Random Forest. However, none of the above mentioned configurations yielded consistently better results on the trial data than the two feature-based SVM.

To identify hypernyms among a set of terms  $T$ , we classify using a model trained on the trial data all possible word pairs except identical ones:  $\{(t_i, t_j) : i \neq j; (t_i, t_j) \in T \times T\}$ . The pairs classified using the positive class are added to the taxonomy.

### 3.5 Taxonomy Construction

At this point of the taxonomy construction, we obtained a noisy graph, which may contain cycles and disconnected components. To remove cycles and to obtain a directed acyclic graph taxonomy we used the unsupervised graph pruning approach of Faralli et al. (2015), which searches for a cycle  $C$  using topological sorting of Tarjan (1972) and then removes a random edge of  $C$  until no cycles are detected in the graph.

Besides, to improve connectivity of the taxonomy we connect all the nodes of each disconnected component with zero out degree to the taxonomy root.

## 4 Evaluation

To assess quality of the taxonomies several complementary measures were used. The first type of measurements are structural measures, such as the number of connected components (c.c.), the number of intermediate nodes (i.i.), i.e. the number of

nodes with out degree equal to zero, and the presence of cycles. Second, system outputs were compared against the corresponding domain gold standards and performances are evaluated in terms of F-score. Here precision and recall are based on the number of edges in common with the gold standard taxonomy over the number of system edges and over the number of gold standard edges respectively. To better compare against gold standard taxonomies the task included the evaluation of a cumulative measure (Velardi et al., 2013), namely Cumulative Fowlkes & Mallows Measure (F&M), where the similarity between the system and the reference taxonomies are measured as the combination of the hierarchical cluster similarities. Finally, the organizers performed manual quality assessment to estimate the precision of the hypernyms. To compute this measure, annotators labeled a sample of 100 hypernym relations as correct or wrong. The taxonomy extraction was evaluated on four languages, namely English, Dutch, French and Italian, and three different domains (Food, Science and Environment). A detailed description of the evaluation settings and metrics can be found in (Bordea et al., 2016).

## 5 Results

Table 3 presents a summary of evaluation of our method on the SemEval 2016 Task 13 dataset. Overall 5 systems participated in the challenge: JUNLP, TAXI, NUIG-UNLP, USAAR and QASITT. We represent the respective best scores across our four competitors in the *BestComp* column.

**Gold Standard Comparison.** The organizer-provided *Baseline* system implemented a string inclusion approach that covers relations between compound terms. A similar mechanism was used by the USAAR system (Tan et al., 2016), which improved over the baseline in terms of precision at the cost of recall. USAAR achieved the highest precision scores for English, as they used substring-based methods that yield high precision (c.f. Figure 1). Yet substrings cannot retrieve hypernyms of non-compound terms.

The main mechanisms we added in TAXI with regard to the substring-based methods are statistics over pattern-based extractions over large domain specific corpora and our taxonomy construction step

**Table 3:** Overall scores obtained by averaging the results over domains (Environment, Science, Food) and languages (NL, FR, IT) for the multilingual setting. The *BestComp* lists the respective best scores across four our competitors. The best scores excluding the baseline are set in boldface. Definitions of the measures are available in Section 4.

that improves structure of the resource. These united mechanisms are not used in other submissions to the challenge. The NUIG-UNLP team (Pocostales, 2016) relies on vector directionality in dense word embedding spaces. Such approximation of patterns based on distributional similarity provided good recall, but attained low precision.

The QASSIT team (Cleuziou and Moreno, 2016), who ranked second in the competition, uses patterns to extract hypernym candidates, but they rely solely on the Wikipedia. Subsequently, an optimization technique based on genetic algorithms is used to learn the parametrization of a so-called pre-topological space, which leads to desired structural properties of the resulting taxonomy. While we use simpler optimization procedure based on supervised learning, TAXI outperforms QASSIT in terms of comparisons with the gold standard. Possible reasons why our method performs better are (1) QAS-SIT use no substring features, (2) this team relies on smaller general-purpose corpora, while we use larger domain-specific corpora.

Finally, JUNLP relies on substrings and relations extracted from BabelNet. We find the latter to be undesirable for taxonomy extraction. Indeed, a rich lexical resource, such as BabelNet can be considered as a taxonomy in itself. Interestingly, even with the BabelNet-based features the system did not always reach the top precision and recall.

**Manual Evaluation.** Our system was ranked first in terms of manual judgments for the Dutch, Italian and French reaching the average precision across languages and domains of 0.625. Precision for different language-domain pairs ranged from 0.90 for the Italian-Science pair to 0.23 for the French-Environment pair. For English, our system was ranked second with the average score of 0.20, while

the substring-based USAAR system obtained the score of 0.49 and the third-ranked system obtained the score of 0.09. We attribute lower precision in the English run to absence in the supervised ranking scheme of a limit on the number of extracted hypernyms per word.

Further detailed comparisons with other systems with breakdowns with regard to different languages, domains and evaluation schemes are presented by Bordea et al. (2016) and on SemEval website.<sup>4</sup>

**Discussion.** One shortcoming of our method is its coverage: for instance 774 terms of 1,555 of the English food domain are still not attached to any node, which is a typical issue with pattern-based approaches since not all taxonomic relationships are spelled out explicitly in corpora. To tackle this shortcoming, we plan to use hypernym expansion based on distributional semantics (Biemann and Riedl, 2013).

## 6 Conclusion

We presented a technique for taxonomy induction from a domain vocabulary. It extracts hypernyms from substrings and large domain-specific corpora bootstrapped from the input vocabulary. Multiple evaluations based on the SemEval taxonomy extraction datasets of four languages and three domains show state-of-the-art performance of our approach. An implementation of our method featuring all language resources, is available for download.<sup>5</sup>

# Duluth at SemEval–2016 Task 14 : Extending Gloss Overlaps to Enrich Semantic Taxonomies

Ted Pedersen

## Abstract

This paper describes the Duluth systems that participated in Task 14 of SemEval 2016, Semantic Taxonomy Enrichment. There were three related systems in the formal evaluation which are discussed here, along with numerous post-evaluation runs. All of these systems identified synonyms between WordNet and other dictionaries by measuring the gloss overlaps between them. These systems perform better than the random baseline and one post-evaluation variation was within a respectable margin of the median result attained by all participating systems.

## 1 Introduction

The goal of Task 14 in SemEval–2016 was to enrich a semantic taxonomy with new word senses. In particular, this task sought to augment WordNet<sup>1</sup> with senses that are present in another dictionary. Task 14 drew glosses of words not found in WordNet from a variety of sources that will collectively be referred to as OtherDict in this paper.

The method the Duluth systems took was based on scoring overlaps between WordNet and OtherDict glosses. A OtherDict sense was assigned to the WordNet sense with the highest overlapping score. Overlaps are defined to be exact matches between words and phrases in the glosses. Each overlap is assigned a score that is the square of the number of words in the overlap, and then all the overlaps between a pair of glosses is summed to provide the final score.

<sup>1</sup><http://wordnet.princeton.edu>

The premise of relying on overlaps is that senses that are defined using many of the same words are certainly related, and indeed if they are defined using the same words they are likely synonyms. This is a well established and reliable intuition that goes back at least to (Lesk, 1986). Closely related words that may not be synonyms (such as hyponyms or hypernyms) will use many of the same words in their definitions, but then have specific differentia that distinguishes among them.

Task 14 asked participants to distinguish between merging a OtherDict sense into an existing WordNet synset (i.e, a synonym) or attaching it as a hyponym (i.e., a more specific example) of a WordNet sense. However, our systems only merge OtherDict senses into WordNet synsets. It seems clear though that this merge versus attach problem can be tackled by setting some kind of threshold for the amount of overlap, where more significant degrees of overlap should result in a synonym merge whereas less overlap could indicate a hyponym attach. As yet we have not been successful in determining a reliable method for finding such a threshold. As a result we simply assumed every OtherDict sense would attach to its closest (most overlapping) WordNet sense.

Each Duluth system carried out the same pre-processing on both the WordNet and OtherDict glosses. In addition, the WordNet glosses were extended using additional information from WordNet such as the glosses of its hypernyms, hyponyms, derived forms, and meronyms. This follows naturally from the structure of WordNet and the intuitions that underlie the Extended Gloss Overlap measure (Banerjee and Pedersen, 2003b), which is

implemented in WordNet::Similarity (Pedersen et al., 2004) and UMLS::Similarity (McInnes et al., 2009). Unfortunately there was not time to expand the OtherDict glosses in similar ways, although this is at least a possibility since some other dictionaries (such as Wiktionary) provide hyponyms and hypernyms, among other relations.

Task 14 allowed two kinds of systems to participate : *resource-aware* that only used dictionary content, and *constrained* that used other resources beyond dictionaries. The Duluth systems are considered resource-aware since they only use information from WordNet and OtherDict.

## 2 Systems

All the Duluth systems start by pre-processing both WordNet and OtherDict glosses. This consists of removing any character that is not alphanumeric, and then converting all remaining characters to lower case. Compounds known to WordNet are identified in the WordNet glosses, but not as it turns out in the OtherDict glosses. This very likely reduced the number of overlaps we found since a WordNet compound such as *light-year* will not match *light year*, which is the form that would occur in OtherDict.

In the following sections we describe the Duluth systems. Since the only distinction between them is how they reconstruct WordNet glosses we will provide a running example to illustrate each system. We will use the noun *feline#n#1* for this purpose. The original WordNet entry for this sense (prior to pre-processing) is shown here :

- *feline#n#1* – (any of various lithe-bodied roundheaded fissiped mammals, many with retractile claws)
- *hypernym* : *carnivore* – (a terrestrial or aquatic flesh-eating mammal; “terrestrial carnivores have four or five clawed digits on each limb”)
- *hyponym1* : *cat, true cat* – (feline mammal usually having thick soft fur and no ability to roar: domestic cats; wildcats)
- *hyponym2* : *big cat, cat* – (any of several large cats typically able to roar and living in the wild)
- *meronym* : *feline* – (a clawed foot of an animal especially a quadruped)

- *derived* : *feline#a#1* – (of or relating to cats; “feline fur”)

The Duluth systems build upon each other to some extent, so they are presented in an order that more easily illustrates those connections rather than their numeric order (which has no particular significance).

### 2.1 Duluth2

Duluth2 is the most basic of the Duluth systems. Each WordNet sense is represented by its gloss where all stop words and single character words have been removed. The stoplist comes from the Ngram Statistics Package (Banerjee and Pedersen, 2003a) and includes 392 words<sup>2</sup>.

To continue our example, the first noun sense of *feline* is represented by Duluth2 as shown below - it has simply gone through pre-processing and then had stop words removed.

- *feline#n#1* : lithe bodied roundheaded fissiped mammals retractile claws

This system represents a baseline for the overlap measures, since we are comparing the original WordNet and OtherDict glosses after having done minimal pre-processing.

### 2.2 Duluth1

Duluth1 is a natural extension of Duluth2, where each WordNet gloss is expanded by concatenating to it (in the following order) : the glosses of the hypernyms of the sense<sup>3</sup>, the glosses of all the hyponyms of the sense, the glosses of any derived form of the sense, and the glosses of all the meronyms of the sense. This significantly expands the size of each WordNet gloss, to the point where our initial attempts to simply use these extended glosses in matching took too much time to finish during the available window of time for the evaluation. We were also concerned about the significant disparities in size among WordNet glosses, and of course with the unexpanded OtherDict glosses.

---

<sup>2</sup><http://cpansearch.perl.org/src/TPEDERSE/Text-NSP-1.31/bin/utils/stoplist-nsp.regex>

<sup>3</sup>In general each sense has only one hypernym, although this is not always true in WordNet.

As a result we decided to shorten the WordNet glosses in Duluth1 by removing any word that is made up of four characters or less (rather than using a stoplist), and then only taking the first nine words in the expanded gloss. For many words this means that just the original gloss and the gloss of the hypernym and perhaps part of the gloss of a hyponym would be included. The OtherDict glosses were processed in a similar fashion, where any word with 4 or fewer characters was removed.

Our running example is shown below. Note that this is quite similar to Duluth2, except that *various* is included below (but was excluded in Duluth2 since it is in the stoplist), and that *terrestrial* is included (since it is the first word in the gloss of the hyponym).

- feline#n#1 : various lithe bodied roundheaded fissiped mammals retractile claws terrestrial

### 2.3 Duluth4

Note that Duluth4 was not included in our official evaluation. Rather this was run after the evaluation period, and it proved to be our most accurate result. Duluth4 is similar to Duluth1 in that it expands the WordNet glosses, but only does so with the glosses of its hypernyms and hyponyms (and does not include the derivational forms or meronyms, as Duluth1 does). Stop words are removed using the same list as Duluth2.

We can see in our running example that this provides a larger gloss, but it is not as large as what Duluth1 provided (before pruning it back to just the first nine words).

- feline#n#1 : lithe bodied roundheaded fissiped mammals retractile claws terrestrial aquatic flesh eating mammal terrestrial carnivores four five clawed digits limb feline mammal having thick soft fur ability roar domestic cats wild-cats several large cats typically able roar living wild

### 2.4 Duluth3

There are many minor variations between words in WordNet and OtherDict glosses, and it is difficult to normalize the glosses in order to eliminate them. Instead, we decided to have one system that relied

|            | Wu & Palmer | Lemma Match | Recall | F1    |
|------------|-------------|-------------|--------|-------|
| First Word | .5140       | .4150       | 1.00   | .6790 |
| Median     |             |             |        | .5900 |
| Duluth4(*) | .3810       | .0550       | 1.00   | .5518 |
| Duluth2    | .3471       | .0433       | 1.00   | .5153 |
| Duluth3    | .3452       | .0167       | 1.00   | .5132 |
| Duluth1    | .3312       | .0233       | 1.00   | .4976 |
| Random     | .2269       | .0000       | 1.00   | .3699 |

**Table 1:** Task 14 results, (\*) indicates post-evaluation run.

on character tri-grams, since that could allow for matches between portions of words, rather than requiring the exact matches that all the other Duluth systems insist upon.

Duluth3 expands each WordNet gloss with the gloss of its hypernyms and its hyponyms (like Duluth4, although stop words are not eliminated in Duluth3). Then all spaces are removed from each expanded gloss, and it is broken into three character ngrams. Glosses were limited to 250 of these tri-grams, mainly so that they could finish running in the available time during the evaluation.

If one studies the running example carefully you can reconstruct the gloss, which is similar to Duluth4 except that it includes stop words.

- feline#n#1 : any ofv ari ous lit heb odi edr oun dhe ade dfi ssi ped mam mal sma nyw ith ret rac til ecl aws ate rre str ial ora qua tic fle she ati ngm amm alt err est ria lca rni vor esh ave fou ror fiv ecl awe ddi git son eac hli mbf eli nem amm alu sua lly hav ing thi cks oft fur and noa bil ity tor oar dom est icc ats wil dca tsa nyo fse ver all arg eca tst ypi cal lya ble tor oar and liv ing int hew ild

## 3 Results and Discussion

Despite seemingly significant differences in how the WordNet glosses were expanded, Table 1 reveals that there were only minor differences in results among Duluth1, Duluth2, and Duluth3. This seems to support the conclusion that gloss overlaps provide a reliable and robust starting point for this problem. Indeed, the simplest of our approaches (Duluth2, which used WordNet glosses minus stop words) was slightly more effective than two more elaborate variations (Duluth1 and Duluth3). Recall that Duluth1

| gloss size | token count | Wu & Palmer | Lemma Match | F1     |
|------------|-------------|-------------|-------------|--------|
| 1          | 195,242     | 0.3033      | 0.0050      | 0.4654 |
| 5          | 973,463     | 0.3336      | 0.0183      | 0.5003 |
| 9          | 1,701,884   | 0.3312      | 0.0233      | 0.4976 |
| 10         | 1,866,198   | 0.3278      | 0.0200      | 0.4937 |
| 20         | 3,023,538   | 0.3296      | 0.0200      | 0.4958 |
| 30         | 3,575,586   | 0.3476      | 0.0300      | 0.5159 |
| 40         | 3,871,786   | 0.3471      | 0.0383      | 0.5153 |
| 50         | 4,059,495   | 0.3444      | 0.0400      | 0.5123 |
| 100        | 4,466,581   | 0.3511      | 0.0400      | 0.5197 |

**Table 2:** Duluth 1 post-evaluation variations.

normalized gloss lengths by taking only the first nine words in the expanded glosses, and that Duluth3 attempted a kind of poor man’s stemming by using character trigrams.

Duluth4 is an obvious extension of Duluth2, in that it expands glosses with their hypernym and hyponyms. This results in a modest but significant improvement on the systems submitted for the formal evaluation, and suggests that focusing on expanded gloss content in relatively straightforward ways can pay dividends. This system at least begins to approach the median score attained by the systems participating in the task. That said, even this result considerably lags the baseline First Word (Jurgens and Pilehvar, 2015) provided by the organizers.

Table 2 shows the results of additional experiments were carried out with Duluth1. Here the gloss sizes were varied from 1 to 100, where 9 is the value used during the formal evaluation. Note that the size of the OtherDict glosses was always 5,533 (tokens) and that the recall attained was always 1.00.

Table 2 shows that generally speaking increasing the number of words in the WordNet glosses results in a small but steady improvement in performance. However, it is important to keep in mind that as the WordNet glosses are growing, the OtherDict glosses are fixed at the same size. This seems to make it clear that the most important avenue moving forward is to expand the OtherDict glosses with additional content, comparable to that with which WordNet is expanded.

## 4 System Implementation Details

The Duluth systems are implemented using UMLS::Similarity, which provides measures of semantic relatedness and similarity for the Unified Medical Language System. In addition, it also allows a user supplied dictionary to be automatically included and utilized by the Lesk measure. Thus, the Duluth systems created dictionaries from OtherDict and WordNet suitable for use by the Lesk measure in UMLS::Similarity (via the `-dict` option). WordNet was accessed using the Perl module WordNet::QueryData<sup>4</sup>.

# TALN at SemEval-2016 Task 14: Semantic Taxonomy Enrichment Via Sense-Based Embeddings

**Luis Espinosa-Anke, Horacio Saggion and Francesco Ronzano**  
TALN - Department of Information and Communication Technologies  
Universitat Pompeu Fabra  
Carrer Tànger 122-134, 08018 Barcelona (Spain)  
`{luis.espinosa, horacio.saggion, francesco.ronzano}@upf.edu`

## Abstract

This paper describes the participation of the TALN team in SemEval-2016 Task 14: Semantic Taxonomy Enrichment. The purpose of the task is to find the best point of attachment in WordNet for a set of Out of Vocabulary (OOV) terms. These may come, to name a few, from domain specific glossaries, slang or typical jargon from Internet forums and chatrooms. Our contribution takes as input an OOV term, its part of speech and its associated definition, and generates a set of WordNet synset candidates derived from modelling the term’s definition as a sense embedding representation. We leverage a BabelNet-based vector space representation, which allows us to map the algorithm’s prediction to WordNet. Our approach is designed to be generic and fitting to any domain, without exploiting, for instance, HTML markup in source web pages. Our system performs above the median of all submitted systems, and rivals in performance a powerful baseline based on extracting the first word of the definition with the same part-of-speech as the OOV term.

## 1 Introduction

Semantic knowledge, expressed in terms of concepts and relations holding among them, is an essential enabling component of NLP applications (Jurgens and Pilehvar, 2015). One of the best known semantic repository is WordNet (Miller et al., 1990), a manually created semantic network with a coverage of over 200k English senses and 155k word forms. However, as knowledge domains advance and expand, novel terms beyond the coverage of Word-

Net are coined on a regular basis. Thus, the need for automatic approaches which are able to gather information from unstructured online sources and structure them is in high demand. In this context, WordNet has become the reference semantic network in previous attempts to formalize novel knowledge. The SemEval-2016 Task 14: Semantic Taxonomy Enrichment (Jurgens and Pilehvar, 2016) aims at providing an experimental ground on the task of, given an Out-of-Vocabulary (OOV) term, and an associated definition and part of speech, find the best point of attachment in WordNet (its most similar synset). This is a challenging problem because an OOV term may be defined without any explicit mention to its closest WordNet synset. For instance, for the OOV term (from training data) “lectionary”, the associated definition is “The book that contains all the readings from the Scriptures for use in the celebration of the liturgy”, and the best point of attachment is `sacred_text#n#01`. However, if one was to simply obtain the first head word of the definition and retrieve its first sense, the result would be `book#n#01`, with a score of 0.125/1 according to the official evaluation metric (see Section 4).

In this paper we describe our approach to such task. We base our method on the intuition that unseen terminology may be *understood* in terms of how terms are defined. Hence, we propose an algorithm which, for each definition, performs part-of-speech tagging and parsing, generates a set of noun and verb phrases, and then takes advantage of a vector space representation of word and phrase senses for modelling the definition. Our algorithm produces several WordNet attachment candidates as

the modelling takes place, e.g. by obtaining the definition’s centroid and mapping it to WordNet, or by parsing the OOV term and searching for a mapping between its head and WordNet. For this task, we submitted the three runs of our system with the highest scores on the training data. Moreover, the task organizers provided two baselines: One which selected a random WordNet synset, and one which extracted the first word in the definition with the same part-of-speech, and assigned it its first sense in WordNet (*BaselineFirst*). The experimental results suggest that the baseline was a very strong competitor, ranking way above the median of the participating systems. Our best run was 3 points below the baseline and 5 points above the median according to a metric designed to compute the distance between two nodes in a hierarchical cluster (see Section 4).

The rest of this paper is structured as follows: After presenting an overview of related work (Section 2), we describe in detail the methodology followed for our submission (Section 3), then we provide evaluation results as compared with baseline systems and the participants’ median score, along with a discussion of a few interesting cases. Finally, we outline directions of future work in a novel and exciting task, which opens a very interesting research problem to be tackled in the future.

## 2 Related Work

Expanding current semantic knowledge is a task that may be approached either by expanding WordNet with knowledge derived from structured or semi-structured repositories, or by learning hyponym-hypernym hierarchies separately in order to obtain novel knowledge. Within the former group, we find projects like BABELNET (Navigli and Ponzetto, 2012), a very large multilingual semantic network, or pairwise lexical resources alignments (Miller and Gurevych, 2014; Pilehvar and Navigli, 2014). These approaches, however, are not designed to capture novel terminology due to the fact that, for an alignment to occur, there must exist a direct correspondence between lemmas. This is addressed in projects belonging to the latter group, starting from (Snow et al., 2006), and following more recently with extraction of information from the web (Velardi et al., 2013; Luu Anh et al., 2014) or from BABELNET’s

glosses (Espinosa-Anke et al., 2016). These approaches, however, do not perform a direct mapping against WordNet, but rather separate taxonomies with their own hierarchical structure.

## 3 Method

Our approach to finding the best match in WordNet for an OOV term is based on transforming the associated textual definition into a representative vector. However, performing this action over plain text would introduce an ambiguity problem due to the occurrence of polysemic entities and specific lexical and syntactic formulations within the definition. Therefore, we leveraged SENSEMBED (Iacobacci et al., 2015), a state of the art vector space representation of word senses designed with BABELNET as a reference sense inventory. In SENSEMBED, each vector includes a concatenation of lemma and BABELNET synset. We exploit the mapping BABELNET → WordNet in order to find the best candidate for the given OOV term.

Let  $t$  be an OOV term, and  $d$  its associated definition, our sense-finding algorithm aims at extracting a suitable WordNet sense for  $t$ . To attain this goal, we perform a set of steps which generate a candidate set  $\mathcal{C}$ , which we will afterwards rank according to certain criteria. The different candidate rankings that we obtain constitute the three runs of our submission. Let us explain how each candidate is obtained.

### Candidate Retrieval

First, we parse both  $t$  and  $d$  using the parser described in (Bohnet, 2010). Note that  $t$  may be a multiword term including prepositional phrases (e.g. “margin of error”) and hence simply tagging and retrieving the last token would not suffice. We traverse the parse trees obtained in both cases in a depth-first-fashion until a lemma with a WordNet synset with the same part-of-speech as  $t$  is found. This generates two candidate WordNet synsets  $c_t^{wn}$ , and  $c_d^{wn}$ , which correspond to the first sense of the matching lemma. After completing this first step,  $\mathcal{C} = \{c_t^{wn}, c_d^{wn}\}$ .

The process of retrieving these candidates is inspired by the baseline *BaselineFirst* provided by the task organizers, which retrieved the first word in the definition with the same part-of-speech as the novel term. We evaluated a (non-submitted) *baseline* ver-

sion of our system, which only considers  $c_t^{wn}$  and  $c_d^{wn}$ . We obtained slightly worse performance than the organizers' baseline on both trial and training data, mostly due to parsing errors.

The second step of the algorithm aims at finding optimal candidate synsets for  $t$  by modeling  $d$  in terms of its vector representation. We proceed as follows. First, after stopword removal, we apply a shallow parsing technique over part-of-speech tags in order to isolate both single and multiword NPs and VPs. Specifically, we group all textual chunks that match the following regular expressions:

$$\text{NP} = <\text{JJ} \mid \text{NN}.\star>^+$$

$$\text{VP} = <\text{VB}.\star><\text{NP}>?$$

This step results in  $d_{ch}$ , the set of noun and verb phrases identified in a definition. We did not consider multiword expressions including a prepositional phrase, as these introduced a considerable amount of noise. For example, for  $d = \text{"Genetic drift is a mechanism of evolution"}$ ,  $d_{ch} = \{\text{genetic\_drift, drift, mechanism, evolution}\}$ . Then, for each  $ch \in d_{ch}$ , we obtain, where possible, all its available senses in SENSEMBED and store them in two separate sets. The first one, denoted as  $D_{Senses}$ , contains all senses extracted from all  $ch \in d_{ch}$  without distinguishing the original chunk from which they come from. It is simply a set of senses. The second set, denoted as  $D_{chSenses}$ , isolates all available senses corresponding to each chunk in an individual set, and thus constitutes a set of sets.

We use these two sets for obtaining (1) A *centroid sense*  $\mu$  over the definition's associated senses  $D_{Senses}$ , and (2) The set containing only the *best sense* for each chunk. For the former case,  $\mu(D_{Senses})$  is obtained as follows:

$$\mu = \frac{1}{|D_{Senses}|} \sum_{s \in D_{Senses}} \frac{s}{\|s\|} \quad (1)$$

As for the latter, *best sense* refers to the closest sense to  $\mu$  by cosine score obtained from the set of senses retrieved for each chunk, namely  $d_{chSen} \in D_{chSenses}$ , which is computed as follows:

$$\text{bestS}(d_{chSen}) = \operatorname{argmax}_{s \in d_{chSen}} \frac{s \cdot \mu}{\|s\| \|\mu\|} \quad (2)$$

The set of best senses per chunk is simply  $D_{bestS} = \{\text{bestS}(d_{chSen}), d_{chSen} \in D_{chSenses}\}$ , and will be used to generate the last candidate in our process.

At this stage, we obtain three more candidates to our candidate set, namely (1) The closest vector to the centroid from of all available senses in SENSEMBED,  $\mu^{wn}$ ; (2) The sense  $\text{bestS}(d_{chSen})$  appearing at the first position of the sentence, denoted as *firstBest*; and (3) The sense in  $D_{Senses}$  with highest cosine similarity with  $\mu$ , denoted as *highestBest*. In our sample sentence,  $\mu^{wn} = \text{branching\_ratio}_{bn}$ <sup>1</sup>,  $\text{firstBest} = \text{drift}_{syn}$ , and  $\text{highestBest} = \text{drift}_{syn}$ .

Finally, we introduce one last additional candidate to our candidate pool. We observed that  $\mu$  may not be an optimal centroid for the sentence as it is computed by considering all possible senses for each extracted chunk. For this reason, we take advantage of the fact that we have an available set of best senses for each chunk, namely  $D_{bestS}$ , and create a *sense-aware centroid*, denoted as  $\mu_{best}^{wn}$ . Finally,  $\mathcal{C} = \mathcal{C} \cup \{\mu^{wn}, \text{firstBest}, \text{highestBest}, \mu_{best}^{wn}\}$ .

## Ranking Candidates

Having obtained a set of candidate WordNet synsets  $\mathcal{C}$  for an OOV term  $t$ , we propose a ranking scheme aimed at providing three possible outcomes for our system. Note that we may not have all candidates available from all the previously described steps, as there may be BABELNET synsets without a direct WordNet mapping, definitions may be very short (even one word), or there may be no available candidate with the same part-of-speech as  $t$ 's head.

We submitted three runs of our system, which we describe as follows:

- **RunHeads** The baseline *BaselineFirst*, provided by the organizers, performed well, i.e. it found the exact correct attachment for almost half of the training instances. Based on this observation, in this submission we prioritized those cases in which there was a direct mapping between the first sense of the definition root and a WordNet synset ( $c_d$ ). If

---

<sup>1</sup>We denote with subscript *syn* those WordNet senses obtained via direct mapping from SENSEMBED, and with subscript *bn* those only found in BABELNET.

this was not the case, we searched for the mapping of  $t$ 's head ( $c_t$ ), as we found that in many cases, when  $t$  was a multiword expression, an optimal point of attachment could be found thanks to its head word. If none of these attempts were successful, we opted for selecting candidates in the following order:  $\mu_{best}^{wn}$ ,  $\mu^{wn}$ , *firstBest*, and *highestBest*.

- **RunSenses** This run first incorporated a voting scheme based on candidates in  $\mathcal{C}$  providing one same answer. If this was the case across three or more candidates, this was the synset selected by the system. However, if agreement across candidates was below three, priority was given to candidates coming from the definition modeling via SENSEMBED, and if no candidate was found, the system searched for mappings in  $c_d^{wn}$  and  $c_t^{wn}$ .
- **RunHyps** This run of our system was the most conservative approach. From all possible candidates extracted either via SENSEMBED, or from  $c_d$  and  $c_t$ , we computed the number of hyponyms each candidate had in the WordNet hierarchy. Then, our system selected as answer the most general synset, i.e. the one with the highest number of hyponyms. Our hypothesis was that by including the most generic terms possible (upper in the hierarchy) we would be less likely to incur in wrong senses of highly specific terms, where different senses may be placed more sparsely than in more generic ones.

## 4 Evaluation

Evaluation is performed over several criteria. First, the distance between the selected point of attachment and the gold standard is computed via the Wu & Palmer similarity (**W&P**) (Wu and Palmer, 1994). Second, a Recall measure (**R**), aimed at allowing systems to not provide an answer in doubtful cases, where the chances of an incorrect attachment would be high. It is simply computed as the percentage of items answered by the system. Finally, a score on *lemma match* (**LM**) is provided, in order to cover cases where the system identifies a correct lemma but selects the wrong sense of the lemma.

### 4.1 System Performance

We observe in the results shown in Table 1 that the three runs performed similarly, with only a few noticeable differences which we comment as follows. First, *RunHeads* and *RunSenses* seem to perform similarly. This may be due to the fact that in some cases no candidate was obtained from the sense-based modeling and hence the system resorted to direct matching from definition and term heads<sup>2</sup>. Another reason can be found in cases in which the definition is semantically very compact, i.e. all its extracted chunks belong to a similar semantic field and therefore the centroid vector we obtain is the same as the definition head, and also the first synset of the definition. This is the case, for instance, the term “complex disease”, with definition “A complex disease is caused by the interaction of multiple genes and environmental factors”. Here, the gold synset was *disease#n#01*, and this answer was provided by  $c_t$ , *firstBest*, and  $\mu_{best}$ .

Another interesting discussion can be derived from observing the difference between scores in **LM** by the first two systems, on one hand, and *RunHyps* on the other. While *RunHyps* ranks 2nd in our local rank, its **LM** score is more than 10 points below its closest competitor. This is due to the fact that, since *RunHyps* is a conservative approach more aimed at providing generic answers rather than matches, it shows a reasonable performance in terms of **W&P**, but falls short in **LM** as it almost never will find the correct point of attachment at the top of WordNet's hierarchy.

In terms of comparative evaluation, all our submitted systems rank below the baseline *Baseline-First*, which shows that a simpler approach based on majority class (selecting the first WordNet synset for a given lemma, which usually corresponds to the most generic or widespread sense) is difficult to beat. However, in comparison with the median of all participating systems, all our submissions achieve **F1** scores between 4 and 5 points higher.

---

<sup>2</sup>In general we were reasonably satisfied with the coverage of SENSEMBED, as with our approach, we found at least one candidate BABELNET synset with WordNet mapping in the vast majority of cases. For instance, our run *RunHeads* missed only two nouns and four verbs. In these cases we set a default point of attachment *entity#n#01* and *breathe#v#01* respectively.

| <b>Subm</b>          | <b>W&amp;P</b> | <b>LM</b> | <b>R</b> | <b>F1</b>    |
|----------------------|----------------|-----------|----------|--------------|
| <i>RunHeads</i>      | 0.476          | 0.36      | 1        | 0.645        |
| <i>RunSenses</i>     | 0.463          | 0.353     | 1        | 0.635        |
| <i>RunHyps</i>       | 0.471          | 0.24      | 1        | 0.641        |
| <i>BaselineFirst</i> | 0.513          | 0.415     | 1        | <b>0.678</b> |
| <i>Median</i>        | -              | -         | -        | 0.590        |

**Table 1:** Evaluation summary for our submission

## 5 Future Work

We computed an *upper bound* on the training data, i.e. the score we would have achieved if, for each case, we had selected the best of the candidates proposed by our system. This artificial upper bound reached a **W&P** score of almost 0.70, which suggests that our approach has clear and well defined room for improvement. We are currently investigating potential ways to address this issue in order to surpass the baseline scores.

## Abstract

Automatic enrichment of semantic taxonomies with novel data is a relatively unexplored task with potential benefits in a broad array of natural language processing problems. Task 14 of SemEval 2016 poses the challenge of designing systems for this task. In this paper, we describe and evaluate several machine learning systems constructed for our participation in the competition. We demonstrate an f1-score of 0.680 for our submitted systems — a small improvement over the 0.679 produced by the hard baseline.

## 1 Introduction

This article describes our systems submitted for SemEval2016, task 14 on taxonomy enrichment.<sup>1</sup> The two submitted runs are based on Gaussian-kernel SVMs, and fall respectively under the constrained and the unconstrained condition of the shared task, namely using only WordNet and the training data, or incorporating outside sources. We chose our submitted models by evaluation on the trial data in lieu of a development set. Our runs perform better than the very hard baseline with a small 2% margin, while the best-performing heuristic outperforms the baseline by a 5% margin.

## 2 Related Work

Existing methods for taxonomy enrichment can roughly be divided into two categories: relying on alignment between multiple taxonomies, or relying on machine learning-based rating of subgraphs.

In (Jurgens and Pilehvar, 2015), Wordnet is extended with technical terms and rare lemmas from Wiktionary. In (Suchanek et al., 2007), relation-extraction is used to unify WordNet and Wikipedia. (Navigli and Ponzetto, 2012) further automates the alignment process itself. In (Toral et al., 2008), named entities are brought from Wikipedia to WordNet through pattern matching.

In (Snow et al., 2006), the probabilities of taxonomies are evaluated based on evidence vectors associated to edges. A similar approach formulated in terms of factor graphs can be seen in (Bansal et al., 2013). Finally, (Yamada et al., 2011) employ a hybrid strategy, scoring edges by likelihood of appearance in Wikipedia. Our approach also falls in the second category, relying on a machine learning process to rank hypernym-hyponym edges.

## 3 Data

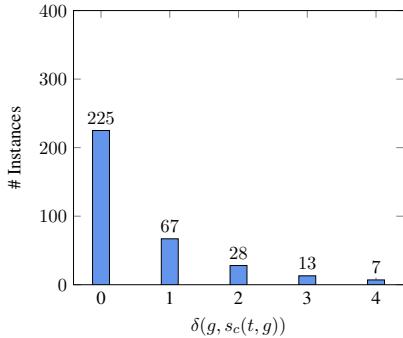

There are three data splits: *train*, *trial*, and *test*, described in Table 1. We use the trial data for model selection. Notice that attach-actions represent the vast majority of instances. We therefore focus exclusively on finding correct integrations and disregard the merge-attach distinction.

Several observations can be made from the distribution of the labels in the training set. First, we define the *closest* synset  $s_c(t, g)$  of a term  $t$  with gold standard  $g$  as the synset such that a lemma of that synset is represented in some description sentence  $d \in D(t)$  and the shortest path  $\delta(g, s_c(t, g))$  in the taxonomy is minimized. Here,  $D(t)$  is the set of description sentences corresponding to  $t$ . In Figure 1, we plot  $\delta(g, s_c(t, g))$  versus number of instances.

<sup>1</sup><http://alt.qcri.org/semeval2016/task14/>

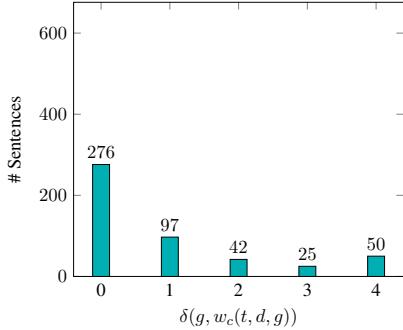

| Dataset | # Nouns | # Verbs | # Total | Sentences / instance | Tokens / sentence | # Attach | # Merge |
|---------|---------|---------|---------|----------------------|-------------------|----------|---------|
| Train   | 349     | 51      | 400     | 1.69                 | 17.73             | 367      | 33      |
| Trial   | 93      | 34      | 127     | 1.02                 | 12.18             | 71       | 56      |
| Test    | 512     | 82      | 600     | 1.21                 | 18.45             | 569      | 31      |

**Table 1:** Overview of the datasets, showing the composition of nouns and verbs, merge-action and attach-actions, and the mean number of description sentences per term and number of tokens per description sentence.

**Figure 1:** Number of instances in the training set such that  $\delta(g, s_c(t, g))$  corresponds respectively to 0, 1, 2, 3, and 4.

As is apparent from the Zipfian-like distribution,  $s_c$  constitutes an excellent guess for  $g$ . Defining  $w_c(t, d, g)$  for each  $d \in D(t)$  in similar fashion as the synset minimizing  $\delta(g, w_c(t, g))$ , an analogous observation can be made for each description sentence. The result can be seen in Figure 2 below:

**Figure 2:** Number of sentences in the training set such that  $\delta(g, w_c(t, d, g))$  corresponds respectively to 0, 1, 2, 3, and 4.

We again observe a Zipfian-like distribution, suggesting that each  $w_c(t, d, g)$  represents a good candidate for  $s_c(t, g)$ . As terms often have multiple description sentences, we therefore have for each term several good guesses for  $s_c(t, g)$  and therefore  $g$ . These observations form the basis of the strategies discussed in Section 5.2.

## 4 Features

Our systems use both lexical and syntactic features, with distributional features included in the second run. As a first step, we POS-tag and dependency parse the description sentences using the Mate parser in (Bohnet et al., 2013).<sup>2</sup> Additionally, we apply the unsupervised word sense disambiguation algorithm described in (Agirre and Soroa, 2009).<sup>3</sup>

### 4.1 Constrained Features

Description words are represented through features based on position, word shape, morphology, POS-tag, and dependency structure. Word senses are incorporated through the depths defined in (Devitt and Vogel, 2004). Morphological and shape features derived from the candidate term are also included, along with a binary feature representing the description word appearing in the target term.

For the direct classification strategies, we also use features derived from the candidate synset. These include POS-tag, overlap between synset- and term-description, and the length of the shortest path to the description. For the ranking systems, we also utilize pairwise features: the relative distance and position in the description sentence, the relative distance and position in the dependency tree, and the difference in number of overlapping lemmas between the description sentence and the most likely senses.

### 4.2 Embedding Features

We extend the features defined above with Skip-Gram embeddings as discussed in (Mikolov et al., 2013). We train the Gensim model (Řehůřek and Sojka, 2010) on a corpus consisting of the description sentences and the Wikipedia entries for each term, padded with the English part of the PolyGlot corpus presented in (Al-Rfou et al., 2013).

<sup>2</sup>Available at: <https://code.google.com/archive/p/mate-tools/wikis/ParserAndModels.wiki>.

<sup>3</sup>Available at: <http://ixa2.si.ehu.es/ukb/>.

Word-level features are extended with embeddings for the word itself and the dependency head. Term-level features are extended with the sum of the embedding vectors of each word in the n-gram. Synset-level features are extended with the mean of the embedding vectors for each lemma. Finally, all pairwise features are extended with cosine distances.

## 5 Experiments

In this section, we explain the strategies we attempted. In all cases, we discount the merge action, focusing only on attaching.

### 5.1 Direct Classification

For comparison, we first attempt direct classification: Given a term and a candidate synset, predict whether that synset is a correct integration for the term. Enrichment is done by ranking all synsets according to prediction probability. We tried a linear logistic regression classifier, and a non-linear neural network classifier with a single hidden layer containing 100 units.

### 5.2 Right Word Classifier

As shown in Section 3, one can narrow down the search space by a large margin through finding  $w_c(t, d, g)$ . We propose to determine  $w_c$  through a machine learning process. Then, we estimate  $s_c(t, g)$  by taking a majority vote over sentences. We experiment with four versions of the strategy.

We consider letting each sentence vote for the most likely sense of the best candidate for  $w_c(t, d, g)$  with a weight of 1. Secondly, we consider including votes for the second-best candidate and the second-most likely senses, weighted by hyperparameters  $\alpha$  and  $\beta$ . We determine the values for  $\alpha$  and  $\beta$  through cross-validation on the training set. We perform word sense disambiguation either through most frequent sense, or through Personalized Pagerank.

Ranking problems can be approached as pointwise regression, or as pairwise classification. Ranking by classification probability as discussed in the previous section corresponds to a pointwise regression with logistic loss. Following (Hang, 2011), transforming a pointwise problem into a pairwise problem can improve performance, especially when training data is scarce.

To transform the training set into a pairwise training set  $\mathcal{L}_{pairwise}$ , we combine for each description sentence  $d$  with content words of appropriate POS-tag  $W_{t,d}$  every pair  $(w_1, w_2) \in W_{t,d} \times W_{t,d}$  such that one equals  $w_c(t, d, g)$  and the other does not. If  $w_1$  is the match and  $w_2$  is not, we add  $(w_1, w_2)$  to  $\mathcal{L}_{pairwise}$  with the positive label. Else, we add  $(w_1, w_2)$  to  $\mathcal{L}_{pairwise}$  with the negative label. We train a classifier on this dataset, observing that a relation  $\prec_{t,d}$  is induced as positive and negative predictions on  $w_1$  and  $w_2$  correspond respectively to  $w_1 \succ_{t,d} w_2$  and  $w_1 \prec_{t,d} w_2$ .

We experiment with various classifiers and parameter settings through cross-validation. As  $(w_1, w_2) \in \mathcal{L}_{pairwise} \Leftrightarrow (w_2, w_1) \in \mathcal{L}_{pairwise}$ , the dataset is balanced and chance performs at an accuracy of 0.5. The best-performing classifier was the Gaussian kernel SVM, with an accuracy of 0.81.

Through this classification, we learn for each term  $t$  a relation  $\prec_{t,d}$  on the words  $w \in W_{t,d}$  of each description sentence  $d \in D(t)$ . This relation, however, is asymmetric and therefore does not constitute an ordering. We therefore define a new ordering  $\prec_{t,d}^*$  averaging over both directions of  $\prec_{t,d}$ :

$$p(w_1 \prec_{t,d}^* w_2) = \frac{p(w_1 \prec_{t,d} w_2) + p(w_2 \succ_{t,d} w_1))}{2}$$

We then let  $w_1 \prec_{t,d}^* w_2$  if and only if  $p(w_1 \prec_{t,d}^* w_2) > 0.5$ . As  $\prec_{t,d}^*$  is an ordering on the words of each description sentence, we let the largest element with respect to  $\prec_{t,d}^*$  be our guess for  $w_c$ .

## 6 Results

The results for each system can be seen in Table 2. We provide results on the training data, the test data, and the trial data which was used as a development set in the model selection process. Apart from the submitted runs, all systems have a perfect recall of 1.0. For the submitted runs, a software error caused recall to drop to 0.97 as description words containing underscores were incorrectly processed.

The best-performing system on the trial data under both conditions is the vote-based ranking without sense disambiguation, outperforming the *first word, first sense*-baseline by a small margin. Following this observation, we chose to submit the constrained and unconstrained variants of this system - marked in bold in Table 2.

| System                | Train |          | Trial |          | Test        |             |
|-----------------------|-------|----------|-------|----------|-------------|-------------|
|                       | F1    | Lemma M. | F1    | Lemma M. | F1          | Lemma M.    |
| Random                | 0.35  | 0.00     | 0.39  | 0.00     | 0.37        | 0.00        |
| First-word fist-sense | 0.64  | 0.33     | 0.66  | 0.25     | 0.68        | 0.42        |
| Logistic Regression   | 0.53  | 0.17     | 0.46  | 0.15     | 0.47        | 0.15        |
| NN-classification     | 0.53  | 0.18     | 0.46  | 0.14     | 0.50        | 0.17        |
| Rank-FS               | 0.69  | 0.43     | 0.66  | 0.28     | 0.68        | 0.42        |
| Rank-WSD              | 0.72  | 0.42     | 0.65  | 0.29     | 0.70        | 0.42        |
| Rank-vote-FS          | 0.70  | 0.42     | 0.67  | 0.27     | <b>0.67</b> | <b>0.43</b> |
| Rank-vote-WSD         | 0.72  | 0.43     | 0.66  | 0.27     | 0.70        | 0.41        |
| Rank-embed-FS         | 0.69  | 0.39     | 0.67  | 0.28     | 0.68        | 0.41        |
| Rank-embed-WSD        | 0.73  | 0.42     | 0.67  | 0.28     | 0.68        | 0.42        |
| Rank-embed-vote-FS    | 0.70  | 0.42     | 0.67  | 0.28     | <b>0.68</b> | <b>0.43</b> |
| Rank-embed-vote-WSD   | 0.73  | 0.42     | 0.67  | 0.28     | 0.69        | 0.41        |

**Table 2:** Performance reported as the f1 of Wu & Palmer-score and recall, along with Lemma Matches. Results are shown for the baselines, the direct classifiers, and the constrained and unconstrained versions of the ranking-based systems. The submitted runs are marked in bold. Recall is 1.00 for all systems except for the submitted runs, where a software error caused a recall of 0.97.

## 7 Discussion

Investigating the errors made by the voting-based first-sense systems, we see a pattern in which hyponyms of the correct integration mistakenly are chosen. Examples include *steroid* instead of *anabolic steroid*, *drug* instead of *opiate*, and *person* instead of *woman*. Although these errors occur under both conditions, they are slightly more frequent in the constrained system. In (Levy et al., 2015), evidence is presented that distributional embeddings mainly encode hierarchical *level* rather than hierarchical *branch*. Our findings seem to support this conclusion. Refining the usage of the embeddings may well resolve this particular source of error.

In Table 1, we see how the training dataset not only on the average has more description sentences per term, but also longer description sentences. As the Personalized Pagerank algorithm relies on a context created from these sets of tokens, this may be the source of the poor performance of sense disambiguation compared to most frequent sense on the trial data seen in Table 2.

Similarly, the voting component was observed to have almost no effect on the test and trial data, while improving the performance on the training data by a wide margin. When the number of description sentences is smaller, it follows naturally that the number of candidates for  $s_c$  drops, thus reducing the effectiveness of voting.

Examining the difference between the predictions made by our systems and the baseline, we notice that no terms exist where our prediction is equal to the gold standard, and the baseline is not. Rather, the improvement demonstrated by our systems comes in the form of wrongful guesses being closer to the gold than is the case for the baseline. This is further supported by the Zipfian observed in Section 3: our guesses mostly fall within a distance of 0–2 edges of the gold standard.

## 8 Conclusion

We have described several strategies for taxonomy enrichment, showing F1-scores of respectively 0.68 and 0.70 for the submitted and the best-performing systems. Our results show much better performance on the training data, even for the unsupervised sense disambiguation component. We have argued that the difference in number of description sentences and number of tokens per description sentence accounts partially for this difference, and therefore propose the gathering of additional evidence from outside sources to be added to the descriptions as the natural next step for future work. As our system demonstrates high performance for candidate generation and low performance for candidate selection, another possibility for future work would be to combine our approach with a filtering strategy in an ensemble or pipeline.

## Abstract

In this paper we describe the participation of the Joint Research Centre, EC, in task 14 - Semantic Taxonomy Enrichment at SemEval 2016. The algorithm which we propose transforms each candidate definition into a term vector, where each dimension represents a term and its value is calculated by TF.IDF. We attach the candidate term as a hyponym to the WordNet synset with the most similar definition. The results we obtained are encouraging, considering the simplicity of our approach. The obtained F measure is below the average, but above one of the baselines.

## 1 Introduction

In this paper we describe the participation of the Joint Research Centre, EC, in task 14 - Semantic Taxonomy Enrichment at SemEval 2016. We participate for the first time in a similar task. We opted for a relatively simple method for searching of relevant synsets, which does not exploit any external dictionary or another semantic resource. We called our system Deftor (DEFinition vecTOR). Deftor is a system which represents the definitions (glosses) as lexical vectors and finds the most similar one for each new lemma.

Automatic enrichment of taxonomies and knowledge bases is very important especially for rapidly changing domain. The taxonomy enrichment task is quite challenging, mostly because of the many possibilities when attaching a new term to an existing taxonomy: First, a new word can be attached as a hyponym to different concepts, which describe it at dif-

ferent levels of abstraction. For example, in WordNet the *hurricane* is a hyponym of *cyclone*, which is a hyponym of *windstorm*, which itself is a hyponym of *storm* and the *storm* is a hyponym of *atmospheric phenomenon*. It is not always easy to decide where to attach a concept: in the above mentioned case the definition of *storm* and *windstorm* are not very different. In this case, it is also difficult to decide if a new concept should be merged with a similar concept from WordNet or it should be attached as a hyponym. Another problem are the multiple aspects from which a concept can be perceived. For example, one can consider *hurricane* to be a *natural disaster*. It is also a *weather condition* or *cause of death*. All these considerations unfortunately make taxonomy enrichment task quite ambiguous and difficult to tackle. In some cases, the right attachment of a new concept will be difficult also for a human expert. Although the task is quite complicated, as we have pointed out, we applied a simple approach which is based on comparison of the lexical content of the definitions of the new concepts and the WordNet synsets.

Our approach to the taxonomy enrichment task represents each synset from WordNet and the candidate new terms as word vectors from their definitions and then attaches each new term as a hyponym to the synset for which the cosine similarity of its definition vector and the definition vector of the new term is the highest.

The algorithm which we propose transforms each candidate definition into a *definition vector*, a term vector, where each dimension represents a term and its weight is calculated by TF.IDF. In this way we

represent each WordNet definition, as well as the definitions of the new terms for inclusion in WordNet. Moreover, we expanded each definition vector with the definitions of the words from this vector.

We then calculated the cosine similarity between each WordNet synset definition and the definition of the candidate term whose place in the WordNet hierarchy is to be identified. Then, we attach the candidate term as a hyponym to the synset with the most similar definition.

Using this method we obtained results which are encouraging, considering the simplicity of our method - it relies solely on WordNet and no additional dictionaries or other resources were used. The results we obtained are somehow below the average, but above the weaker baseline.

## 2 Related Work

There are plenty of scientific papers, which address the taxonomy/ontology enrichment task and in particular the automatic enrichment of WordNet. See among the others (Haridy et al., 2010), (Navigli et al., 2004) and (Nimb et al., 2013). Existing work falls in one of the following categories: 1. Adding new semantic relations in an existing ontology (Montoyo et al., 2001). 2. Adding new senses for existing terms, e.g. (Nimb et al., 2013) 3. Adding new terms (Jurgens and Pilehvar, 2015). The new terms which are added may belong to already existing terminology (Stankovic et al., 2014), to a particular domain (e.g. biomedical (Poprat et al., 2008), medical (Smith and Fellbaum, 2004), or architectural (Bentivogli et al., 2004)), or they can belong to one well defined class like in (Toral and Monachini, 2008) who adds proper nouns to WordNet. The new terms may be taken from dictionaries or extracted from a corpus. In several cases the exploited resource is Wikipedia, like (Ruiz-Casado et al., 2005) and (Ponzetto and Navigli, 2009). Most of the work based on Wikipedia are limited mainly to the noun concepts; to overcome this limitation (Jurgens and Pilehvar, 2015) proposed to extend WordNet with novel lemmas from Wiktionary. For the WordNet enrichment task different resources have been exploited and different approaches have been experimented: distributional similarity techniques (Snow et al., 2006), structured based approaches

(Ruiz-Casado et al., 2005), creation of a new ontology and its merging with the existing one by alignment based methods (Pilehvar and Navigli, 2014) or considering the attributes distribution (Reisinger and Pașca, 2009).

The taxonomy enrichment task can be considered as a specific case of the ontology learning and population task, (Buitelaar and Cimiano, 2008), whose purpose is automatic learning of semantic classes and relations. Ontology population is about finding instances, which belong to certain ontological classes, like *Paris* is an instance of the class *city*.

## 3 Algorithm

As we pointed out earlier our method is based on similarity of *definition vectors*. In order to create a definition vector for a word sense, we perform part-of-speech tagging of its gloss and we represent each gloss as a list of lemmas of its non-stop words. Words are downcased. After that, as a second step, each definition vector is being expanded with the lemmas from the glosses of its words, obtained on the first step. For example, if the WordNet definition for *computer* is *a machine for performing calculations automatically*, then our algorithm creates a first version of the definition vector with the non-stop lemmas *machine*, *perform*, *calculation* and the TF.IDF values of these words. Then, the algorithm takes the glosses of all the WordNet senses of the words in the first version of the vector. In this particular case, we will add to the definition vector of *computer* the words from the glosses of all the senses of *machine*, *perform*, and *calculation*. Moreover, part-of-speech tags of these words are known, since we perform part of speech tagging of the glosses. As an additional step of pre-processing we extract the genus from the gloss - usually the first word which defines the more generic concept under which is the defined term

We have processed all the WordNet synsets, where each synset is represented as a definition vector. Then an inverted index was created for each definition vector, in which a word points to the definition vectors in which it appears. Then, for each new term  $t$ , we do the following

1. Find the definition vector  $d$  of  $t$ .

2. For each word  $w$  from  $d$  we find via the inverted index all the synsets whose definition vectors contain  $w$  and whose part-of-speech is the same as the one of  $t$ . Let's denote the set of definition vectors of these synsets as  $D$ .
3. We find the similarity of  $d$  and each vector  $d_i \in D$ . The similarity is being calculated as  $d.d_i.\cos(d, d_i)$ , this formula was empirically derived from the training data.
4. If the part of speech of  $t$  is verb, we add to the above-calculated similarity score the similarity of the glosses of the genus of  $t$  and the genus of the synset under consideration
5. The synset with highest similarity is taken and then the new term is attached as its hyponym. If the similarity of the best synset is found to be under a certain threshold, then we do not attach the new term and we skip it

## 4 Evaluation

The evaluation shows that our system can be improved significantly, but still results are encouraging considering the simplicity of our approach. The F1 of our only run was found to be 0.5132, which is below the baseline First word, first sense, but much above the baseline Random synset, which shows the feasibility of our approach.

It goes without saying that our results can be improved, nevertheless we propose an approach whose main advantage is its simplicity and it is independent of external resources. Our method is potentially multilingual and can be applied on taxonomies in languages other than English. Our system Deftor does not rely on any external knowledge and it uses only part-of-speech tagging and lemmatization as a pre-processing step. Since P.O.S. taggers and lemmatizers are available in different languages, we can easily adapt Deftor between languages and between domains, since the exploited algorithm does not depend on the taxonomy domain. Moreover, the simplicity of our approach make it quite efficient and easy to implement.

## Abstract

This paper presents a solution to Semeval 2016 Task 14 which asks for a system that is able to insert new lemmas into WordNet. Our system aims to do this by overlapping words in the definitions of the to-be-inserted lemma and all senses in WordNet. This paper includes the results of our system and also includes the baseline provided by Task 14, with our system scoring higher than the random baseline, and lower than the first word baseline.

## 1 Introduction

Semeval 2016 Task 14 called for a system that could help enrich the WordNet taxonomy with new words and their senses. This translates to inserting new lemmas and senses that were previously not in WordNet into their (human perceived) correct place. The system was also to determine whether a sense would merge into the chosen synset or attach itself as a new hyponym. Task 14 allowed for one of two types of systems:

1. A resource-aware system, which could use any dictionary, or
2. Constrained, which used any resource other than a dictionary.

We opted with the former, resource-aware. While any dictionary could be used, we chose to use the definitions provided in the data set from Wiktionary, along with definitions from WordNet.

## 2 Methods

Our system solves the given problem in four steps:

1. Pre-processing: Acquire all necessary data from WordNet and store it in one step. The data needed includes each word’s definitions, hypernyms, hyponyms, and synsets.
2. Overlaps: Score each sense on how well it matches each new lemma.
3. Refining chosen sense: Verify that the sense chosen in overlaps was more deserving than the other senses of the same lemma.
4. Determining attach or merge: Decide whether or not the new lemma should be attached to the synset of the chosen sense, or merged into it.

### 2.1 Pre-processing

As the implementation of our system was underway, it was clear that the system would be making a large amount of calls to WordNet. As we accessed more and more data from WordNet<sup>1</sup>, our program took longer to finish each time which created a problem for testing out changes quickly. In response, the pre-processing method was created.

Pre-processing aims to consolidate all calls to WordNet in the beginning of the program, so no duplicate calls need to be made. It does this by first obtaining all nouns and verbs from WordNet and storing them in their respective arrays (one array for nouns and one for verbs). Pre-processing

<sup>1</sup><http://search.cpan.org/dist/WordNet-QueryData/QueryData.pm>

then iterates through each word and retrieves each sense of each word, since the senses are what will determine which synset the new lemma will be merged or attached to later on. The senses are stored in a separate array, which is iterated through, one by one, in the Overlap step to obtain a score for each sense. Next, it iterates through each sense and obtains that sense's gloss. Pre-processing cleans each gloss by making all letters into lowercase, removing punctuation, and also removing this list of common stop words (*the—is—at—which—on—a—an—and—or—or-up*) from each gloss. This list of stop words was determined by finding common, less helpful words in the trial/test data. These stop words were found by outputting what words were being overlapped, and these appeared the most frequently even though they rarely added positively to the overlaps scores. It then stores the cleaned gloss in a hash that maps the gloss to the corresponding sense. Finally, Pre-processing obtains the hypernyms, hyponyms, and synsets for each sense and stores them in their respective hashes (hypernyms, hyponyms, and synsets).

## 2.2 Overlap

The Overlap step is the main step in our system for determining where the new lemmas would be inserted into WordNet. Ideas were borrowed from both (Lesk, 1986) and Extended Gloss Overlaps (Banerjee and Pedersen, 2003).

### 2.2.1 Lesk

Lesk overlaps work by comparing two words' definitions and seeing if words in those definitions overlap onto one another. Words that share more overlaps score higher with the Lesk algorithm and therefore are more similar. However, one weakness with the Lesk algorithm is that different dictionaries might define even the same word differently, which means the number of overlaps is highly dependent on the dictionary used.

### 2.2.2 Extended Gloss Overlaps

To address the room for error in the Lesk overlaps, Extended Gloss Overlaps (EGO) incorporate not only the definitions of each word being compared, but also the definitions of the hypernyms and hyponyms of each word. EGOs use WordNet to re-

trieve the hypernyms/hyponyms and their respective definitions for scoring. It was after EGOs that our system of scoring and calculating overlaps is based on.

### 2.2.3 Overlap Step

Our Overlap step works by iterating through each sense obtained from WordNet and creating an expanded sense by adding information from each sense. The expanded sense is then compared to the to-be-inserted lemmas creating a score to determine how alike the terms are. It should be noted that only corresponding parts of speech were compared as to improve time and not cause nouns to be mapped to verbs and vice versa.

For each sense to be compared, the expanded sense was created. First the sense's gloss was obtained from the hash initialized in pre-processing. Next the sense's immediate hypernyms and their glosses were retrieved and added to the expanded sense. Likewise, the sense's immediate hyponyms and their glosses were retrieved and added to the expanded sense. Finally, the sense's corresponding synset and their corresponding glosses were retrieved and added to the expanded sense. Next before any word overlaps could be processed, the new lemma's gloss needed to be cleaned up.

To provide clarity, we will act as if *ink* (taken from provided trial data) is being inserted into WordNet. For reference *ink*'s provided definition was "Tattoo work." The lemma was cleaned up following the same steps as the WordNet glosses followed in the pre-processing step. *Ink*'s definition would now become "tattoo work", since all letters are made lowercase. However, since *ink* did not contain any stop words on the list, none were removed.

Now the system steps through each word in the lemma's gloss and checks for overlaps in the glosses of the expanded sense's gloss, each hypernym's gloss, each hyponym's gloss, and finally each synset's gloss. If the word being checked is part of the lemma of each sense, it receives a bonus score. The bonus score was originally set to  $(10 * \text{the length of the lemma})$  but was later changed to  $(2 * \text{the length of the lemma})$ . This bonus was limited to compound words of at most two words. The decision to limit the length of compound words was arrived at since larger compounds like *Standing-*

*on-top-of-the-world* would score higher than *World-wide* just because they were much longer compounds, even though they occur less often.

Since *ink*'s definition contains the word *tattoo*, any sense with *tattoo* in its lemma will receive the bonus. This means that *tattoo#n#..* (i.e. any noun sense of *tattoo*) would receive a bonus. The same holds true for *work#n#..* (i.e. any noun sense of *work*). The overlapping of words were also weighted by the number of characters present in those words (or more simply length of those words), so longer words carried a heavier weight in the score than shorter ones. As with *ink*, when the word *tattoo*, in the definition of *ink*, overlaps with another compared word it adds 6 to the score since *tattoo* contains 6 letters, whereas *work* would only add 4 to the score.

The final score of the sense was calculated by dividing the number of overlaps by the total length of words from the new term.

$$\begin{aligned} \text{score} = & (\text{SenseLaps} + \text{HypeLaps} \\ & + \text{HypoLaps} + \text{SynsLaps} \\ & + \text{BonusLapsTotal}) / \text{GlossLength} \end{aligned} \quad (1)$$

The sense with the highest score at the end was presumed to be the chosen sense to either attach or merge to.

Our system determined that *ink* belonged to *tattoo#n#3* whose definition from WordNet was, “the practice of making a design on the skin by pricking and staining”. Since *ink* had a short definition provided from Wiktionary, the largest score came from the fact that *tattoo* gained the bonus score from overlapping with the definition. The correct answer provided in the key was *tattoo#n#2*, the reason for the differences was most likely the fact that our system did not identify present participle words, since *tattoo#n#2* contained the word “tattooing”.

### 2.3 Refining the chosen sense

Now that the sense had been chosen, a new measure was implemented to make sure that, in fact, the correct sense had been chosen. This step was added since it was often the case that the first sense of a word was a better choice, however, a different sense of the same word would tie causing it to replace

the first sense. When refining the sense, the system starts by assuming the first sense of the chosen word was the correct sense. This means that even though the system chooses *tattoo#n#3* for *ink*, Refine sense resets it to *tattoo#n#1* until evidence shows that *tattoo#n#3* is more deserving.

The system then performs a mini overlap, similar to the one above, limiting to just the senses of the chosen lemma and their glosses. If a sense other than the first one, had more words similar to the new term than the first one, then it would become the chosen sense of the word. The chosen sense is then cemented as the correct sense and the system moves on to merging or attaching.

### 2.4 Merge or Attach

The smallest amount of time (in developing this program) was spent on the problem of merging or attaching. This was due to the limited amount of time, and that time being focused more on determining the correct word over whether it should be merged or attached. Our system determines whether the term should be merged or attached by looking at the frequency of the chosen sense as obtained from the WordNet frequency() function. If the frequency was low (if it was equal to zero), then it was assumed to be a rarer sense so the program would attach the new term. If it was higher (greater than zero), then the opposite was assumed and merge was chosen. Our test data results are shown in the following contingency table.

|     |        | system |        |     |
|-----|--------|--------|--------|-----|
|     |        | merge  | attach |     |
| key | merge  | 7      | 25     | 32  |
|     | attach | 121    | 447    | 568 |
|     |        | 128    | 472    | 600 |

*ink* was chosen to be attached to *tattoo#n#3* which means the frequency was greater than zero.

## 3 Results

On the 600 word test data set that was provided for SemEval Task 14, our system (*UMNDuluth Sys 1*) scored as shown in Table 1.

The SemEval14 organizers also included a baseline score on the data set, which is in the table under *baseline*. As mentioned in the methods section,

| <b>System</b>                     | <b>Wu &amp; Palmer</b> | <b>Lemma Match</b> | <b>Recall</b> | <b>F1</b> |
|-----------------------------------|------------------------|--------------------|---------------|-----------|
| UMNDuluth Sys 1 (2 bonus)         | 0.3395                 | 0.0984             | 0.9983        | 0.5067    |
| UMNDuluth Sys 2 (10 bonus)        | 0.3857                 | 0.1467             | 1             | 0.5567    |
| UMNDuluth Sys 3 (25 bonus)        | 0.3802                 | 0.2117             | 1             | 0.5509    |
| UMNDuluth Sys 4 (50 bonus)        | 0.3809                 | 0.2100             | 1             | 0.5517    |
| UMNDuluth Sys 5 (100 bonus)       | 0.3735                 | 0.0517             | 1             | 0.5439    |
| UMNDuluth Sys 6 (500 bonus)       | 0.3791                 | 0.2083             | 1             | 0.5498    |
| Baseline: First word, first sense | 0.5139                 | 0.415              | 1             | 0.6789    |
| Baseline: Random synset           | 0.2269                 | 0                  | 1             | 0.3699    |
| <i>Median of Task14 Systems</i>   |                        |                    |               | 0.5900    |

**Table 1:** SemEval Task 14 Scores

originally, our system weighted definitions that overlapped with senses' words as 10 times the length of the word. This was changed close to the end of development as it looked as it might give compound words too high of a score to reach with non-compound words. The 2 times amount was what was submitted and scored above. However, the 10 times amount was run against the same data and scored labeled by *UMNDuluth Sys 2*.

The Wu & Palmer Similarity, as defined by SemEval16 Task 14 task organizers<sup>2</sup>, is calculated by finding the “similarity between the synset locations where the correct integration would be and where the system has placed the synset.” This score is between 0 and 1. The Lemma Match, again defined by the task organizers, is scored by, “the percentage of answers where the operation is correct and the correct and system-provided synsets share a lemma.” Recall refers to the percentage of lemmas attempted by the system. If 600 were attempted out of 600, then recall equals one.

## 4 Discussion

As the system was being built, we had the idea to originally use more information from Wiktionary<sup>3</sup>. However, when calls to Wiktionary were added in the system, the system slowed down to a halt, taking sometimes over 5 minutes per new lemma, even with the pre-processing. Since it was very impractical to wait this long, additional calls to Wiktionary were taken out of the program.

Another functionality that was thought to be used

was the idea of adding in the level of the word in WordNet to the calculations. The level of each word in WordNet was thought to be used in the calculation of merge/attach. Unfortunately, the calls for this information to WordNet slowed the system to a halt at times, this meant the same fate as extra Wiktionary calls.

As seen in Table 1, our submitted system had a recall of less than one. This error most likely occurred because of time constraints. Since the system had to process 600 words, the 600 word file was split four ways to allow four instances of the system to process the data at once. In the splitting of the word file, a word was most likely lost.

Time constraints also was the reason of the difference between UMNDuluth Sys 1 and Sys 2. As stated in the results, Sys 1 had a bonus overlap multiplier of two while Sys 2 had a bonus of 10. The two multiplier was tested only on a small set of words, and little to no difference appeared between Sys 1 and Sys 2. However, it was discovered after the test data was turned in that the bonus multiplier scores higher when it is set to 10 as it is in Sys 2.

When seeing the improvement that occurred between Sys 1 and Sys 2, more tests were run by increasing the bonus. These are shown in Sys 3-6, which appear to peak between the 25 and 50 multiplier.

In the future, it would be interesting to see how additional Wiktionary data could help improve the choice of the system.

## Abstract

This paper describes the VCU systems that participated in the Semantic Taxonomy Enrichment task of SemEval 2016. The three systems are unsupervised and relied on dictionary-based similarity measures. The first two runs used first-order measures (Lesk and First-order vector), and the third run used a second-order measure (Second-order vector). The first-order measures obtained a higher Wu & Palmer score than the second-order measure on the test data. All three runs obtained a higher Wu & Palmer and F1 score than the random baseline but not the first-word first-sense baseline.

## 1 Introduction

Semantic knowledge bases are used in a number of NLP applications, e.g. Word Sense Disambiguation ((Agirre et al., 2014) (Agirre et al., 2010)) and Information Retrieval (Uddin et al., 2013). These knowledge bases span across a number of domains, e.g. WordNet, Gene Ontology, and Medical Subject Headings. Building and maintaining these knowledge bases is expensive and manually intensive (Martinez-Gil, 2015). Semantic taxonomy enrichment aims to aid in the maintenance process by automatically placing new terms into an existing taxonomy.

The Semantic Taxonomy Enrichment task (SemEval 2016 Task 14) objective was to automatically incorporate new word senses into WordNet<sup>1</sup>, a lexical dictionary of English terms that are linked together based on a number of relations (e.g. is-a).

In this task, systems were provided a list of *out-of-vocabulary* terms (OOVs), their part-of-speech (POS), and a brief description of the term (OOV description). The goal of this task was to automatically identify which WordNet synset the OOV should be associated with and whether the association was synonymous (*merge*) or the OOV is a hyponym of the synset (*attach*).

Semantic similarity measures have been shown useful in the development of terminologies and ontologies (Vizenor et al., 2009). These measures quantify how related two terms are. The measures that we focus on for this task rely on definitional information extracted from knowledge sources such as WordNet. Our approach to the shared task is a modification of these measures relying on WordNet’s gloss information, and the OOV descriptions.

We categorize the measures we evaluated as first-order and second-order measures. The first-order measures conduct a direct comparison between the words in the WordNet synset’s gloss and the words in the OOV description. Second-order measures incorporate additional context by creating a vector for each word in the synset’s gloss (or OOV description) containing words that co-occur with it from an external corpus. These word vectors are then averaged to create a single co-occurrence vector for the OOV or synset.

The VCU systems were implemented using the freely available, open source UMLS-Similarity package (McInnes et al., 2009) (version 1.45), which includes support for user-defined dictionaries and corpora, in addition to the first-order and second-order measures.

<sup>1</sup><https://wordnet.princeton.edu/>

The paper is organized as follows. First, we describe the details of the three VCU systems that participated in this task. Second, we discuss the evaluation metrics. Lastly, we discuss the results of the systems.

## 2 VCU Systems

There were three VCU systems. VCU-Run-1 uses the *Lesk* measure; VCU-Run-2 uses the *First-order vector* measure; and VCU-Run-3 uses the *Second-order vector* measure. Our goal was to compare the different measures on the task of identifying the appropriate placement for an OOV in WordNet. The measure used to identify the appropriate WordNet synset for a given OOV is the only difference between the three runs.

In the VCU systems, an OOV, its POS and text description is taken as input. First, the WordNet synsets are filtered based on their POS (see POS Filtering). Second, a score is assigned to each WordNet synset (see Measures). Third, the synset with the highest score is assigned to the OOV; if the score is greater than 0.7 it is labeled *merge* (the two terms are synonymous), otherwise *attach* (the OVV is a hyponym of the synset). The 0.7 score was set at development time and more work is required to determine what threshold should be used.

### 2.1 Measures

The VCU systems explored using three dictionary-based measures to identify the degree to which the OOV was similar to a WordNet synset for placement in the taxonomy. The first-order measure referred to as Lesk and First-order vector; and the third is a second-order measure referred to as Second-order vector. This subsection describes these measures.

#### 2.1.1 Lesk

The Lesk measure, initially proposed by (Lesk, 1986), quantifies the relatedness between two terms by counting the number of overlaps between their two definitions. An overlap is defined as the longest sequence of one or more consecutive words that occur in both definitions. The length of the overlap is squared to give a greater weight to longer overlaps. For example, given the definitions *a very large number* and *a very large indefinite number*. The overlap *very large* would be given the score 4, the overlap

*number* would be given a score of 1, and the total Lesk score would be 5.

#### 2.1.2 First-order vector

First-order vector is a modification of the Lesk measure. It treats each word in the definition as an element in a vector. A vector is created for the WordNet synset and the OOV where the element in the vector is the number of times the associated word occurred in their respective definitions. The cosine similarity is then used to quantify the degree to which the two terms are similar. Figure 1 shows a simple example where the OOV definition is *a very large number* and the WordNet definition is *a very large indefinite number*.

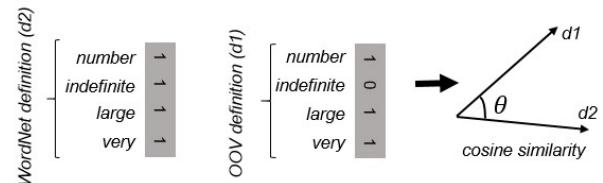

Figure 1: First-order vector example

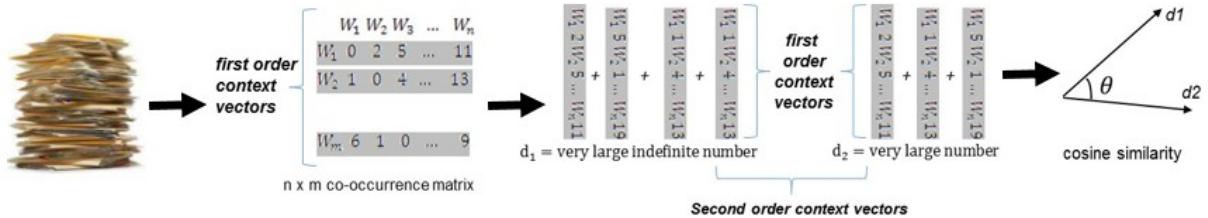

#### 2.1.3 Second-order vector

One of the disadvantages to first-order measures is that they rely on the exact matching of the words in the definitions. Therefore, *a humongous sum* would obtain a Lesk and First-order vector score of zero when compared to a *a very large number* even though both descriptions are clearly associated. The Second-order vector measure was introduced by (Patwardhan and Pedersen, 2006) to alleviate this.

In this measure, a vector is created for each word in the definition containing the words that co-occur with words from an external corpus. These word vectors are averaged to create a single co-occurrence vector for the OOV or synset. The similarity between the OOV and synset is then calculated by taking the cosine between their respective second-order vectors. Figure 2 shows a simple example using the “very large number” example again from above.

## 2.2 Definition Creation

The *definitions* we use in the VCU systems consist of: 1) the OOV description and 2) the WordNet synset’s gloss.

**Figure 2:** Second-order vector example

When implementing Lesk in WordNet, (Banerjee and Pedersen, 2002) found that the WordNet glosses were short, and did not contain enough overlaps to distinguish between multiple synsets, therefore, they extended this measure to include the glosses of the related concepts. This modification has been shown to improve the performance of both Lesk and Second-order vectors on the tasks of Word Sense Disambiguation (Banerjee and Pedersen, 2002) and Semantic Similarity (Patwardhan, 2003) (McInnes and Pedersen, 2013). The VCU Systems included the glosses of the following WordNet relations: holonyms (*holo*), hypernyms (*hype*), hyponyms (*hypo*), and meronyms (*mero*). Therefore, our WordNet synset *definition* contains not only the gloss of the synset but also the glosses of the related synsets.

The stop words were removed from the OOV descriptions and WordNet glosses prior to processing using the stoplist from the Ngram Statistics Package<sup>2</sup> (NSP), and all of the words were lower cased. No additional pre-processing (e.g. stemming) was conducted.

### 2.3 Matrix for second-order measure

In the VCU system, the second-order co-occurrence matrix was created using bigram counts obtained from the GigaWord Corpus 2nd Edition Agence France-Presse, English Service (afp\_eng) data. We selected only those bigrams based on the following criteria: (1) neither word in the bigram was a stop word in the NSP stoplist; and (2) the bigram occurred at least twice in the corpus. The Ngram Statistics Package (Banerjee and Pedersen, 2003) was used to collect the bigram and their frequency counts.

<sup>2</sup><https://sourceforge.net/projects/ngram/>

The resulting matrix contained 59,217 rows and 70,726 columns, representing 4,487,663 unique bigrams. The matrix is not symmetric because the co-occurrences are bigrams. Therefore, the number of times *school bus* was seen in the text is different than the number of times *bus school*. All the words in the corpus were lower cased prior to processing.

### 2.4 Part-of-Speech Filters

Due to the number of synsets in WordNet, we filtered them based on two criteria: (1) the WordNet synset has the same POS as the OOV; and (2) the WordNet synset contained a word of the same POS as a word in the OOV description. These criteria were adaptations of the first-word/first-sense baseline that was provided by the organizers to reduce the number of possible synset choices. To obtain the POS of the words in the OOV descriptions, we used the OpenNLP POS Tagger (Baldridge et al., 2002).

## 3 Evaluation Metrics

The VCU system was evaluated using four metrics: WuP, Lemma Match, Recall and F1. WuP is based on the similarity metric proposed by (Wu and Palmer, 1994). It was used to evaluate how close the system came to identifying the correct synset. In this metric, the similarity is twice the depth of the two synsets ( $synset_{sys}$  and  $synset_{gold}$ ) Least Common Subsumer (LCS) divided by the sum of the depths of the individual synsets as defined in Equation 1. The LCS is the most specific ancestor shared by two synsets using WordNet's hypernymy/hyponymy relations.

$$WuP = \frac{2 * \text{depth}(\text{lcs}(synset_{sys}, synset_{gold}))}{\text{depth}(synset_{sys}) + \text{depth}(synset_{gold})} \quad (1)$$

| System    | Measure             | WuP    | Lemma Match | Recall | F1     |
|-----------|---------------------|--------|-------------|--------|--------|
| VCU-Run-1 | First-order Lesk    | 0.4190 | 0.1706      | 0.9967 | 0.5900 |
| VCU-Run-2 | First-order vector  | 0.4317 | 0.1605      | 0.9967 | 0.6024 |
| VCU-Run-3 | Second-order vector | 0.4076 | 0.1237      | 0.9967 | 0.5786 |
| Baseline  | Random              | 0.2269 | 0.0000      | 1.000  | 0.3699 |
| Baseline  | First word/sense    | 0.5134 | 0.4150      | 1.000  | 0.6790 |

**Table 1:** VCU System Test Results

Recall determines how many of the OOV terms were assigned to a WordNet synset. The F1 score is the F-measure (harmonic mean) of WuP and Recall. The Lemma Match is the percentage of system synsets that exactly matched the gold standard.

## 4 Results and Discussion

Table 1 shows the VCU system results for the Semantic Taxonomy Enrichment task, and the two baselines provided by the organizers (Random and First-word First-sense). The Random baseline chooses a random synset of the appropriate POS. The First-word First-sense (First word/sense) assigns the first synset whose word is also the first head word in the OOV description with the same POS.

The Recall results show that the VCU systems did not assign all of the OOVs to a WordNet synset. Investigation into this found that the POS filter (see Section 2.4) was too aggressive and no WordNet synset met the filtering criteria. The WuP and Lemma Match results show that the VCU systems obtained a higher score than the random baseline but not the First word/sense baseline.

The results between the three VCU system runs show that the First-order measures obtained a higher Lemma Match, WuP and F1 score than the Second-order vector measure. This indicates that the additional contextual information from the corpus did not provide useful information, hurting the performance. The co-occurrence matrix created for the Second-order vector measure was based on text from the GigaWord corpus. Looking back, we believe that utilizing a more up-to-date text such as Wikipedia, or using WordNet as a corpus itself as (Pedersen, 2014) may increase the performance the results.

The results between the first-order measures show Lesk obtained a lower WuP score than First-order vector, but a higher Lemma Match. Analysis of the mappings found that Lesk was merging all of the OOVs to the WordNet synsets rather than attaching

them as a hyponym. When assigning *attach* rather than *merge* to each of the mappings, the WuP score for Lesk increased to 0.4461 (higher than First-order vector’s 0.4317). This indicates that additional work is required to determine whether the attachment of the OOV to the synset should be a *merge* or an *attach*.

## 5 Conclusion and Future Work

In this paper, we described the VCU systems that participated in the Semantic Taxonomy Enrichment task of SemEval 2016. The three systems are unsupervised and relied on dictionary-based similarity measures. The first two runs used First-order measures (Lesk and First-order vector), and the third run used a second-order measure (Second-order vector). The first-order measures obtained a higher Wu & Palmer score than the second-order measure.

Analysis of the OOV mappings to WordNet synsets by the measures highlighted three areas of future work. First, more attention needs to be paid in determining whether the new term should be merged as a synonym or attached as a hyponym to the synset. Second, a more indepth analysis of the definitions used to represent the context of the new terms and the WordNet synsets needs to be conducted. Lastly, although the Second-order vector did not perform as well as the First-order measures, the type of the corpus used to create the second-order vectors needs to be explored.

## Acknowledgments

WordNet was accessed using WordNet-QueryData<sup>3</sup>. The VCU systems were implemented using UMLS-Similarity<sup>4</sup>. I would like to thank Ted Pedersen for help in understanding the task, and useful brainstorming discussions.

# GWU\_NLP at SemEval-2016 Shared Task 1: Matrix Factorization for Crosslingual STS

Hanan Aldarmaki and Mona Diab

Department of Computer Science

The George Washington University

{aldarmaki; mtdiab}@gwu.edu

## Abstract

We present a matrix factorization model for learning cross-lingual representations for sentences. Using sentence-aligned corpora, the proposed model learns distributed representations by factoring the given data into language-dependent factors and one shared factor. As a result, input sentences from both languages can be mapped into fixed-length vectors and then compared directly using the cosine similarity measure, which achieves 0.8 Pearson correlation on Spanish-English semantic textual similarity.

## 1 Introduction

Semantic textual similarity (STS) is a measure of relatedness in meaning between a pair of variable-length textual snippets, such as sentences. Using unsupervised vector space models, words and sentences can be mapped into dense vector representations that capture implicit syntactic and semantic information. These representations can then be directly compared using well-known distance or similarity measures, such as the Euclidean distance or cosine similarity, which reflect their overall semantic relatedness.

Such distributed representations of words, or word embeddings, can be learned using global word co-occurrence statistics as in matrix factorization models (Guo and Diab, 2012; Pennington et al., 2014), or using local context as in neural probabilistic language models (Bengio et al., 2003; Collobert and Weston, 2008; Socher et al., 2013). A variable-length sentence can be mapped into a fixed-length vector either by combining word embeddings

or directly learning sentence representations as in the paragraph vector model proposed in (Le and Mikolov, 2014).

In crosslingual STS, the challenge is to compare sentences from two different languages. We address this problem by directly learning crosslingual vector representations for words and sentences, which allows us to calculate the STS scores without the need for explicit translation or mapping. Several models can be used for learning cross-lingual compositional representations (Klementieva et al., 2012; Shi et al., 2015; Pennington et al., 2014; Cavallanti et al., 2010; Mikolov et al., 2013; Coulmance et al., 2015; Pham et al., 2015). We propose a relatively simple and nuanced unsupervised model inspired by the monolingual weighted matrix factorization (WMF) model proposed in (Guo and Diab, 2012), which we extend to the cross-lingual setting.

The WMF model learns word representations by decomposing a sparse tf-idf matrix into two low-rank factor matrices representing words and sentences. The weights are adjusted to reflect the confidence levels in reconstructing observed vs. missing words in the original matrix. Representations for variable-length sequences can be calculated by minimizing the reconstruction error as described in Section 2.1. In this paper, we propose to extend this model to the cross-lingual setting by modeling two languages in parallel to obtain shared semantic representations. The proposed model has a simple loss function and only uses sentence-aligned data for learning the shared representations. We describe the model in two variations in Section 2.2. This model yields a performance of 0.8 Pearson correlation in

Semeval’s English-Spanish crosslingual STS task.

## 2 Related Work

The weighted matrix factorization model we extend was first proposed in (Guo and Diab, 2012) to learn distributed vector representations for words in the monolingual space. The GloVe algorithm proposed (Pennington et al., 2014) is also a weighted matrix factorization method, but it includes additional word-specific bias terms and uses a different weighting scheme.

As mentioned above, we extend the WMF model proposed in (Guo and Diab, 2012) to bilingual and multilingual settings by forcing the two monolingual components to use a shared factor. (Shi et al., 2015) proposes a similar approach for learning bilingual embeddings. They extend GloVe (Pennington et al., 2014) to the bilingual case using a matrix of bilingual co-occurrence counts with word alignments in addition to the monolingual components. This model is similar in spirit to our model, but it has a different objective function that incorporates cross-lingual co-occurrence statistics or word alignments.

## 3 Proposed Approach

### 3.1 Background: Weighted Matrix Factorization (WMF)

In the WMF model proposed in (Guo and Diab, 2012), a large corpus is represented as an  $m \times n$  matrix  $X$ , where each  $X_{ij}$  cell is the tf-idf weight of word  $i$  in sentence  $j$ . This sparse matrix is then factorized into a  $k \times m$  matrix  $P$  and a  $k \times n$  matrix  $Q$ , such that  $X = P^T Q$ . The factorization results in  $k$ -dimensional representations for words and sentences: the columns in  $P$  are latent  $k$ -dimensional representations for words, and the columns in  $Q$  are latent  $k$ -dimensional representations for the training sentences.

The values of  $P$  and  $Q$  can be calculated by minimizing the following weighted loss function:<sup>1</sup>

$$C = \sum_{i,j} W_{ij} (P_i^T Q_j - X_{ij})^2 + \lambda (\|P\|^2 + \|Q\|^2) \quad (1)$$

where  $\lambda$  is a regularization parameter to avoid overfitting, and  $W$  is an  $m \times n$  weight matrix. The

---

<sup>1</sup>Single subscripts refer to column vectors in all equations.

weights reflect the confidence levels associated with the reconstruction errors of the corresponding items in  $X$ . A small weight is assigned to all missing words,  $\{X_{ij} \in X | X_{ij} = 0\}$ , to reflect some appropriate level of uncertainty:

$$W_{i,j} = \begin{cases} 1, & \text{if } X_{i,j} \neq 0 \\ w_m, & \text{if } X_{i,j} = 0 \end{cases}$$

where  $w_m \ll 1$ ; In other words, we assign minimal confidence that each word in the vocabulary could legitimately appear in any given sentence, while the confidence level is highest for observed words.

By fixing  $P$ , the cost function becomes quadratic in  $Q$  and the global minimum is achieved using the matrix  $Q_{min}$  that satisfies  $C'(Q_{min}) = 0$ . The  $j^{th}$  column in  $Q_{min}$  is calculated as follows:

$$Q_j = (PW^j P^T + \lambda I)^{-1} PW^j X_j \quad (2)$$

where  $W^j$  is a diagonal matrix with coefficients  $W_{ij}$  in row/column  $j$  (the  $j^{th}$  column of  $W$ ).

Similarly, the vectors in  $P_{min}$  are calculated by fixing  $Q$  and minimizing the cost function  $P(Q)$ :

$$P_i = (QW^i Q^T + \lambda I)^{-1} QW^i X^T i \quad (3)$$

where  $W^i$  is a diagonal matrix with coefficients  $W_{ij}$  in row/column  $i$  (the  $i^{th}$  row of  $W$ ).

Thus, alternating least squares (ALS) is used to minimize  $C(P, Q)$  by iteratively fixing  $P$  to calculate  $Q$ , then fixing  $Q$  to calculate  $P$  using equations (2) and (3).<sup>2</sup>

To generate vector representations for additional sentences after training,  $P$  is fixed and  $Q$  is calculated for the new sentences using equation (2). In other words, we calculate the representations that minimize the loss function (1), which is quadratic when  $P$  is fixed.

### 3.2 Cross-lingual WMF

Here we describe our proposed extension of the WMF model for learning bilingual semantic representations. Given a parallel corpus of  $n$  sentence pairs, we generate an  $m \times n$  tf-idf matrix  $X$  for language 1 sentences, and an  $l \times n$  tf-idf matrix  $Y$  for

---

<sup>2</sup>Details on similar calculations and speedup recommendations are found in (Hu et al., 2008).

language 2 sentences, where  $m$  and  $l$  are the number of words in the vocabulary of each language. The learning objective of the bilingual WMF model is to factorize both  $X$  and  $Y$  into two language-specific factors and one shared factor. More precisely, the desired factorization would result in a  $k \times m$  matrix  $P$ , a  $k \times l$  matrix  $A$ , and a  $k \times n$  matrix  $Q$ , such that  $X = P^T Q$  and  $Y = A^T Q$ . To achieve these bilingual objectives, we define two methods for calculating the loss function for both languages as detailed below: A global bilingual loss function (b-WMF), and a monolingual loss function with an explicit shared factor (x-WMF).

### 3.2.1 b-WMF: Bilingual Loss Function

We define a global loss function for both languages as follows:

$$C = \sum_{i,j} W_{ij} (P_i^T Q_j - X_{ij})^2 + \sum_{d,j} U_{dj} (A_d^T Q_j - Y_{dj})^2 + \lambda (\|P\|^2 + \|Q\|^2 + \|A\|^2) \quad (4)$$

where  $U$  is the weight matrix for  $Y$ , defined similar to  $W$ .

This objective function is convex if we fix two of the factor matrices and minimize with respect to the remaining factor. Alternating least squares can be used to estimate the factors iteratively using the following three equations:

$$\begin{aligned} Q_j &= (PW^j P^T + AU^j A^T + \lambda I)^{-1} (PW^j X_j + AU^j Y_j) \\ P_i &= (QW^i Q^T + \lambda I)^{-1} QW^i X_i^T \\ A_d &= (QU^d Q^T + \lambda I)^{-1} QU^d Y_d^T \end{aligned} \quad (5)$$

To generate vector representations for additional sentences in either language, the language-specific factors  $P$  and  $A$  are fixed, and the semantic vectors  $Q_j$  are calculated using equation (2) for language 1 and equation (6) for language 2.

$$Q_j = (AU^j A^T + \lambda I)^{-1} AU^j Y_j \quad (6)$$

In other words, the two models are independent once the training is complete, but the resultant representations are expected to reflect shared semantic components.

### 3.2.2 x-WMF: Monolingual Loss Functions

Alternatively, we can define two loss functions with a shared factor:

$$\begin{aligned} C_1 &= \sum_{i,j} W_{ij} (P_i^T Q_j - X_{ij})^2 + \lambda (\|P\|^2 + \|Q\|^2) \\ C_2 &= \sum_{d,j} U_{dj} (A_d^T Q_j - Y_{dj})^2 + \lambda (\|A\|^2 + \|Q\|^2) \end{aligned} \quad (7)$$

Minimizing  $C_1$  and  $C_2$  separately is equivalent to training two separate monolingual models. To achieve the bilingual objective, we only train  $C_1$  as a monolingual model, and then we use the learned factors  $P$  to find  $A$ . If we assume that the compositional representations generated by  $P$  are optimal, then we can use it to fix  $Q$  in  $C_2$ , and the loss function becomes quadratic in  $A$ ; all we have to do is find the values of  $A$  that minimize  $C_2$ . Given a parallel corpus and word representations  $P$ , we calculate  $Q$  using equation (2), then calculate  $A$  using equation (5).

The training procedure is carried out as follows:

1. Independently train a monolingual WMF model for a pivot language.
2. Using a parallel corpus and the trained word representations  $P$  for the pivot language, generate sentence representations  $Q$  using equation (2)
3. Using the same parallel corpus, and fixing  $Q$  as calculated in step 2, calculate word representations  $A$  for the second language using equation (5).

Note that we only use the alternating least squares (ALS) algorithm for training the pivot model; the parameters of the second model,  $A$ , are calculated deterministically in one step. This method can be readily extended to more than two languages. Using one trained monolingual model, we can quickly learn representations for any number of languages using sentence-aligned data.

## 4 Empirical Evaluation

### 4.1 Data

**Monolingual Data:** For the monolingual English model, the training set consists of 700K sentences derived from various resources. We extract and combine the following sets: a random set of 150K sentences from LDC’s English Gigaword fifth edition (Parker et al., 2011), a random set of 150K sentences from the English Wikipedia<sup>3</sup>, the Brown Corpus (Francis, 1964), Wordnet (Miller, 1995) and Wiktionary<sup>4</sup> definitions appended with examples.

**Bilingual Data:** We extract training data for the bilingual models from WMT13 (Macháček and Bojar, 2013) sentence-aligned parallel corpora, specifically version 7 of the EuroParl parallel corpus (Koehn, 2005), the multiUN parallel corpus (Eisele and Chen, 2010), and news commentary data. We train the bilingual model using a sample of 1M sentence pairs from these datasets.

All sentences in our data are tokenized and stemmed, and number sequences are replaced with a special token as a normalization step. We use the Stanford CoreNLP toolkit (Manning et al., 2014) for English preprocessing, and Treetagger tools (Schmid, 1995) for Spanish. Words that appear less than 5 times in the training set are discarded from the vocabulary.

### 4.2 Parameter Settings

We train our bilingual b-WMF models strictly using the bilingual parallel data. On the other hand, we train the English pivot model used in x-WMF strictly using the English monolingual data, while the parallel corpora are only used for training the Spanish component of the x-WMF models. For the b-WMF models and the English monolingual model, we run the ALS algorithm for 20 iterations. We use the following parameters for all models:  $k=100$ ,  $w_m = 0.01$  and  $\lambda = 20$ .<sup>5</sup>

<sup>3</sup><http://en.wikipedia.org>

<sup>4</sup><http://www.wiktionary.org>

<sup>5</sup>These parameters are tuned empirically and we found these values to be robust across models.

| Model | News | Multi Source | Mean |
|-------|------|--------------|------|
| b-WMF | 0.83 | 0.72         | 0.78 |
| x-WMF | 0.87 | 0.73         | 0.80 |
| UWB   | 0.91 | 0.82         | 0.86 |

**Table 1:** Cross-lingual STS EN-SP Test results using Pearson Correlation Coefficient.

### 4.3 Cross-lingual Semantic Textual Similarity

Semantic Textual Similarity (STS) is a measure of the degree of similarity between two sentences. STS scores range from 0 to 5, where higher values indicate closer semantic content. In the crosslingual STS test sets, the sentences can either be English or Spanish. We use the TextCat (Cavnar and Trenkle, 1994) tool to identify the languages before processing.

Using the b-WMF and x-WMF cross-lingual models, we generate sentence vectors for the given pairs, then we calculate the cosine similarity between each pair. Since most of the output is positive, and negative values are generally very close to zero, we round up negative similarity values to 0.

Table 1 shows the results on the test data of Semeval 2016 EN-ES cross-lingual STS shared task. The evaluation metric is the Pearson Correlation Coefficient. The x-WMF models performs slightly better than b-WMF in this task, and we achieve rank 4 in the official STS semeval evaluation. We also show the results of the official first rank system UWB.

## 5 Discussion and Conclusions

We proposed a new unsupervised approach for generating cross-lingual semantic representations for variable-length sequences using a weighted matrix factorization model. The models successfully learned cross-lingual compositional representations as evident in the high correlation scores in the crosslingual STS task.

Learning a monolingual WMF model involves optimizing a non-convex loss function, but the loss function becomes quadratic once we fix one of the factors. As a result, learning any additional languages becomes trivial once we fix the sentence representations using a pivot model. The model naturally extends to several languages since the additional factors are calculated deterministically. Moreover, the model is simple and robust as we learned

good representations using relatively small parallel datasets and without parameter optimization.

## Abstract

We describe the systems entered by the National Research Council Canada in the SemEval-2016 Task1: Crosslingual Semantic Textual Similarity. We tried two approaches: One computes a true crosslingual similarity based on features extracted from lexical semantics and shallow semantic structures of the source and target fragments, combined using a linear model. The other approach relies on Statistical Machine Translation, followed by a monolingual semantic similarity, relying again on syntactic and semantic features. We report our experiments using trial data, as well as official final results on the evaluation data.

## 1 Introduction

The SemEval-2016 Semantic Textual Similarity (STS) evaluation (task1) introduced a crosslingual track. Given a Spanish-English bilingual fragment pair, the goal is to compute the degree of equivalence between them. This offers additional challenges compared to the “STS Core” track, where both fragments are in the same language (English or Spanish in 2014-15). The crosslingual track requires potentially to detect which fragment is in which language, perform further language processing accordingly, and estimate lexical and semantic similarities across languages.

In our work, we investigated two approaches. In the first approach, we try to build a true crosslingual similarity based on a number of features computed from both fragments. One of these features projects Spanish words into an English embedding space in

order to compute similarities in that space. Other features compute various kinds of syntactic and semantic overlap between the fragments. These features are combined in a linear model estimated on the trial data, and combined with an isotonic regression (de Leeuw et al., 2009) layer in order to account for non-linearity in the scores.

The second approach uses a Statistical Machine Translation system to map Spanish fragments to English, then relies on a monolingual semantic similarity between the translated fragment and the English fragment. Various monolingual similarity features, using embeddings, syntactic and semantic information, are computed and combined again using a linear model followed by an isotonic regression layer.

In the next section, we describe the two approaches and their components: SMT system, crosslingual and monolingual feature extraction, and the output layer fitting the features to the semantic similarity scores. We then describe the corpora used to fit the features to the output similarity score, and make various modeling choices (Section 3). We present our experimental results on the trial and test data in Section 4.

## 2 System description

We describe our two approaches: the direct crosslingual similarity using embedding mapping (EMAP run) and the use of Machine Translation followed by a monolingual semantic similarity (MT1 and MT2).

### 2.1 Crosslingual Embedding Mapping

**Feature Extraction:** We evaluate the semantic similarity of the given text based on two levels: lex-

ical semantics and shallow semantic structure.

One of the trivial ways to evaluate the crosslingual lexical similarity is using the alignment probability of an alignment model trained with a large-scale parallel corpus.<sup>1</sup> However, the alignment model does not evaluate the meaning similarity of words as well as the vector space model which is explicitly trained to evaluate semantic similarity. We therefore propose to combine the two models: given a Spanish word, we first look up in the alignment model for a list of the most probable (5-best) aligned English word (the *mapping* step); we then evaluate the lexical similarity of each entry in the 5-best list against the target English word using a word embeddings model. In our experiments, we used pretrained word2vec (Mikolov et al., 2013) embeddings.<sup>2</sup> The resulting crosslingual lexical similarity of the targeted pair of Spanish and English words is the highest similarity between the 5 mapped words and the target English word. We then reconstruct the semantic phrasal similarity by averaging the English-idf-weighted crosslingual embeddings mapped lexical similarity according to the 1-1 maximal matching alignment of the lexicons in the two phrases.

In addition to the flat lexical semantic feature, we use XMEANT (Lo et al., 2014), the crosslingual semantic frame based machine translation evaluation metric, for generating shallow structural semantic features. We use MATE (Björkelund et al., 2009) for Spanish shallow semantic parsing and SENNA (Collobert et al., 2011) for English shallow semantic parsing. In evaluating machine translation quality, the confusion of semantic roles is a major source of errors due to reordering. However, in evaluating STS, confusion of semantic roles is less frequent while missing information in one of the test fragments is more frequent. This motivates a further simplification of the 12 semantic role types (Lo et al., 2014) into 5 semantic role types: action, agent, patient, beneficiary and others. The same phrasal semantic similarity function mentioned above is used for evaluating the role fillers similarity, instead of the ITG-constrained crosslingual phrasal similarity function (Lo et al., 2014).

As a result, for each pair of the test sentences,

| Feature | Description                        |
|---------|------------------------------------|
| 1       | Embedding-based phrasal similarity |
| 2       | XMEANT score                       |
| 3,4     | p,r for semantic role: action      |
| 5,6     | p,r for semantic role: agent       |
| 7,8     | p,r for semantic role: patient     |
| 9,10    | p,r for semantic role: beneficiary |
| 11,12   | p,r for semantic role: others      |

**Table 1:** Features used by the cross-lingual and monolingual semantic similarity. p,r stands for precision and recall.

we extracted 12 features (Table 1). The first feature is the simple phrasal similarity by considering the whole string of the testing sentences as one phrase. The second feature is the XMEANT score. The remaining 10 features are the precision and recall of the 5 semantic role types used in XMEANT.

**Fitted Output Layer:** Most of the extracted features are correlated with the gold standard semantic similarity score, by capturing various aspects of the similarity. In order to combine these features, we estimate a linear combination by fitting a least mean squares linear regression on the trial data gold standard similarity score.<sup>3</sup> Although it may be desirable to combine features in a non linear way, the amount of available annotated data severely limits our capacity to estimate non-linear models. We improve the modeling slightly by fitting a non-linear transformation of the estimated score produced by the linear combination, with the constraint that the transformation preserves the ordering of scores. This is done through isotonic regression, using the efficient implementation available in R (de Leeuw et al., 2009). In order to avoid overfitting to the limited number of training example, we use a 10-fold cross-validation estimator on the trial data to select the appropriate features and check the performance of the isotonic regression layer.

## 2.2 MT + Monolingual Similarity

**Statistical Machine Translation.** All Spanish text was translated to English using an SMT system based on *Portage*, the NRC’s phrase-based SMT technology (Larkin et al., 2010). The system was

<sup>1</sup>Part of the MT system described in Section 2.2.

<sup>2</sup><https://code.google.com/archive/p/word2vec/>

<sup>3</sup>We use the `glm` function in R.

trained using standard resources – Europarl, Common Crawl (CC) and News & Commentary (NC) – totaling approximately 110M words in each language. Phrase extraction was done by aligning the corpora at the word level using HMM, IBM2 and IBM4 models, using the union of phrases extracted from these separate alignments for the phrase table, with a maximum phrase length of 7 tokens. Phrase pairs were filtered so that the top 30 translations for each source phrase were retained. The following feature functions are used in the log-linear model: three 5-gram language models with Kneser-Ney smoothing (Kneser and Ney, 1995), i.e. one for each of Europarl, CC and NC data, combined linearly (Foster and Kuhn, 2007) to best fit NC data; lexical estimates of the forward and backward translation probabilities obtained either by relative frequencies or using the method of (Zens and Ney, 2004); lexicalized distortion (Tillmann, 2004; Koehn et al., 2005); and word count. The parameters of the log-linear model were tuned by optimizing BLEU on the development set using the batch variant of MIRA (Cherry and Foster, 2012). Decoding uses the cube-pruning algorithm of (Huang and Chiang, 2007) with a 7-word distortion limit.

For any given input in Spanish, the SMT system produces the translation that is most likely with regard to its own training data; that translation may be arbitrarily distant from the English sentence to which it will be compared in the STS task. These arbitrary surface differences may complicate the task of measuring semantic similarity. To alleviate this problem, we bias the MT system to produce a translation that is as close as possible on the surface to the English sentence. This is done by means of log-linear model features that aim at maximizing  $n$ -gram precision between the MT output and the English sentence. The relative weights of these features are set to maximize BLEU on the trial data. This optimization is performed separately from that of the other features, using a simple grid-search approach. Systems MT1 and MT2 are the top-ranking systems in this regard: MT1 uses unigram/bigram/trigram weights 16/4/1, while MT2 uses 16/2/2.

**Feature Extraction.** The features extracted in this run are essentially the same as those in the crosslingual approach, except that the lexical semantic sim-

ilarity is now directly evaluated using the monolingual word embeddings model. Similarly, the structural semantic similarity is now evaluated using MEANT (Lo et al., 2015) instead of XMEANT, and the semantic role similarity features are obtained by evaluating the semantic parses in the same languages.

**Fitted Output Layer.** This output layer is essentially the same as the one in the crosslingual approach, but estimated on the monolingual features. One key advantage here is that we rely on a monolingual semantic similarity. We can then fit the monolingual models on English trial and test data from previous STS tasks. We combine the 2012 to 2014 development and test sets totaling 10,662 examples, instead of the 103 trial bilingual pairs available for the crosslingual task.

### 3 Textual Similarity Data

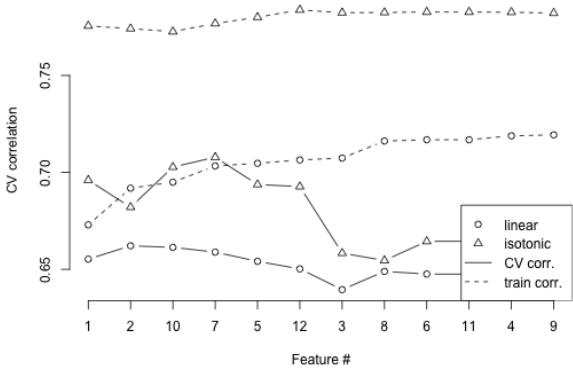

**Monolingual.** In order to estimate parameters of the monolingual similarity, we use 10,662 English pairs from the 2012 to 2014 development and test sets. We test this similarity on the 2015 test data, comprising 3000 examples in 5 different test sets.

**Crosslingual.** We use the 103 Spanish-English pairs provided as trial data for the crosslingual task for two purposes. We estimate the crosslingual similarity output layer, and we compute performance estimates for all our runs. In order to tune the output layer (in particular to select the relevant features), we compute an unbiased estimator of the prediction performance using cross-validation on the data used for fitting (103 examples in crosslingual, 10,662 in monolingual).

## 4 Experimental results

### 4.1 Results on trial data

For the crosslingual embedding mapping (EMAP run), the only gold standard data available is the 103 trial set pairs. In order to get an unbiased estimate of the performance, we compute a 10-fold cross-validation estimator. We use it to select the best subset of features. Figure 1 shows that the choice of features has a large impact, with estimated performance ranging from 0.64 (for all features) to 0.71 with the four features with highest correlation with the gold

**Figure 1:** Cross-validated correlation when adding new features, ranked by individual correlation with the gold standard. The optimal CV estimate (solid+triangle curve) is obtained with four features (1, 2, 7 and 10).

|      | Top1 | Linear | Isotonic |
|------|------|--------|----------|
| EMAP | .674 | .659*  | .708*    |
| MT1  | .714 | .723   | .731     |
| MT2  | .713 | .720   | .727     |

**Table 2:** Estimated results on the trial data (\* estimates from 10-fold cross-validation).

standard. These four features are: the crosslingual similarity score, the XMEANT score and two semantic role features. The cross-validated correlation for the linear model and isotonic regression are 0.659 and 0.708, respectively (Table 2). For our submitted run EMAP, we re-estimated the linear mode and isotonic regression on all 103 trial examples and used those models to estimate scores on the two test sets (301 and 2973 examples, respectively).

For the MT1 and MT2 runs, the monolingual similarity is trained on the available monolingual STS data from 2012 to 2014. In order to test the resulting similarity, we apply it to the 2015 test data, and obtain an average correlation of .713 on the five test sets, significantly below the best performing system at the 2015 task (.801 average). We also apply the monolingual STS to the trial data after forced decoding and feature extraction and obtain an estimated trial correlation of .727–.731 (Table 2).

| Run  | News<br>(301) | MultiSource<br>(294) | Mean  |
|------|---------------|----------------------|-------|
| MT1  | 0.876         | 0.646                | 0.762 |
| MT2  | 0.878         | 0.631                | 0.756 |
| EMAP | 0.719         | 0.411                | 0.567 |

**Table 3:** Official evaluation results for our three runs.

## 4.2 Test results

Test results computed by the organizers are shown in Table 3. Average test results and results on the News part are significantly higher than estimated on the trial data. A large difference is not unexpected considering the test data was clearly very different from the trial data. The average fragment length is 3-4 times larger on News than on trial, for example. We can conjecture that the higher performance on the News test set may actually be due to the longer fragments providing more information to estimate the similarity. On the Multisource test set, on the other hand, all our runs perform poorly. We also note that the performance of the EMAP run is much worse, relative to the MT runs, than could be anticipated from the trial data performance (Table 2). We analyse these differences below.

## 4.3 Analysis

**MT vs EMAP:** As noted above, performance of EMAP was disappointing on the test set, and the gap with MT runs much larger than expected from the trial data. Two main reasons can explain this. First, MT uses monolingual word embeddings directly, and second, we could use 10,662 monolingual pairs with reference STS scores to fit and tune the feature combination model. By contrast, for lack of cross-lingual embedding vectors, the EMAP run had to rely on word alignment to map Spanish words to English embeddings, and the feature combination model could only use 103 cross-lingual pairs with reference STS scores.

**MultiSource performance** is lower than performance on the News part of the test set for almost all systems involved in the evaluation (FBK being the notable exception). The difference is particularly pronounced for our runs: our MT runs are only .035 below the top run on News, which is likely not

significant on 301 examples;<sup>4</sup> our performance on MultiSource, on the other hand, is .17 to .40 below the top runs. Given that this gap is especially pronounced for our systems, we can not rule out formatting errors or inconsistencies on our side. Further investigation will be needed to clarify this.

**Running Time:** One attractive feature of both our approaches is that they rely on shallow semantic features which are easy and fast to obtain using semantic role labeling. The MT runs rely on a SMT system which is expensive to train, but this can be done off-line. Once trained, producing translations is of the order of ten sentences per second. The linear feature combination model is also fast to train and apply, requiring a single dot product between the 12 features and a similarly-sized parameter vector.<sup>5</sup>

## 5 Conclusion

We described the systems used for the submissions of the National Research Council Canada to the crosslingual semantic textual similarity task. We experimented with two approaches. The first estimates a true crosslingual similarity combining lexical semantics and shallow semantic structure. The second uses Machine Translation in combination with a monolingual semantic similarity. We found that the latter outperforms the former. We conjecture that this may be due to the very limited amount of crosslingual data available. By contrast, there are very large corpora available for training a reasonably efficient MT system, and we can rely on a lot of data from previous STS tasks to build a monolingual semantic similarity. Test results indicate that our approach performs relatively well on the News test set, but suffers on the Multisource test set. In addition, the crosslingual approach performs much worse on average on the test data than estimated on the limited trial data. This suggests that it is hard to build a competitive, truly crosslingual approach from little reference data, when it is possible to rely on thousands to millions of examples to build a SMT+monolingual similarity pipeline.

---

<sup>4</sup>Assessing statistical significance would require access to the predictions of the best run.

<sup>5</sup>Prediction for the 301+2973 test examples takes 24ms.

# MayoNLP at SemEval-2016 Task 1: Semantic Textual Similarity based on Lexical Semantic Net and Deep Learning Semantic Model

Naveed Afzal<sup>\*</sup>, Yanshan Wang<sup>\*</sup>, Hongfang Liu

Department of Health Sciences Research

Mayo Clinic, Rochester, MN

{Afzal.Naveed, Wang.Yanshan, Liu.Hongfang}@mayo.edu

## Abstract

Given two sentences, participating systems assign a semantic similarity score in the range of 0-5. We applied two different techniques for the task: one is based on lexical semantic net (corresponding to run 1) and the other is based on deep learning semantic model (corresponding to run 2). We also combined these two runs linearly (corresponding to run 3). Our results indicate that the two techniques perform comparably while the combination outperforms the individual ones on four out of five datasets, namely *answer-answer*, *headlines*, *plagiarism*, and *question-question*, and on the overall weighted mean of STS 2016 and 2015 datasets.

## 1 Introduction

There is a growing need for an effective method to compute semantic similarity between two text snippets. Many natural language processing (NLP) applications can benefit from effective semantic textual similarity (STS) techniques such as paraphrase recognition (Dolan et al., 2004), textual summarization (Aliguliyev, 2009), automatic machine translation evaluation (Kauchak and Barzilay, 2006), tweets search (Sriram et al., 2010), and student answer assessment (Rus and Lintean, 2012; Niraula et al., 2013).

The SemEval STS task series (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015) have provided a vital platform for this task by making available a huge collection of sentence pairs with manual annotation for each sentence pair. The objective of the task is to compute semantic similarity between a pair of sentences in the range [0, 5], and where 0 indicates no similarity and 5 indicates complete similarity.

The approaches for computing semantic similarity between text snippets can be broadly classified into three approaches: information retrieval vector space model (e.g. Meadow, 1992; Sahami and Heilman, 2006), text alignment on the basis of semantic equivalence (e.g. Mihalcea et al., 2006) and machine learning models on the basis of lexical, syntactic and semantic features (e.g. Saric et al., 2012).

In this paper, we describe two techniques for the SemEval 2016 English STS task: the first one adopts the text alignment technique on the basis of semantic equivalence by leveraging a semantic net and corpus statistics; and the second technique is a machine learning models where we utilize a deep learning semantic model.

In the following, we present our techniques in detail and provide the evaluation results of our systems on STS 2016 and 2015 datasets. Conclusions and future directions are also provided.

## 2 System Description

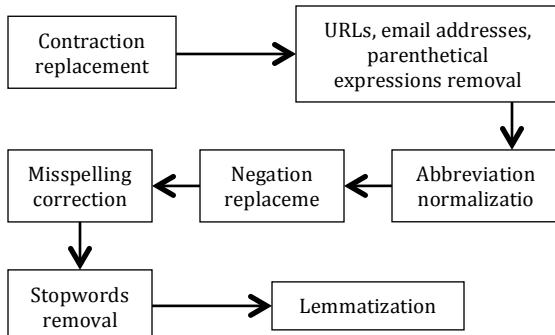

This section describes the data and our systems in detail.

### 2.1 Data

There are five datasets in the SemEval 2016 English STS task: *answer-answer*, *headlines*, *plagiarism*, *postingediting* and *question-question* collected from different sources in this year's English STS task. Each dataset consists of sentence pairs with human-assigned similarity score in the range of 0-5.

## 2.2 Preprocessing

In the preprocessing phase, for each sentence, we use regular expressions in Python<sup>1</sup> to find and replace all text contractions with their respective complete text. For example, “wouldn’t” is replaced with “would not”. All the URLs, email addresses, and parenthetical expressions (in the cases for abbreviation definition) are removed. Then we normalize common abbreviations with their expansions by using synonyms of those abbreviations in a lexical database, WordNet<sup>2</sup>, (for example, “USA” is replaced with “United States of America”) and a manually crafted abbreviation list based on STS 2015 data (for example, “govt” is replaced with “government”, “1.6lb” and “5m” are replaced with “1.6 pound” and “5 million”). Moreover, we replace all the negations such as ‘not present’ with ‘absent’ using WordNet antonyms, and correct misspelled words using an English dictionary provided by a dictionary module pyenchant<sup>3</sup> in Python. Stopwords are removed for datasets *headlines*, *plagiarism* and *postediting*, according to the Stanford stopwords list. For the datasets of *answer-answer* and *question-question*, stopwords are not removed since many pairs only contain stopwords, such as sentence pair “Can you do this?” “You can do it, too”, etc. Finally, the remaining words in each sentence are lemmatized to their base forms using the lemmatizer provided by natural language toolkit (NLTK) in Python. The entire preprocessing workflow is illustrated in Figure 1.

**Figure 1:** Workflow of preprocessing

<sup>3</sup> <https://pypi.python.org/pypi/pyenchant/>

## 2.3 Run 1

Our first technique (official run 1), illustrated in Figure 2, is inspired by the work of Li et al. (Li et al., 2006) where the textual similarity computation is based on both syntactic and semantic similarities.

The main differences of our technique comparing to theirs include preprocessing and synsets selection. We select the most similar pair of synsets from WordNet instead of just picking the first noun synset for each word.

After the preprocessing phase, the textual similarity is derived from the combination of semantic (semantic vectors) and syntactic information (syntactic vectors) present in a sentence pair as detailed in the following.

**Figure 2:** System architecture (Run 1)

We first form a joint word vector (JWV) by collecting unique words that occur in the sentence pair. The semantic similarity is computed by comparing the semantic meaning hidden in the

sentences and the syntactic similarity is computed according to the word order in the two sentences.

To compute semantic similarity of the pair, each sentence is mapped to a vector: if  $i$ th word in J WV is present in the sentence, we assign a value 1 to the  $i$ th entry; otherwise, we calculate the semantic similarity score between the  $i$ th word and each word in the sentence and choose the highest score to be the  $i$ th entry with the aid of the WordNet using the following strategy.

For every two words in the WordNet, we use the path length and depth of two words in the WordNet to calculate  $i$ th entry:

$$s(w_i, w_j) = e^{\alpha l} \cdot \frac{e^{\beta h} - e^{-\beta h}}{e^{\beta h} + e^{-\beta h}},$$

where  $l$  is the length of the shortest path between words  $w_i$  and  $w_j$ ,  $h$  returns a measure of depth in the WordNet, and  $\alpha, \beta$  are constants (0.2 and 0.45 respectively in our experiment).  $\alpha$  and  $\beta$  are dependent on the knowledge base and for WordNet we have used the values for alpha and beta found to be best by Li et al., (2003). The reason behind using depth along with the length of the shortest path is that in the WordNet, words at upper layers are more generic comparing to words at lower layers. If  $s(w_i, w_j)$  is greater than a threshold (0.2 in our experiment) then we set the value to be the score, otherwise we set the value to 0.

The similarity score of the  $i$ th entry is then normalized by multiplying information content score of the  $i$ th word. The information content of word is defined by (Resnik, 1995):

$$I(w) = 1 - \frac{\log(n+1)}{\log(N+1)},$$

where  $N$  is the total number of words in the Brown corpus,  $n$  is the frequency of the word  $w$  in the corpus. According to this definition, the information content score is between 0 and 1. In our system, the information content of each word was computed using the Brown corpus (Francis and Kučera, 1979).

The semantic similarity is then defined as  $S_{sem}$ , which is the cosine similarity between the two vectors corresponding to the sentence pair.

Similarly, to compute syntactic similarity, each sentence is mapped to a syntactic vector. The

dimension of the syntactic vector is identical as the size of the J WV. If the  $i$ th word in the J WV occurs at the  $j$ th position in the sentence, then the value of the  $i$ th entry in the vector is  $j$ . If the  $i$ th word does not exist in the sentence, the value of the  $i$ th entry is the position of the most similar word obtained from WordNet using  $s(w_1, w_2)$ . Different from the form of semantic similarity measure, syntactic similarity should take word order information into consideration. Therefore, the syntactic similarity is defined by:

$$s_{syn} = 1 - \frac{|o_1 - o_2|}{|o_1 + o_2|},$$

where  $o_1$  and  $o_2$  represent syntactic vector for sentences  $s_1$  and  $s_2$  respectively. From the definition of syntactic vector, we see that it contains the basic structural information of a sentence and measure the word order similarity between two sentences.

Since semantic similarity represents the lexical similarity while syntactic similarity contains information about the orders between words, both contribute in conveying the similarity of the sentences. Therefore, the final sentence pair similarity is defined by combining semantic similarity and syntactic similarity, i.e.

$$S(s_1, s_2) = \Omega s_{sem} + (1 - \Omega) s_{syn}$$

Since syntax plays a subordinate role for semantic processing of text we used  $\Omega$  ( $\Omega = 0.85$ ) in the final similarity.

## 2.4 Run 2

Our second system (run 2) is built upon a Deep Structured Semantic Model (DSSM) proposed by Huang et al., (2013). DSSM is a deep learning based technique that is proposed for semantic understanding of textual data. It maps short textual strings, such as sentences, to feature vectors in a low-dimensional semantic space. Then the vector representations are utilized for document retrieval by comparing the similarity between documents and queries. DSSM is reported to outperform other semantic models applying to document retrieval (Huang et al., 2013). However, the performance has not been evaluated to measure the degree of

similarity in the underlying semantics of paired snippets of text.

DSSM uses the typical deep neural network (DNN) architecture to represent a sentence (document) in the semantic vector space. Unlike other DNN where bag-of-word (BoW) term vectors are used as input, DSSM employ a novel word hashing method to reduce the dimensionality of the BoW vectors. Specifically, each word (for example, ‘girl’) is attached with a word starting mark and an ending mark (i.e., ‘#girl#’) and split into letter trigrams (i.e., #gi, gir, irl, rl#). By doing so, the dimension is reduced to the number of trigrams, which is 3073 in our system. Then, each word representing by a vector of letter trigrams is used as input to the DNN.

The layers in DNN consists of three parts, namely, word hashing layer, hidden layers, and top layer, where the layer functions are:

$$l_1 = W_1 x,$$

$$l_i = f(W_i l_{i-1} + b_i), i = 2, \dots, N - 1,$$

and

$$y = f(W_N l_{N-1} + b_N),$$

where  $x$  is the input term vector,  $y$  the output vector,  $l_i, i = 1, \dots, N - 1$  the hidden layers,  $W_i$  the  $i$ th weight matrix,  $b_i$  the  $i$ th bias, and  $f(\cdot)$  the *tanh* activation function. The feature vectors generated by the word-hashing layer are projected through the hidden layers, and formed as semantic feature vectors in the top layer.

After obtaining the semantic feature vectors for each paired snippets of text, cosine similarity is utilized to measure the semantic similarity between the pair. Since the elements of semantic vector are nonnegative and the range of cosine similarity is  $[0, 1]$ , we used the simplest linear transformation to map the range into  $[0, 5]$ .

Regarding the implementation of DSSM, we exploit the Sent2Vec tool. Sent2Vec provides DSSM and convolutional DSSM (C-DSSM) (Gao et al., 2014; Shen et al., 2014). Based on our experiments on the SemEval 2015 English STS datasets, the performance of DSSM is slightly superior to C-DSSM without statistical significance. Therefore, DSSM is utilized in the official run 2. In the DSSM, we used one hidden layer with 1000 hidden nodes in the neural networks. A larger number of hidden layers or

hidden nodes may be applied though we used the simplest one due to the computational complexity.

## 2.5 Run 3

Our run 3 is a linear combination of run 1 and run 2, i.e.,

$$S_{run3} = \alpha \cdot S_{run1} + \beta \cdot S_{run2}$$

where the equal weights are assigned to run 1 and run 2, i.e.,  $\alpha = \beta = 0.5$

## 3 Evaluation

We submitted 3 runs at SemEval 2016 English STS task based on the Section 2.

| Dataset                                 | Run 1   | Run 2   | Run 3   | Best    |
|---|---------|---------|---------|---------|
| <b>answer-answer</b><br>(254 pairs)     | 0.58873 | 0.57739 | 0.61426 | 0.69235 |
| <b>headlines</b><br>(249 pairs)         | 0.73458 | 0.75061 | 0.77263 | 0.82749 |
| <b>plagiarism</b><br>(230 pairs)        | 0.76887 | 0.80068 | 0.80500 | 0.84138 |
| <b>postediting</b><br>(244 pairs)       | 0.85020 | 0.82857 | 0.84840 | 0.86690 |
| <b>question-question</b><br>(209 pairs) | 0.69306 | 0.73035 | 0.74705 | 0.74705 |
| <b>Weighted Mean</b>                    | 0.72646 | 0.73569 | 0.75607 | 0.77807 |

**Table 1:** Official Results of evaluation on STS 2016 data

Table 1 shows the performance of each official run. This is reported as the Pearson correlation between the scores produced by our systems and the human annotations. The last row shows the value of weighted mean that is the sum of all datasets correlation scores. The weight assigned to a dataset is proportional to its number of pairs.

Our run 1 performed better than run 2 on the following datasets: *answer-answer* and *postediting* while run 2 performed better than run 1 on the following datasets: *headlines*, *plagiarism* and *question-question*. Our run 3 that is a linear combination of run 1 and run 2 is the best performing system in terms of weighted mean.

### 3.1 Performance on STS 2015 Data

We also applied our systems on the SemEval 2015 English STS task data. Table 2 shows the evaluation results on STS 2015 data. We can observe that mean run 3 outperforms run 1 and run 2 in terms of overall weighted mean. However, for *answers-students* dataset the performance of run 1 is better than other runs, and for datasets *belief* and *images* run 2 perform better than other two runs. The reason might be that run 1 considers word order information, which is crucial information when describing math or chemistry problems in dataset *answers-students*.

| Dataset                                | Run 1  | Run 2  | Run 3  | Best   |
|--|--------|--------|--------|--------|
| <b>answers-forums</b><br>(375 pairs)   | 0.7049 | 0.6660 | 0.7246 | 0.7390 |
| <b>answers-students</b><br>(750 pairs) | 0.7422 | 0.6770 | 0.7416 | 0.7879 |
| <b>belief</b><br>(375 pairs)           | 0.7287 | 0.7439 | 0.7389 | 0.7717 |
| <b>headlines</b><br>(750 pairs)        | 0.7630 | 0.7749 | 0.7776 | 0.8417 |
| <b>images</b><br>(750 pairs)           | 0.8198 | 0.8576 | 0.8367 | 0.8713 |
| <b>Weighted Mean</b>                   | 0.7604 | 0.7536 | 0.7719 | 0.8015 |

**Table 2:** Results of evaluation on STS 2015 data

## 4 Conclusions and Future Work

In this paper, we presented three systems for measuring the semantic similarity between two sentences. The systems will be released in the future at GitHub.<sup>1</sup> Our systems give promising results on both English STS datasets 2015 and 2016. Our first system relies on a lexical database and corpus statistics. A lexical database represents common human knowledge about a natural language while a corpus reflects the actual usage of language and words. Our second system utilizes

deep learning semantic model while our third system is an ensemble of system 1 and 2.

In our future work, we would like to investigate the different contributions of syntactic similarity and semantic similarity in run 1 and improve the performance of run 1 by adding new corpora to increase the impact of corpus statistics. For the second system, we would like to test whether adding additional hidden layers into the deep neural net improves the performance. Currently, our third system is a linear combination of system 1 and 2 by using heuristic weights since no training data were given in the task and we concerned about over-fitting if the data from previous years were used to train our system. In the future we would like to investigate whether the performance could be improved by applying supervised or unsupervised machine learning algorithms to calculate the optimal weights based on the previous data sets. Moreover, we would like to extend our systems into the biomedical domain with the use of biomedical lexical databases and biomedical corpora.

## Acknowledgments

Our participation of STS is partially supported by the grants received from NIGMS R01 GM102282 and from National Library of Medicine R01LM11934.

## Abstract

We present in this paper a system for measuring Semantic Text Similarity (STS) in English. We introduce three novel techniques: the use of *Types*, methods of linking phrases, and the use of a *Surprise Factor* to generate 8,370 similarity measures, which we then combine using Support Vector and Kernel Ridge Regression. Our system out performs the State of the Art in SemEval 2015, and our best performing run achieved a score of .7094 on the 2016 test set as a whole, and over 0.8 on the majority of the datasets. Additionally, the use of Surprise, Types and phrase linking is not limited to STS and can be used across various Natural Language Processing tasks, while our method of combining scores provides a flexible way of combining variously generated Similarity Scores.

## 1 Introduction and Motivation

The goal of Semantic Text Similarity (STS) is to find the degree of overlap in the meaning of two pieces of text. This ranges from text fragments that are exact semantic equivalents, to others that have no semantic relation. STS has a wide variety of applications, including text summarisation (Aliguliyev, 2009), machine translation (Kauchak and Barzilay, 2006), and search optimisation (Sriram et al., 2010).

The STS task, which has been set by the SemEval conference for the past number of years (Agirre et al., 2014; Agirre et al., 2015), requires that submitted systems assign a score between 0 (the sentences are on different topics) and 5 (the sentences mean

exactly the same thing) that reflects how similar two sentences are.

Most systems that tackled SemEval’s STS task in previous years have involved three main approaches: The first is text alignment, based on the content words’ meaning (Sultan et al., 2015; Sultan et al., 2014b). The second represents text as vectors, which are used to find the similarity score using a vector similarity metric (such as cosine). Third, machine learning approaches are used to compute multiple lexical, semantic, and syntactic features to classify each sentence pair’s similarity.

We make use of both text alignments and vector representations, while limiting comparisons to words of the same *Type* (Section 4.1), a novel concept we introduce in addition to methods of phrase linking (Section 4.2) and establishing common noun importance (Section 4.3). These, combined with several different weight combinations we pick for each word *Type*, provide us with 8,370 semantic relation measures (Section 5). The overall algorithm for generating the several similarity measures is presented in Algorithm 1. We choose a subset of these measures using methods detailed in Section 6.1, combine them with a limited set of features and use Support Vector Regression and Kernel Ridge Regression to generate a Similarity Score (Section 6.2).

Our approach also handles definitions separately from arbitrary sentences, as we observed that their structure is significantly different. Since the test data provided this year did not contain a definition data set, this paper focuses on our generic approach, with definition similarity discussed briefly in Section 7.

## 2 Preprocessing

Due to the varied nature of the input presented we perform various data cleaning operations. We start by expansion of common contractions (e.g. “isn’t”) and informal contractions (e.g. “howz”, “coulvے”). We then perform a spell check and hyphen removal, which are conditional, in the sense that a word is not modified unless the modified form appears in the other sentence. All remaining hyphens are replaced by spaces, a method different from those that previously handled hyphens (Han et al., 2013).

We also perform case correction, as has been done previously (Hänig et al., 2015), since we observe several instances wherein sentence capitalisation is not suitable for parsing (e.g. headlines and forums).

## 3 Similarity Measures

We use two measures, which are boosted based on different parameters described in Section 4.

### 3.1 Alignments

The first measure makes use of the aligner developed by Sultan et al. (2014a), which was used to achieve State of the Art results in 2014 and 2015 (Sultan et al., 2014b; Sultan et al., 2015).

Our use of the aligner disregards sequences thus making use of the aligner more as a synonym finder, with the additional power of the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013).

### 3.2 Word Embeddings

Word embeddings provide a method of mapping words or phrases to vectors, whose cosine distance represents semantic similarity. They have proved to be powerful in many NLP tasks, and have been used by top ranking systems at SemEval STS (Sultan et al., 2015; Hänig et al., 2015). We use word2vec<sup>1</sup>, with the model trained by Google on the Google News dataset, through its Python interface Gensim<sup>2</sup>.

We make use of word2vec in two distinct ways. The first is by extracting the mean of the vector representation of each word in a Type and finding its cosine similarity between the two sentences. The second is by adding the word2vec similarity scores of words not aligned within the same Type. We also

provide the option of disregarding word pairs that have a score of less than 0.3, a method similar to that by Hänig et al. (2015).

## 4 Boosting Similarity

In this section, we detail the variations used to generate different similarity measures. These variations are not used simultaneously, but are instead combined as described in Algorithm 1 (Section 5), which iterates through all possible variations to generate a different similarity score associated with each combination.

### 4.1 Type Specific Comparison

Given a sentence pair, we calculate their similarity based only on how similar corresponding Parts-of-Speech (POS) are, a method previous systems have made use of, either implicitly (Kashyap et al., 2014; Sultan et al., 2015) or explicitly (Hänig et al., 2015).

We extend this idea by defining what we call word *Types*, which further subdivide each POS. A Type represents an abstract concept that several words can share. Consider the sentence pair “A man is sitting on a stool”, “A boy is sitting on a chair”. Although the words “man”, “boy”, “stool” and “chair” are all nouns, an effective strategy for comparing these sentences would be to compare the first two and the last two words independently, before then adding up their similarity. To achieve this we categorise words into different Types, which are then compared across sentences. In this case, such a categorisation might place the first two into the Type “Person” and the others into the category “Artifact”. This problem could very easily extend to the problem of Word Sense Disambiguation, which we avoid by use of a heuristic.

We calculate the Type of a noun by the use of WordNet (Miller, 1995) hypernyms:  $W_1$  is considered a hypernym of  $W_2$  if  $\forall e \in W_2$ ,  $e$  is an instance of  $W_1$ . We recursively find hypernyms until we reach a manually selected set of concepts (such as food.n.02). We manually combine sets of such concepts to define a Type. As a concrete example, we combine the WordNet concepts “communication.n.02”, “food.n.02” and other similar concepts into the Type “thing.r1”. As a single word can be part of several Types, based on the particular sense

<sup>1</sup><https://code.google.com/p/word2vec/>

<sup>2</sup><https://radimrehurek.com/gensim/models/word2vec.html>

of the word, we pick the most frequently occurring Type for each word.<sup>3</sup>

## 4.2 Phrase Linking

Consider sentences with the the phrases “Prime Minister” and “Prime Number”. Although the word “Prime” is present in both sentences, the context in which it is being used makes this irrelevant. In this particular case, the semantic similarity of the sentences is dependent on the head of the phrase that the word “Prime” is contained in (i.e. “Minister” and “Number”). This is also the case with phrases that contain adjectives and adverbs.

We address this by finding phrases that consist of adjectives, adverbs and nouns, and varying the importance of the semantic similarity between words that are not the head of that phrase. The similarity of each word, that is part of such a phrase, but not the head of the phrase, is additionally weighted in three different ways: The first assigns a zero or one weight based on whether or not the head of the phrase is aligned, the second provides a weight based on the number of words, following this word, that are aligned in the phrase and the third simply ignores the phrase structure.

## 4.3 Noun Importance

Consider the following sentence pairs with relations assigned by human annotators: “A *boy* is playing a guitar.”, “A *man* is playing a guitar.”, rel: 3.2; and “A man is cutting up a *potato*.”, “A man is cutting up *carrots*.”, rel: 2.4. Although both pairs of sentences differ by exactly one noun, the first pair was considered to be more closely associated than the second. We associate this to what we call the “Surprise” and assign a value to this, which we call the “Surprise Factor”.

Surprise is based on the work by Dunning (1993), who observed that the assumption of normality of data is invalid as “simple word counts made on a moderate-sized corpus show that words that have a frequency of less than one in 50,000 words make up about 20-30% of typical English language news-wire reports. This ‘rare’ quarter of English includes many of the content-bearing words . . .”

---

<sup>3</sup>The termination concepts, corresponding Types, definitions for non-noun types, and Weights are provided online at: [www.harishmadabushi.com/SemEval2016/Appendix.pdf](http://www.harishmadabushi.com/SemEval2016/Appendix.pdf)

We define the Surprise Factor of a noun or phrase to be proportional to the number of Web Search Hits for that phrase or term, while inversely proportional to the Search Hits in the case of proper nouns. Intuitively this makes sense, as words that are more common will generate less Surprise, carry less information, and will also be more widely used on the Internet.

We incorporate this idea of Surprise by adding the option of additionally weighting nouns by the total number of Web Search Hits or Results<sup>4</sup>. We define,  $H_i$  to be the the number of Web Search Hits for the noun  $i$ ,  $HT$  the total number of hits for all nouns  $HT = \sum_{i=0}^N H_i$ ,  $N_i$  the fraction of the Search Hits that noun  $i$  captures  $N_i = \frac{H_i}{HT}$ , and  $NT$  the normalised total of all nouns ( $C$ ) in a given sentence  $NT = \sum_{i=0}^C N_i$ . We define the Surprise of word  $i$  in terms of the above in Equation 1.

$$S_i = \frac{N_i}{NT} \quad (1)$$

## 5 System Overview

Algorithm 1 provides an overview of the system we use to generate the various Similarity Scores, We call each combination that generates a score a “Method”. We use thirty weights for Types<sup>3</sup>, while providing the option of dividing the scores by the number of WordNet Synsets (UseSSToWeight), which captures any dilution due to a word’s different senses. We also scale word2vec scores by different values. This gives us a total of 8,370 “Methods”.

In calculating the similarity score, we capture the fraction of each Type that is aligned and scale it by the weight of that Type. This is captured in Equation 2 where  $score_t$  represents the Similarity Score assigned to Type  $t$  by either of the measures detailed in Section 3,  $count_t$  represents the number of words of Type  $t$  in *both* sentences,  $w_t$  the weight of Type  $t$  in the current iteration, and  $T$  is the total number of Types.

$$5 \times \left( \frac{\sum_{t=0}^T score_t \times w_t \times 2}{\sum_{t=0}^T count_t \times w_t} \right) \quad (2)$$

            Return SimScores (the list of similarity scores);

```

**Algorithm 1:** Calculating Semantic Similarity Scores

## 6 Combining Similarity Scores

As described above, we use variations to generate thousands of Similarity Scores, each of which we call a “Method”. Each Method’s performance varies depending on the input. In this section, we detail the process for combining these Methods, which is performed using either Support Vector Regression (SVR) or Kernel Ridge Regression (KRR).

### 6.1 Picking a Subset of Methods

We first select a subset of the Methods, which are then passed on to either the SVR or KRR model. To do this, each of our Methods is ranked using three metrics with respect to the training set: The first is by use of the Pearson Correlation (a criterion we call “Method”), the second is by the sum of the absolute error between Similarity Scores (a criterion we call “Error”). The third metric aggregates the the rankings from the two criterion described above, and we call this criterion “Combine”. We select the top 50 methods using one of the three selection criterion.

### 6.2 Generating Similarity Scores

In addition to using scores from the chosen Methods, we add the following features to some of our submitted runs: a) a binary value to represent whether each of the sentences were case corrected, b) the length of each of the sentences, c) the number of contin-

uous aligned or unaligned sequences, d) the maximum and minimum lengths of continuous aligned or unaligned sequences, and e) a binary value to represent alignments that are non-sequential.

It should be noted that the specific Methods we choose for use in the SVR or KRR will depend on the training data picked. We found, by testing our system using several different combinations of training data, that the best results were achieved when our system was trained on the headlines data from the years 2015, 2014 and 2013. The method selection criterion, regression model and parameters used for each of the runs submitted are detailed in Table 1. Although some of the settings are very similar (e.g. run2), we noticed that these minor changes translated to significant differences in performance.

| Run  | Headlines |           | Other Datasets |           |
|------|-----------|-----------|----------------|-----------|
|      | Model:    | KRR       | Model:         | SVR       |
| Run1 | Features: | False     | Features:      | False     |

## 7 Finding Similarities between Definitions

In order to find similarities between definitions, we first identify the word that a definition is defining. We achieve this by use of OneLook’s reverse dictionary search<sup>5</sup>, which returns a number of candidate

<sup>5</sup><http://www.onelook.com/reverse-dictionary.shtml>

words for a given definition. For each definition, the similarity of the top 10 candidates is then computed using Word2Vec and five similarity metrics provided by WordNet: Path distance, Leacock-Chodorow, Wu and Palmer, Jiang-Conrath and Lin. The final score is scaled between 0 and 5 and averaged across the 10 candidates returned by OneLook.

We found this method of calculating similarities between definitions to be very good at telling if two definitions refer to the same word, but not ideally suited for measuring *how* similar they are. As a consequence, we found that results were clustered around 0 and 5. The system produced a Pearson correlation of 0.69 on the SemEval 2014 definitions data set.

## 8 Results and Analysis

| Dataset     | Best   | Run1   | Run2   | Run3   |
|-------------|--------|--------|--------|--------|
| Mean        | .77807 | .70940 | .70168 | .70911 |
| postediting | .86690 | .81272 | .80835 | .81333 |
| ques-ques   | .74705 | .56040 | .47904 | .56451 |
| headlines   | .82749 | .81894 | .82352 | .81894 |
| plagiarism  | .84138 | .82066 | .82406 | .81958 |
| ans-ans     | .69235 | .52460 | .55217 | .52028 |

**Table 2:** Performance on the 2016 STS Test Set

We list the performance of our system in Table 2. Our system’s poor performance on the ans-ans and ques-ques datasets can be attributed to our choice of training data, which, although well suited for previous years, was not well suited for these datasets.

However, our system produces State of the Art results on the 2015 Test Sets. A breakdown of each of the run’s performance against the 2015 STS data set is provided in Table 3. We note that the results we have reported for previous State of Art for individual data sources are not the results from just the winning system but the State of Art across all Systems for that data source. Our system also achieves comparable results (0.7793) to that presented by Sultan et al. (2015) (0.779) on the 2014 STS dataset. The weighted mean reported by us does not include definitions as we decided to consider them independently.

Table 4 provides a comparison of our system against the previous State of the Art for the STS 2014 data set. The overall State of Art across all data sets was reported by Sultan et al. (2015) based

on their 2015 System.

## 9 Conclusion and Future Work

In this paper we have described the system we used for participation in the SemEval STS Monolingual Task which made use of Types, Phrase Linking, and a method of establishing common noun importance.

In the future, we intend to experiment with including features for each of the Methods during the training phase, other kinds of phrases, and different Type definitions. We also intend to use the STS data for learning the weights of different Types for use in other NLP applications.

We believe that Types have significant potential and intend to explore them in greater detail. Our immediate objectives will be in better defining types, re-categorising common noun Types based on clearer instructions to manual annotators, including finer definitions of Types for proper nouns using named entity recognition, and exploring methods of defining Types for verbs, adverbs and adjectives. We also intend to explore the use of Types in Question Classification and Question Answering.

## Abstract

This paper describes three unsupervised systems for determining the semantic similarity between two short texts or sentences submitted to the SemEval 2016 Task 1, all of which make use of only off-the-shelf software and data making them easy to replicate. Two systems achieved a similar Pearson correlation coefficient (0.64661 by simple vector, 0.65319 by word alignments). We include experiments on using our alignment based system on evaluation data from the 2014 and 2015 STS shared task. The results suggest that beyond the core similarity algorithm, other factors such as data preprocessing and use of domain-specific knowledge are also important to similarity prediction performance.

## 1 Introduction

Given two short texts or sentences, similarity systems or models should output a score that reflects how similar the two texts are in meaning. Semantic textual similarity (STS) formalizes an operation that is an important component of many natural language processing systems and has generated substantial interest within the research community (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). STS methods can be applied in example-based machine translation, machine translation evaluation, information retrieval, text summarization, question answering, and recommendation systems.

---

<sup>\*</sup>Corresponding author

## 2 System Overview

In STS 2016, we submitted three system runs, and all of which were unsupervised. They could be generally divided into two kinds: vector based and alignment based.

### 2.1 Run 1: Simple Vector Method

In this run, we use a sentence vector derived from word embeddings obtained from word2vec (Mikolov et al., 2013). Using these sentence level vector representations, the similarity between two texts can be computed using the cosine operation.

We train word embeddings by running the word2vec toolkit<sup>1</sup> over the fifth edition of the Gigaword corpus (LDC2011T07). We preprocess the Gigaword data with the following tools from the Moses machine translation toolkit (Koehn et al., 2007): the data is tokenized using tokenizer.perl; truecase.perl4 is used to standardize capitalizing.

As illustrated in Equation (1), we construct the sentence vector  $\vec{s}$  by simply summing together the word embeddings,  $\vec{t}_i$ , associated with each token in a sentence.

$$\vec{s} = \sum_{i=1}^{|s|} \vec{t}_i . \quad (1)$$

Here  $|s|$  is the number of tokens that the sentence contains.

The similarity between a pair of sentences is computed as the cosine of their associated sentence level embedding vectors.

## 2.2 Run 2: Weighted Vector Method

The above method weights all word embeddings equally. We submitted an alternative run that weights the word embeddings by the information content (IC) of the concepts referenced by their word sense tagged tokens (Resnik, 1995). Word sense disambiguation is performed using BabelNet (Navigli and Ponzetto, 2012) with the WordNet (Miller, 1995) sense inventory. NLTK (Bird, 2006) is used to obtain the frequencies of words belongs to the WordNet synset. The probability associated with each concept is estimated over the BNC<sup>1</sup> using add one smoothing. Following Resnik (1995), we then compute the information content of each concept as follows:

$$IC(c) = -\log P(c). \quad (2)$$

Here  $P(c)$  refers to the statistical frequency of concept  $c$ .

This method allows us to compute IC based weights only for the nouns and verbs covered by WordNet. We heuristically set the weight of adjectives and adverbs to 5 and other words to 2.

## 2.3 Run 3: Word Alignment Method

Our final run differs from the vector based methods described above and follows a popular alternative approach to assessing sentence similarity through word alignments. We make use of Sultan et al. (2014a)'s open-source monolingual word aligner with default parameters and the similarity formula proposed in Sultan et al. (2015). An unsupervised system based on Sultan et al. (2015)'s similarity formula above took fifth place at STS 2015. Its predecessor, based on a similar formula, took 1st place at STS 2014. As shown in Equation (3), similarity is computed as

$$sts(S^{(1)}, S^{(2)}) = \frac{n_c^a(S^{(1)}) + n_c^a(S^{(2)})}{n_c(S^{(1)}) + n_c(S^{(2)})}. \quad (3)$$

Here  $n_c^a(S^{(i)})$  and  $n_c(S^{(i)})$  are the number of content words and the number of aligned content words in sentence  $S^{(i)}$ , respectively.

| No. | Dataset           | Total Pairs | Pairs with GS |
|-----|-------------------|-------------|---------------|
| 1   | answer-answer     | 1572        | 254           |
| 2   | headlines         | 1498        | 249           |

| 5   | question-question | 1555        | 209           |
|     | Total             | 9183        | 1186          |

**Table 1:** Test sets at SemEval STS 2016.

## 3 Data

As shown in Table 1, the 2016 STS shared task included 5 distinct datasets. Systems were required to annotated between 1,498 and 3,287 pairs per dataset. System performance was evaluated on a subset of each dataset consisting of between 209 to 255 gold standard (GS) pairs.

The GS similarity scores for each pair range from 0 to 5, with the values having the corresponding interpretations:

5 indicates completely equivalence; 4 expresses mostly equivalent with differences only in some unimportant details; 3 means roughly equivalent but with differences in some important details; 2 means non-equivalence but sharing some details; 1 means the pairs only share the same topic; and 0 represents no overlap in similarity.

We note that there is a big gap between 0 and 1 in GS metric: Intuitively, within the range [1,5], scores linearly represent the similarity between two texts. However, there is a much larger conceptual range of topical similarity that spans from pairs on the exact same topic to those that are completely dissimilar.

## 4 Evaluation

The evaluation metric is the Pearson correlation coefficient (PCC) (Brownlee, 1965) between system output and the gold standard. PCC is used for each individual test set, and the final evaluation is measured by weighted mean of PCC on all datasets (Agirre et al., 2012).

### 4.1 STS 2016 Results

Performances of our three systems on each of STS 2016 test sets are showed in Table 2, and the last two columns show the results of the following modified versions of Run 2 and Run 3.

**Run 2':** Word embedding vectors are normalized to have length=1, and the heuristic IC weights are

<sup>1</sup><http://ota.ox.ac.uk/desc/2554>

| No.  | Run 1         | Run 2  | Run 3         | Run 2'        | Run 3'        |
|------|---------------|--------|---------------|---------------|---------------|
| 1    | .48863        | .37565 | <b>.54530</b> | .52210        | <b>.64349</b> |
| 2    | .62804        | .55925 | <b>.78140</b> | .69421        | <b>.80295</b> |
| 3    | .80106        | .75594 | <b>.80473</b> | .78410        | <b>.81391</b> |
| 4    | <b>.79544</b> | .77835 | .79456        | .79666        | <b>.79863</b> |
| 5    | <b>.51702</b> | .51643 | .29972        | <b>.58535</b> | .57826        |
| Mean | .64661        | .59560 | <b>.65319</b> | .67668        | <b>.73044</b> |

**Table 2:** Performance on STS 2016. The last row shows weighted mean which is the final evaluation metric, and the last two columns describe modified versions of Run 2 and Run 3.

adjusted as follows: 6 for adjectives and adverbs and 3 for other words.

**Run 3':** If there is no content word aligned, we make use of longest common substring algorithm to obtain the longest common consecutive words (LCCW) of the compared sentences. Similarity is computed as

$$sts(S^{(1)}, S^{(2)}) = \frac{2 \times |LCCW(S^{(1)}, S^{(2)})|}{|S^{(1)}| + |S^{(2)}|}. \quad (4)$$

Here  $|LCCW(S^{(1)}, S^{(2)})|$  is the number of words that are present in the LCCW of  $S^{(1)}$  and  $S^{(2)}$ .

Words are classified as content words if they are either nouns, verbs, adjectives or adverbs with a small number of exceptions. We elected to classify *think*, *know*, *want* and *act* as non-content words based on their IDF scores.

From Table 2, we make the following observations:

1. From our submitted systems, we obtain the best overall results from Sultan et al. (2015)'s word alignment based method (0.65319). However, the simple vector method (0.64661) is very close in performance with only a 0.00658 absolute difference in the overall correlation scores.
2. Weighting the raw word embeddings by their IC degraded performance on all of the datasets. Run 2' normalized the word embedding vectors before taking the IC weighted vector sum, resulting in significantly improved performance over both the submitted Run 2 as well as over Run 1's simple summation of the embedding vectors. This shows any reweighting of the

**Table 3:** Table 3: Run 3 and Run 3' performance on STS 2014 and 2015. For each year, the third column shows the performance of the submitted unsupervised system with the best overall performance for that year. The forth column shows the best per dataset performance across submitted unsupervised systems.

word level embedding vectors needs to account for differences in the magnitude of the raw embeddings.

3. The best performance of all of our systems is achieved by Run 3', which included additional logic to handle pairs with no aligned content words. However, both Run 3 and Run 3' performed particularly badly on the question-question dataset. Inspecting the data reveals that some sentence pairs have a GS score of 0 even when there is some level of similarity between what is being asked, such as "What's the best way to store asparagus?" vs "What's the best way to store unused sushi rice?". We also observe that many pairs in this dataset set have similarly structured sentences with particular core words playing a decisive role.

## 4.2 Results on Past Test Sets

In order to better frame the performance of our systems, we examined the performance of Run 3 and Run 3', our word alignment base systems, on the STS shared task evaluation sets from 2014 to 2015. Recall that our method is unsupervised and most comparable to Sultan et al. (2015)'s unsupervised system submission. We contrast our results with both Sultan et al. (2014b)'s best shared task

submission and to Sultan et al. (2015)’s supervised extension to the unsupervised system. The results are shown in Table 3.

At the SemEval 2014 STS task, unsupervised DLS@CU2014-run 2 (Sultan et al., 2014b) achieved the highest final PCC score across all 38 submitted systems runs. Sultan et al. (2015) submitted a supervised system that contained only two features: (1) the similarity score from the unsupervised Sultan et al. (2015) system; (2) a complementary feature based on the cosine of the sentence level vector representations obtained by averaging word-level embedding vectors. This system took first place in the 2015 shared task, with the unsupervised Sultan et al. (2015) system coming in 5th place. Our Run 3 and Run 3’ systems are identical to Sultan et al. (2015)’s unsupervised system except for differences in text preprocessing. We observe that our performance may have been diminished by not performing the following preparation steps:

1. Our systems didn’t use a spelling correction module, such as a levenshtein distance of 1 between a misspelt word and a correctly spelt word before running the aligner or finding word vectors.
2. Knowledge of domain-specific stop words was not taken into account in submitted systems.

We suspect these contributed to the performance gap between our system and even the very similar Sultan et al. (2014b) submission.

## 5 Conclusions and Future Work

At SemEval 2016, we submitted three unsupervised STS systems: simple vector method, weighted vector method and word alignment method. Two make use of sentence level embedding vectors and the other applies a known well performing method for calculating STS similarity scores that is based on monolingual word alignments. We observe that both types of systems are able to achieve a similar PCC. Based on observations obtained by running our system on evaluation sets from earlier years, we believe our system could have been improved by including more of the text preprocessing steps performed in prior work.

First, our systems should introduce a spelling correction module to deal with misspelt words, which is a good way to increase the recall of the input. Second, domain-specific knowledge should be taken into account, such as domain-specific stop words, which can adapt to requirements posed by different data domains and applications. In future work, we hope to investigate the use of domain-specific weights for words as well as other methods for term weighting such as TF-IDF.

hideo.itoh@nts.ricoh.co.jp

## Abstract

This paper describes our IR (Information Retrieval) based method for SemEval 2016 task 1, Semantic Textual Similarity (STS). The main feature of our approach is to extend a conventional IR-based scheme by incorporating word alignment information. This enables us to develop a more fine-grained similarity measurement. In the evaluation results, we have seen that the proposed method improves upon a conventional IR-based method on average. In addition, one of our submissions achieved the best performance for the “postediting” data set.

## 1 Introduction

Given two sentences, Semantic Textual Similarity (STS) measures their degree of semantic equivalence (Agirre et al., 2015). This fundamental functionality can be used for many applications such as text search, classification and clustering.

This paper describes our monolingual (English) STS system which participated in SemEval 2016 task 1. Our objective is to improve a conventional IR (Information Retrieval) based method for the STS task. In general, an IR-based method estimates semantic similarity between given sentences using similarity between document search results which are obtained using each sentence as a search query. This scheme allows us to utilize a large document database for handling diverse semantic phenomena. However, in our preliminary experiments using past SemEval test data, a conventional IR-based method was not so effective.

In failure analysis of the method, we found the following:

- It is not sufficient only to measure the commonality among sentences.
- It is necessary to measure the importance of the identified commonality in each sentence.

Based on these findings, we propose a new IR-based method for STS. In this method, word alignment techniques are applied to refine the assessment of commonality. The importance of the commonality in each sentence is measured using IR techniques.

## 2 Related Work

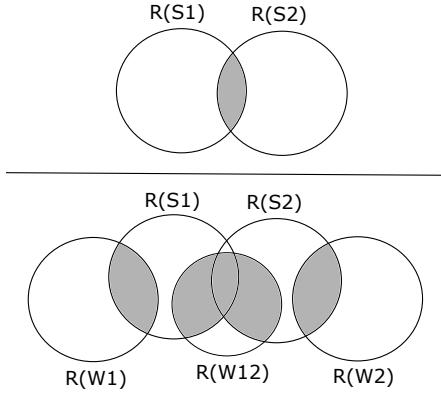

Let us define a conventional IR-based approach more formally and generally. For a given text  $T$ , a document retrieval is performed using  $T$  as a search query. The search target  $U$  is a set of documents. As a result, a document set  $R(T, U)$  is obtained. Because  $U$  has been fixed in our research, we denote  $R(T, U)$  as  $R(T)$ . The semantic similarity between two texts  $T_1$  and  $T_2$  is measured as the similarity between document sets  $R(T_1)$  and  $R(T_2)$ .

Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2007) is a well-known IR-based approach. In their research, Wikipedia articles are used as  $U$ .  $R(T)$  is regarded as a vector of documents and the cosine similarity of vectors is used to measure the semantic similarity.

In previous STS competitions, we can find IR-based approaches in Buscaldi et al. (2013), more recently Buscaldi et al. (2015). In their research,  $R(T)$  is regarded as a list of ranked documents with search scores. They defined an original similarity score using the rank and search score of each document.

### 3 Our Approach

Figure 1 both illustrates our approach and contrasts it with conventional IR-based methods.

**Figure 1:** IR-based Semantic Similarity Measures

A conventional IR-based approach is shown at the top of the figure and is followed by our approach. Each of circles  $R(T)$  represents documents retrieved for a query text  $T$ . Assuming the retrieved documents are ranked by search scores, the top-N documents are used as  $R(T)$ , where  $N$  is a constant. For the STS task, the conventional approach only uses the sentences  $S1$  and  $S2$  as search queries. The similarity between  $S1$  and  $S2$  is measured by calculating the ratio of the gray-colored set intersection to the union of  $R(S1)$  and  $R(S2)$ . Specifically, the similarity function  $Sim$  is given by the Dice coefficient (Dice, 1945) expressed in Formula 1.

$$Sim(S1, S2) = \frac{2|R(S1) \cap R(S2)|}{|R(S1)| + |R(S2)|} \quad (1)$$

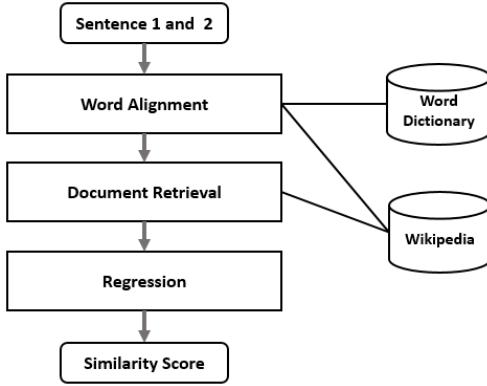

In our approach, additional document sets  $R(W1)$ ,  $R(W2)$  and  $R(W12)$  are used, where  $W12$  is a set of words which are aligned between sentence  $S1$  and  $S2$ , while  $W1$  and  $W2$  are the set of words that are left unaligned in  $S1$  and  $S2$ , respectively. Our method still computes the conventional  $Sim(S1, S2)$  but then also calculate  $Sim(S1, W1)$  and  $Sim(S1, W12)$ . Similarly,  $Sim(S2, W2)$  and  $Sim(S2, W12)$  are also obtained. All together, five similarity values are used as regression features within a model trained to generate the final similarity score. In other words, our approach extends a conventional IR-based scheme by incorporating word alignment information and this allows us to develop a more fine-grained similarity measurement.

$Sim(S1, W12)$  and  $Sim(S2, W12)$  can be regarded as a measurement of the importance of  $W12$ , the aligned words, in sentence  $S1$  and  $S2$  respectively. When  $Sim(S1, W1) > Sim(S1, W12)$ , the aligned material  $W12$  may not be central to the meaning of  $S1$ . Therefore, even if the value of  $Sim(S1, S2)$  is large, the overall meaning of  $S1$  and  $S2$  may not be very similar to each other.

We use the Dice coefficient to keep our system simple. The optimal similarity function is left as an open question for future work.

### 4 System Description

#### 4.1 System Overview

**Figure 2:** System Overview

We show an overview of our system in Figure 2. As data resources, we used the following:

- The Online Plain Text English Dictionary<sup>1</sup>.
- English Wikipedia pages, snapshot on November 2nd, 2015<sup>2</sup>.

For each pair of input sentences, we use a fuzzy word alignment procedure described later in this section to produce the following three sets of words:

**W12:** Aligned words in sentences 1 and 2.

**W1:** Unaligned words in sentence 1.

**W2:** Unaligned words in sentence 2.

Each of the word sets is used as a search query. The search target is a document database built from the Wikipedia data set. We used Apache Solr 5.3.1<sup>3</sup> as our IR system. Top-N document IDs returned by the IR system for a given query are used as the search

<sup>1</sup><http://www.mso.anu.edu.au/~ralph/OPTED/>

<sup>2</sup><https://dumps.wikimedia.org/enwiki/20151102/>

<sup>3</sup><http://lucene.apache.org/solr/>

result. The Dice similarity scores obtained from the different query formulations are then used to construct regression features for a model that is trained to generate the final similarity score.

In the following subsections, we describe the details of each step.

## 4.2 Preprocessing

Each of the input sentences is converted to a word sequence. All non-alphanumeric characters are removed. Words are identified by splitting text using white space. In addition, within-word splitting is performed such as “50mm” to “50” and “mm” whenever the characters transition from numeric to alphabetic and vice versa. Stop words identified using a dictionary<sup>4</sup> are eliminated.

## 4.3 Spell Correction

Apache Solr 5.3.1 provides a function to suggest similar spellings for a query word. This is performed by fuzzy matching between a query word and words in a database index. The result is a list of words sorted by the degree of the similarity in spelling to the original query term. If a query word is found in a database index, its original spelling is always first ranked. We utilized this function for spell correction. Specifically, we replace each word with its top ranked suggested spelling whenever it is different from the original search term.

## 4.4 Use of Wikipedia Redirect Relations

The Wikipedia data includes information on redirection between pages. Most of the redirections are based on different names for the same underlying topic. For titles that correspond to a single word, we can use the redirection relations to identify synonymous words. For this purpose, a database of the redirect relations is constructed. A record within this database corresponds to one redirect relation and it includes the titles of source and target pages of the redirection. For each pair of words w1 and w2 from within sentences 1 and 2, we used the database to search for possible redirect relationships. When a redirect relationship is found to exist, the corresponding pair of words are aligned to each other and added to the aligned word set W12.

---

<sup>4</sup><http://www.ranks.nl/stopwords>

## 4.5 String Matching Based Alignment

Additional alignment pairs between words and phrases are extracted using string matching heuristics. The following alignments are handled.

- Word unigram to bigram alignment (e.g., “backstroke to back stroke”). The global alignment algorithm (Needleman and Wunsch, 1970) is used for this approximate matching.
- Acronym alignment (e.g., “GE” to “General Electric”). This is performed by matching consecutive capitalized letters with a phrase that can be used to construct the given sequence of capitalized letters as an acronym. We do not use a dictionary of acronym for this.

Aligned words or phrases are added to W12.

## 4.6 Dictionary Based Alignment

Using the English word dictionary mentioned in subsection 4.1, the system detects alignments between a word and its derivative forms such as “wear” versus “worn” or “America” versus “American”. Semantic information such as synonyms in the dictionary are not used in order to avoid spurious alignments which would be only appropriate in specific contexts. All of the dictionary aligned words are added to W12.

## 4.7 Spell Expansion

Apache Solr has an API for word stemming. In addition, we can use the suggester mentioned in subsection 4.3, which provides a list of similar spellings for a given word. Both functions are used to compute spelling variations for the purposes of word alignment. Specifically, the built in Porter stemmer<sup>5</sup> (Porter, 1997) is used for English word stemming. Solr’s FuzzySuggester mechanism<sup>6</sup> is called for each term and we retain the top-five suggested alternative spellings as candidates for matching by the aligner. If word w1 and w2 from sentence 1 and 2 share the same spelling in any of the expanded alignment candidates, they are aligned and added to W12.

## 4.8 IR-based Similarity Estimation

After the word alignment processes, the word set W1, W2, W12 are fixed. Using W1, W2, W12 and

---

<sup>5</sup><http://wiki.apache.org/solr/LanguageAnalysis>

<sup>6</sup><http://wiki.apache.org/solr/Suggester>

sentence 1 and 2 as a natural language query (disjunctive word combination), a document search is performed. The BM25 relevance function provided by Apache Solr is used. The search target is the Wikipedia page abstracts<sup>7</sup>. The number of the pages in the database is around 12 million.

The search result is a list of ranked document IDs in descent order of the BM25 score. Top-N are used as  $R(T)$  explained in section 3. The value of N is empirically set to 100 based on preliminary experiments on the STS 2015 data. This produces the document ID sets  $R(S1)$ ,  $R(S2)$ ,  $R(W1)$ ,  $R(W2)$  and  $R(W12)$ .

#### 4.9 Scoring by Regression

The values of the features F1 – F5 are calculated using the expressions given below. The metric  $Sim$  is given by Formula 1 in section 3. The notation  $|X|$  means the number of elements in a set  $X$ .

- F1:**  $\{Sim(S1, W1) + Sim(S2, W2)\} / 2$
- F2:**  $\{Sim(S1, W12) + Sim(S2, W12)\} / 2$
- F3:**  $|W12| / (|W12| + |W1| + |W2|)$
- F4:**  $Sim(S1, S2)$

**F5:** F3 value calculated including stop words.

The features F1 and F2 are newly introduced by our proposal explained in section 3. F3 roughly corresponds to a similar feature used in Sultan et al. (2014)'s well-known word alignment based STS method. F4 is the similarity measure used in conventional IR-based methods explained in section 3. F5 is introduced to handle the case that input sentences contain stop words only.

We used LIBSVM (Chang and Lin, 2011) for support vector regression to generate similarity scores using the training environment provided by the TakeLab tool (Šarić et al., 2012). We used the Radial Basis Function (RBF) kernel. Training on the STS 2015 test data was performed to identify the optimal regression parameters. Similarity scores generated by the regression were trimmed to a range 0.0 - 5.0 by setting similarity scores that are less than 0 or greater than 5 to be 0 and 5, respectively.

If the word set  $W12$  is empty, we use the feature F4 only and directly convert it to a similarity score by  $F4 * c$ , where  $c$  is a constant to adjust scale between the metric  $Sim$  and a similarity score with

<sup>7</sup>The data file “enwiki-20151102-abstract.xml” was used.

range 0.0 - 5.0. The  $c$  value was empirically set to 70 using the STS 2015 test data.

## 5 Results

### 5.1 Evaluation

We submitted three variants of our system to the shared task evaluation. The three systems differed in how they used Wikipedia redirect relationships (explained in section 4.4) to aid in word alignment for each word  $w$  in input sentences.

**RUN-b :** Attempts to match  $w$  with the targets of the redirect relationships. If no matches are found, tries to match  $w$  with the titles of the redirection sources.

**RUN-s :** Attempts to match  $w$  with only the titles of the redirection sources.

**RUN-n :** Does not use Wikipedia redirection relationships.

The evaluation results (Pearson correlation with the gold standard data) of our three submitted runs are shown in Table 1. As a baseline, we also include the performance of our system when configured to operate as a conventional IR-based method. Specifically, the baseline system uses only the features F3, F4 and F5 (see section 4.9). As with Run-n, the baseline does not use the Wikipedia redirect relationships.

| DATA SET          | RUN-b  | RUN-s  | RUN-n  | Baseline |
|-------------------|--------|--------|--------|----------|
| answer-answer     | 0.5087 | 0.5129 | 0.5075 | 0.5287   |
| headlines         | 0.7869 | 0.7800 | 0.7741 | 0.7701   |
| plagiarism        | 0.8266 | 0.8299 | 0.8225 | 0.8212   |
| postediting       | 0.8655 | 0.8625 | 0.8669 | 0.8480   |
| question-question | 0.5625 | 0.5232 | 0.5426 | 0.4566   |
| MEAN              | 0.7116 | 0.7042 | 0.7047 | 0.6891   |

**Table 1:** Evaluation Results on SemEval 2016 Task 1

### 5.2 Discussion

Among the three submitted runs, Run-b has the best performance on average. However, in detailed analysis, we found that the contribution of the Wikipedia redirect relations is small and the differences mainly come from differences in the optimal parameter settings used for LIBSVM training with the parameters arrived at for Run-b resulting in better generalization to the test data. When the hyperparameters that were originally used to train Run-b (cost:10, gamma:1) are also used for Run-n, the mean performance of Run-n increases to 0.7104.

Run-n outperforms the baseline system on all of the data sets except answer-answer. In failure analysis, we found that words in answer-answer typically have larger document frequencies as compare to the other data sets. In other words, answer-answer consists of more general and less topical words. This harms both the performance of our approach and the conventional IR-based baseline.

On the postediting data set, Run-n achieved the best performance of participating systems in the 2016 STS shared task. However, our performance on the question-question data set is relatively poor, lowering the mean performance of our system. Within the question-question data, many of the sentences share the words from common question formulations (e.g., “What is the best way to ..”). The alignment of such words puts too much focus on generic material that is less central to the core meaning of the question.

## 6 Conclusion

We proposed a new IR-based method for STS. The main feature is to extend a conventional IR-based scheme by incorporating word alignment information. The evaluation results show that the proposed method improves upon a conventional IR-based method on average. While we used the Dice coefficient for our IR-based similarity measure for simplicity, future work may see improved performance from alternative mechanisms for contrasting two different collections of ranked documents, such as Webber et al. (2010)’s Rank-Biased Overlap.

# IHS-RD-Belarus at SemEval-2016 Task 1: Multistage Approach for Measuring Semantic Similarity

Maryna Beliuha, Maryna Chernyshevich

IHS Inc. / IHS Global Belarus

131 Starovilenskaya St

220123, Minsk, Belarus

{Marina.Beliuga}@ihs.com,

{Marina.Chernyshevich}@ihs.com

## Abstract

This paper describes the system for rating the degree of semantic equivalence between two text snippets developed by IHS-RD-Belarus for the SemEval 2016 STS shared task (Task 1). To predict the human ratings of text similarity we use a support vector regression model with multiple features representing similarity and difference scores calculated for each pair of sentences.

## 1 Introduction

Measuring semantic equivalence between two texts has become an emerging research subject in recent years. Graded textual similarity notion can be applied to a wide range of NLP tasks such as paraphrase recognition, automatic machine translation evaluation, question answering, text summarization, information retrieval, etc.

The SemEval STS shared task has been held annually since 2012 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014, Agirre et al., 2015) attracting numerous participating teams with various approaches, such as alignment of related content word sequences (Sultan et al., 2015), measuring similarity between vector representations of texts and using machine learning algorithms for computing multiple lexical, syntactic and semantic features.

In this article, we present the system developed by IHS-RD-Belarus for automated measuring of semantic similarity between two sentences using support vector regression (SVR) implemented in

LIBSVM toolbox<sup>1</sup> (Chang and Lin, 2011) with multiple features representing similarity and difference scores calculated for each pair of sentences.

The rest of the paper is structured as follows. In Section 2 we describe the task and the data used to train our system. Section 3 describes in detail the features used by our system. Results and a short conclusion are presented in Section 4 and 5, respectively.

## 2 Task description

Semantic Textual Similarity (STS) measures the degree of equivalence in the underlying semantics of paired snippets of text. It can range from complete unrelatedness to exact semantic equivalence (Agirre et al., 2015).

Given two sentences, participating systems are asked to return a continuous valued similarity score on a scale from 0 to 5, with 0 indicating that the semantics of the sentences are completely unrelated and 5 signifying semantic equivalence. For example, the sentence “*Military plane crashes in south France*” and the sentence “*Military plane crashes in southeastern Turkey, 1 dead*” have a very low similarity score despite many equal words, thus scored 1.0, while the sentence “*Sarkozy announces re-election bid*” and the sentence “*France's Nicolas Sarkozy makes his reelection bid official*” are scored 4.2, as they are considered very similar even though there are many word differences between them.

---

<sup>1</sup> <https://www.csie.ntu.edu.tw/~cjlin/libsvm/>

## 2.1 Dataset

The dataset used for training of our system consists of the datasets provided by the organizers of the STS shared task, specifically 1500 pairs of news-wire headlines, 1500 pairs of image descriptions, 450 pairs of sentences from forum posts, 300 pairs of sentences from news summary, 750 pairs of students answers, 375 pairs of Q&A forum answers and 375 pairs of sentences from committed belief annotation. We excluded some of the datasets provided by the organizers from our training data as they had a negative influence on all the data we used for testing in preliminary experiments. As a development test set we used 20% of each dataset provided by the organizers as training data.

Our intention was to create a universal system, therefore we didn't use any domain specific features and didn't train separate models for predicting the similarity scores of the text snippets provided for evaluation depending on their domain. Thus, we used the same set of data listed above to train our SVR model and the same model was used to predict the similarity scores of all test datasets.

## 2.2 Evaluation

Gold standard scores are averaged over multiple human annotations. Performance of the systems is assessed by computing the Pearson correlation between machine assigned semantic similarity scores and gold standard scores.

## 3 System description

To predict the scores of the test set we use supervised machine learning, specifically a support vector regression model, to combine a large amount of features computed from pairs of sentences. Each feature represents either a similarity or difference score between two text snippets. To obtain the optimal values for SVR parameters  $C$ ,  $g$  and  $p$ , we used grid search. The system we end up submitting had parameters  $C = 10$ ,  $g = 0.1$  and  $p = 0.2$ .

### 3.1 Semantic similarity features

The workflow for computing the similarity measures is based on a multistage aligner using various internal and external resources that align identical or similar words and phrases. As these resources have different degrees of reliability, we

calculate similarity measures, described in Section 3.1.1, after each alignment step and use them as separate features.

The aligning steps performed by our system are illustrated in Figure 1.

**Stage 1.** First, to identify semantically similar words and phrases we use the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013), which is a large database of lexical, phrasal and syntactic paraphrases.

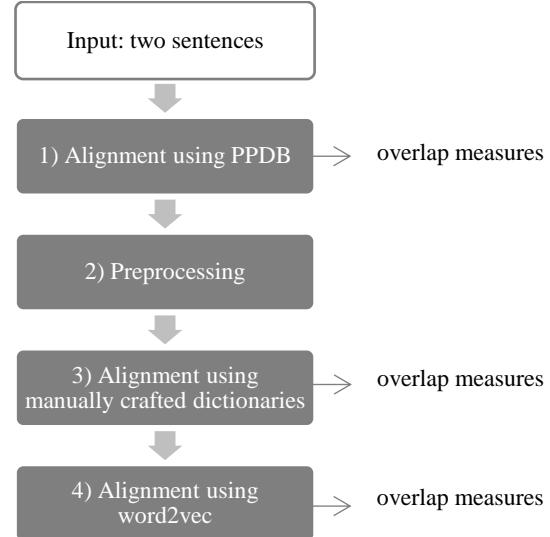

Figure 1: Aligning steps performed by the system

**Stage 2.** To obtain additional word alignments our system performs the following preprocessing steps:

- words are tokenized with IHS Goldfire<sup>2</sup> linguistic processor (Чеусов, 2006);
- words are POS tagged with IHS Goldfire linguistic processor;
- stop words, uninformative adverbs, discourse markers and words that do not contain at least one letter or number are deleted;
- words are lowercased;
- punctuation marks are removed.

On **Stage 3** we apply manually crafted domain independent wordlists such as 14870 pairs of synonymous adjectives, verbs and nouns (“*wrong*” – “*incorrect*”, “*link*” – “*connect*”, “*seller*” – “*vendor*”), 1435 pairs of adjectives and adverbs derived from them (“*clear*” – “*clearly*”), 2953 pairs of ac-

<sup>2</sup> <https://www.ihs.com/products/design-standards-software-goldfire.html>

tions and their agents (“connect” – “connector”), 17556 pairs of verbs and deverbal nouns (“pulse” – “pulsation”), 563 pairs of nouns and denominal adjectives (“sinusoid” – “sinusoidal”). The lists were automatically generated using derivational affixes and then validated on random corpus of two million sentences (a derived synonym was considered valid if it appeared in the corpus more than 3 times). We also used Wikipedia lists of 264 paired country names and nationalities (“british” – “uk”) and 262 paired country names and capitals (“uk” – “London”).

During this stage we also align words having a Levenshtein distance of less than 1 to catch common misspellings.

On **Stage 4** we align words in the sentences using the GoogleNews vectors dataset, available on the word2vec web site<sup>3</sup>, which has a 3,000,000 word vocabulary of 300-dimensional word vectors trained on about 100 billion words. We consider two words to be semantically similar if the cosine between the words is more than 0.7.

### 3.1.1 Word overlap measures

To calculate similarity scores we use two similarity measures which we apply after each alignment step described above.

**Jaccard similarity coefficient.** We measure the similarity score using Jaccard index, which is defined as the amount of word overlap normalized by the union of the sets of words present in the two sentences. It is calculated using the formula:

$$J(S_1, S_2) = \frac{|S_1 \cap S_2|}{|S_1 \cup S_2|}$$

where  $S_1$  and  $S_2$  are the vectors of the first and the second sentence, respectively. We consider the intersection of vectors  $S_1$  and  $S_2$  to be to be the words that are aligned to each other.

**Similarity score using TF-IDF.** A word's TF-IDF score reflects the importance of the word for the particular sentence offset by the frequency of the word in all sentences. It can be used as a weighting factor when calculating semantic similarity of the sentences. Therefore, as one of the features, we calculate the TF-IDF weighted proportion of aligned content words over the sum of the

TF-IDF scores for all words in the two sentences. In other words, given sentences  $S_1$  and  $S_2$ ,

$$sts(S_1, S_2) = \frac{\sum_{w \in (S_1^a \cup S_2^a)} tfidf(w)}{\sum_{w \in (S_1 \cup S_2)} tfidf(w)}$$

where  $\sum_{w \in (S_1^a \cup S_2^a)} tfidf(w)$  is a sum of TF-IDF values of all the aligned words in  $S_1$  and  $S_2$ , while  $\sum_{w \in (S_1 \cup S_2)} tfidf(w)$  is a sum of TF-IDF values of all words in both sentences.

Intuitively, the lower is the sum of TF-IDF values of the aligned words, the less important the aligned words, which makes the total similarity score smaller and vice versa.

### 3.2 Cosine similarity measures

Similarity can also be defined by the cosine of the angle between two vectors. Cosine similarity is one of the most well-known similarity measures as has been broadly applied to numerous information retrieval tasks (Strehl, 2000). We calculated the similarity of pairs of text snippets using the following equation:

$$\cos(A, B) = \frac{\sum_{i=1}^n A_i B_i}{\sqrt{\sum_{i=1}^n A_i^2} \sqrt{\sum_{i=1}^n B_i^2}}$$

where  $A$  and  $B$  are TF-IDF vectors. The cosine similarity score is non-negative and bounded between [0,1].

Following our multi-stage principle we generate word vectors and calculate cosine similarity scores after each of 4 stages of original sentences transformation and use them as separate features. Each step aims to limit words diversity of text:

**Stage 1.** Normalization: change to a lower-case, removal of punctuation marks and stop words.

**Stage 2.** Grammatical transformation of words: nouns to singular form; verbs to infinitive form; adjectives and adverbs to positive degree.

**Stage 3.** Aligning, described in detail in section 3.1.

**Stage 4.** Words expansion: each word in a sentence is expanded with a vector of words with the word2vec similarity of more than 0.6, generated using word2vec and pre-trained Google vectors. We add only words having a zero entry in the vector. The TF-IDF scores of the added words are cal-

---

<sup>3</sup><https://code.google.com/archive/p/word2vec/>

culated in the following way: the TF-IDF of the source word is multiplied by the word2vec similarity. The resulting vectors are approximately 4 times larger than the initial ones.

### 3.3 Syntactic similarity

Word overlap based measures may lead to discrepancies, because they do not capture syntactic relations. The similarity of the words or phrases having the same syntactic roles in two sentences may be indicative of their overall semantic similarity (Oliva et al., 2011) and vice versa. For example, in two expressions “the notebook of my mother” and “my mother cooks amazing” the word “mother” has different syntactic meaning: in the first expression it has just an attributive meaning, while in the second it is a subject. Similarly, if two sentences differ, for example, by their main predicates (e.g., “predict” and “walk”), it can indicate that they are more likely to have significant semantic differences.

To address this issue, we design features that compute similarity scores based on a syntactic analysis of the sentences.

**Noun phrase similarity feature:** To align noun phrases first we extracted all noun phrases from the first and the second sentence and calculated similarity between each pair of noun phrases. Noun phrase extraction was performed by IHS Goldfire linguistic processor that is based on shallow parsing but with support for head word identification.

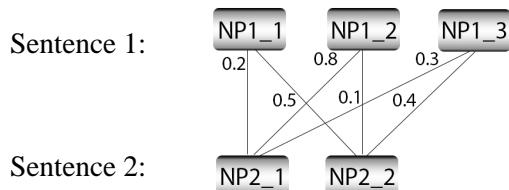

Figure 2: Example of noun phrase alignment

The similarity between two noun phrases is calculated using the WordNet path similarity provided by NLTK<sup>4</sup> and the Levenshtein distance. Path similarity scores denote how similar two word senses are based on the shortest path that connects the senses in the WordNet hypernym-hyponym taxonomy. The similarity between two noun phrases is the sum of the similarity between head words

<sup>4</sup> <http://www.nltk.org/howto/wordnet.html>

$Sim(mw)$  and the similarity of all attributes  $Sim(att)$  divided by 2 in order to penalize the weight of attributes:

$$Sim(np_1, np_2) = Sim(mw) + \frac{Sim(att)}{2}$$

After calculating all pairwise similarity scores, we align each noun phrase from the first sentence with the noun phrase from the second one having the highest similarity score:

$$\begin{aligned} NP1\_1 &: NP2\_2 (0.5), \\ NP1\_2 &: NP2\_1 (0.8), \\ NP1\_3 &: \text{NULL} (0) \end{aligned}$$

The sentence level noun phrase similarity score is calculated as the averaged score of the individual aligned noun phrase similarities.

**Parse trees comparison feature:** At this level of analysis we compare binary verb-centric nodes (Subject-Action, Action-Object, etc.) of the trees extracted with IHS Goldfire linguistic processor while leaving aside the nodes of lesser importance (Main-Attribute, Main-Preposition, etc.). Complete or partial match within the contents of the important verb-centric compared nodes suggests various degrees of syntactic and semantic role equivalence.

We give a higher score to a pair of sentences if they have aligned words in the same or similar verb-centric nodes (the score then equals the count of the number of matching verb-centric nodes) and we give a penalty score if the sentences have no matching nodes or aligned words appear only in non-informative nodes (the score equals minus one). If any of the sentences has no verb-centric nodes at all and therefore the parse tree is not generated the score remains 0.

### 3.4 Differentiation features

Another set of features is used to reveal semantic differences between the sentences.

**Part-of-speech feature:** We assume sentences that differ by uninformative words to have a higher similarity score than sentences that differ by words that have informative POS-tags such as verbs or nouns. Compare a pair of sentences having different determiners “*how is this possible?*” – “*how is that possible?*” and a pair of sentences having different nouns “*I love cats*” – “*I love dogs*”. Therefore, we calculate a weighted sum of weights of all non-matching words having informative POS-tags

(i.e. verbs, nouns, adjectives, adverbs and numerals) based on an empirically determined informativeness weight of the POS-tags.

**Named entity feature:** Comparing, for example, the pair of sentences “*Ten people killed in twin blasts in Nigeria*” and “*Ten killed in new blast in Russia*”, we assume that the impact of named entities to semantic equivalence is disproportionately high. Therefore, we count the total number of non-matching named entities as another feature.

As matching named entities we considered two named entities that match:

- exactly: *Russia - Russia*;
- partially: *Bill Torn - Mr. Torn*;
- country name and nationality pairs list: *british – UK*;
- country name and capital pairs list: *UK – London*.

**TF-IDF feature:** We calculate TF-IDF of all words that differ in two sentences. Taking its mean value as a separate feature allows us to make a conclusion on how different the sentences are: the lower is the value of this feature, the higher is the degree of similarity, and vice versa.

## 4 Results

To assess system performance, the organizers provided five test sets from different domains. Table 1 illustrates the performance of the system developed by our team as compare to the top and median scores of the other systems that participated in the task.

Our system outperformed most other systems achieving very promising results. As seen below, it performed well above the median for all of the datasets and achieved results that are very close to the best performing system on headlines. However, note that most systems showed relatively poor performance on the answer-answer (ans-ans) and question-question (ques-ques) datasets which can be explained by significant differences between the provided training data and these particular test sets.

| Dataset     | Best   | Median | Our system |
|-------------|--------|--------|------------|
| plagiarism  | .84138 | .78949 | .82634     |
| ans-ans     | .69235 | .48018 | .55322     |
| postediting | .86690 | .81241 | .83761     |
| headlines   | .82749 | .76439 | .82539     |

|            |               |               |                |
|------------|---------------|---------------|----------------|
| ques-ques  | .74705        | .57140        | .599           |
| <b>ALL</b> | <b>.77807</b> | <b>.68923</b> | <b>.728312</b> |

Table 1: Performance on the 2016 STS Test Set

## 5 Conclusion

In this paper we present our system for automatic rating of semantic textual similarity developed by our team for the SemEval 2016 STS shared task (Task 1). To measure semantic equivalence of two text snippets we use a supervised system based on a support vector regression model to combine multiple features representing similarity and difference scores calculated for each pair of sentences. Our system performed relatively well on all of the STS 2016 evaluation datasets. We believe that introducing additional features for deeper understanding of textual semantics might further improve performance on the task.

## Abstract

In this paper we describe the JUNITMZ<sup>1</sup> system that was developed for participation in SemEval 2016 Task 1: Semantic Textual Similarity. Methods for measuring the textual similarity are useful to a broad range of applications including: text mining, information retrieval, dialogue systems, machine translation and text summarization. However, many systems developed specifically for STS are complex, making them hard to incorporate as a module within a larger applied system.

In this paper, we present an STS system based on three simple and robust similarity features that can be easily incorporated into more complex applied systems. The shared task results show that on most of the shared tasks evaluation sets, these signals achieve a strong ( $>0.70$ ) level of correlation with human judgements. Our system's three features are: unigram overlap count, length normalized edit distance and the score computed by the METEOR machine translation metric. Features are combined to produce a similarity prediction using both a feedforward and recurrent neural network.

## 1 Introduction

Semantic similarity plays important role in many natural language processing (NLP) applications. The semantic textual similarity (STS) shared task has been held annually since 2012 in order to assess different approaches to computing textual similarity

<sup>1</sup>This work was supported by the Project No. YSS/2015/000988 of National Institute of Technology Mizoram.

across a variety of different domains.

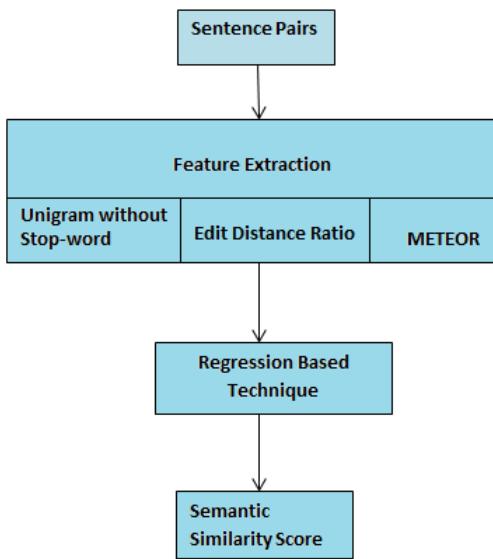

Research systems developed specifically for the STS task have resulted in a progression of systems that achieve increasing levels of performance but that are often also increasingly more complex. Complex approaches may be difficult if not impossible to incorporate as a component of larger applied NLP systems.

The system described in this paper explores an alternative approach based on three simple and robust textual similarity features. Our features are simple enough that they can be easily incorporated into larger applied systems that could benefit from textual similarity scores. The first feature simply counts the number of words common to the pair of sentences being assessed. The second provides the length normalized edit distance to transform one sentence into another. The final feature scores the two sentences using the METEOR machine translation metric. The latter allows the reuse of the linguistic analysis modules developed within the machine translation community to assess translation quality. METEOR's implementation of these modules is lightweight and efficient, making it not overly cumbersome to incorporate features based on METEOR into larger applied systems.

The remainder of this paper is structured as follows. Section 2 provides an overview of our system architecture and Section 3 describes our feature set. Section 4 reviews the neural network models we use to predict the STS scores. Section 5 describes the evaluation data followed by our results on the evaluation data in Section 6.

## 2 System Framework

As shown in Figure 1, our system performs on a neural network based regression over our three textual similarity features. As described in the next section, the three similarity features we use are: unigram overlap count, editdistance and the METEOR score from the machine translation evaluation metric research community. The three features are combined using a neural network in order to predict a pair's final STS score.

**Figure 1:** JUNITMZ STS System Architecture

## 3 Features

### 3.1 Unigram matching without stop-word

The unigram overlap count feature indicates the number of non stop-words that appear in both sentence pairs.<sup>2</sup> Table 1 illustrates the operation of this feature on an STS sentence pair.

The words "to" and "on" are present in both sentences, but we excluded them as stopwords for the purposes of the unigram overlap count.

### 3.2 Edit Distance Ratio

We compute the minimum number of edit operations involving the insertion, deletion or substitution

<sup>2</sup>We obtain our stop word list from <http://www.nltk.org/book/ch02.html>

| Sentence Pair                                     | Score |
|---|-------|
| TSA drops effort to allow small knives on planes. | 6     |
| TSA drops plan to allow small knives on planes.   |       |

**Table 1:** Unigram matching, ignoring stopwords

of individual characters that are required to transform one sentence into another. Commonly known as the Levenshtein distance (Levenshtein, 1966), this string similarity metric captures both similarity in the overall structure of the two sentences being compared as well as some similarity between different word forms (e.g., "California" vs. "Californian").

As shown in equation (1) , we normalize the raw edit distance by the length of the two sentences. The score is then inverted such that a perfect match will have a score of 1.0, and completely dissimilar strings will be assigned a value of 0.0.

$$\text{EditRatio}(a, b) = 1 - \frac{\text{EditDistance}(a, b)}{|a| + |b|} \quad (1)$$

An example of the edit distance ratio feature is given in Table 2.

| Sentence Pair                                     | Levenshtein Distance | Edit Distance Ratio |
|---|----------------------|---------------------|
| TSA drops effort to allow small knives on planes. | 6                    | .8958               |
| TSA drops plan to allow small knives on planes.   |                      |                     |

**Table 2:** Edit Distance Ratio

### 3.3 Meteor

METEOR is a well known evaluation metric from the machine translation community (Denkowski and Lavie, 2014). The method incorporates linguistic analysis modules but in a manner that is lightweight, efficient and robust to the noisy data generated by machine translation systems. The method operates by first computing an alignment between the individual words in a sentence pair. In addition to matching identical words with each other, METEOR also supports matching words based on synonymy relationships in WordNet, entries in a paraphrase database or by word stem. The metric

then computes a weighted F score based on the unigram alignments that is then scaled by a word scrambling penalty. The synonym matching is computed using WordNet. We use the METEOR 1.5 system for our STS Task.

#### 4 Neural Network Framework

We predict STS scores based on three similarity features as described above using Matlab toolkit containing modules for three different neural networks. The neural networks have been used with respect to each of the corresponding runs submitted by our team to the shared task. The inputs of those network were the feature set along with the gold standard similarity scores extracted from the training data whereas the outputs produce the semantic scores for the test dataset. In **Run1**, we use two-layer feedforward network with 10 neurons in the hidden layer and trained using the Levenberg-Marquardt algorithm.<sup>3</sup> **Run2** uses the same network but trained using Resilient Backpropagation algorithm (Riedmiller and Braun, 1992).<sup>4</sup> In case of **Run 3**, we use the framework of Layer Recurrent Network which can be seen as a generalization of simple recurrent networks (Elman, 1990).<sup>5</sup> The inputs of this recurrent neural network were similar like the other 2 neural network with default parameter.

#### 5 Dataset

The 2016 STS shared task includes sentence pairs from a number of different data sources organized into five evaluation sets: News Headlines, Plagiarism, Postediting, Q&A Answer-Answer and Q&A Question-Question. The sentence pairs are assigned similarity scores by multiple crowdsourced annotators on a scale ranging from 0 to 5 with the scores having the following interpretations: (5) complete equivalence, (4) equivalent but differing in minor details, (3) roughly equivalent but differing in important details (2) not equivalent but sharing some details (1) not equivalent but on the same topic (0) completely dissimilar. The individual crowdsourced

scores are aggregated to assign a final gold standard similarity score to each pair.

Table 3 provides example sentence pairs with their corresponding gold standard similarity scores. Systems are assessed on each data set based on the Pearson correlation between the scores they produce and the gold standard. The detailed statistics of the STS-2016 Test datasets are given in Table 4. For the training process we used all gold standard training and test data of year 2012 to 2015 resulting in 12500 sentence pairs.

#### 6 Result

For our training dataset we use trail, training and test data from previous STS competitions. As shown in Table 5, we used different subsets of the data from prior STS evaluations to train different models for the 2016 evaluation sets.

Table 7 illustrates the performance of our three system submission on each of the STS 2016 evaluation sets as assessed by their correlation with the gold standard similarity scores. Overall performance is reported as the weighted mean correlation across all five data sets. The best overall correlation we obtain is 0.62708, which is achieved by run1, the LevenbergMarquardt trained feedforward network. For comparison, the best and mean scores achieved by all systems submitted to the 2016 STS shared task

**Table 7:** System performance on SemEval STS-2016 data.

are provided by Table 6.

While our models are less accurate in their predictions than other systems, we note that our submission is based on simple and robust features that allow it to be more easily integrated into complex downstream applications. With our feature set, we still achieve a strong ( $>0.70$ ) correlation with human judgements on 3 of the 5 shared task evaluation sets. However, our system struggles on both of the Q&A data sets, questionquestion and answeranswer, suggesting additional signals may be necessary in order to correctly handle pairs from this domain.

## 7 Conclusion and Future Work

We have presented an STS system based on three simple robust features. The results of the shared task evaluation show that our feature set is able to achieve a strong ( $>0.70$ ) correlation on 3 of the 5 shared task evaluation sets. The simplicity of our

feature set should make it easier to incorporate into downstream applications. We do note that, similar to submissions from other teams, our systems struggle on the two question answering datasets. We are optimistic that it is possible to also obtain strong correlations on this dataset without resorting to overly complex systems.

In future we plan to investigate using features directly based on resources such as WordNet as well as attempt to generalize our system to the crosslingual formulation of the STS task.

## Acknowledgments

I am very thankful to JUNLP team member for their help in my SEMEVAL task. I am also thankful to the organizer for their support. This work was supported by the Project No. YSS/2015/000988 of National Institute of Technology Mizoram.

## Abstract

Semantic Textual Similarity measures similarity between pair of texts, even though the similar context is projected using different words. This work attempted to incorporate the context space of the sentence from that sentence alone. It proposes combination of Word2Vec and Non-Negative Matrix Factorization to represent the sentence as context embedding vector in context space. Distance and correlation values between context embedding vector pairs used as a features for Support Vector Regression to built the domain independent similarity measuring model. The proposed model yielding performance 0.41 in terms of correlation.

## 1 Introduction

Semantic Textual Similarity (STS) assess the degree to which two snippets of text mean the same thing (Agirre et al., 2015). The modules developed for successful STS systems have a broad range of potential applications including: Discourse Analysis, Information Retrieval, Machine Reading, Machine Translation, Question Answering, Text Summarization and Plagiarism Detection.

Degree of dependence between sentences vary even-though there exist similar words present in them (Example 1) whereas the dependence remains unchanged when the context is being projected with different words (Example 2). For instance,

- S1** : Boy chases the cat.  
**S2** : Cat chases the boy.

### Example 1

- S1** : The rat jumps inside the tub.  
**S2** : Mouse dives into the vessel.

### Example 2

From the above example, representing sentence as context dependent vector in a context space is more informative than the traditional frequency based representation methods. Thus by considering this, the proposed approach measures the similarity between the sentences as prescribed in STS task, which is given in the Table 1.

From the Table 1 it is clear that simple frequency based representation will fail to achieve the objective. Our approach proposes measuring similarity based on contextual information provided by the other words in the sentences instead of measuring similarity using just the words. Words tends to have different meaning with respect to their appearance with context.

In this proposed approach, sentence embedding will be found from word embedding in which words are represented as word embedding vectors with respect to context they occurs. Thereafter the similarity measure is done by finding correlation of the features in the sentence embedding.

Remaining paper details about the related works done on STS in section 2, detailed mathematical explanation is given in section 3 and statistics about the data-set, experiment and observations are explained in section 4.

## 2 Related Works

In this section we discuss the related works carried on the STS and how the current proposal has been built from the previous works.

| Score | Similarity       | Similarity Description          | Sentence Pair  |
|-------|------------------|---------------------------------|--|
| 0     | Different Topic  | Different topics                | S1: As long as it's not completely sealed air will get in<br>S2 : Covers are also there to prevent things from getting in  |
| 1     | Not Equal        | Same topic                      | S1 : Actor Mickey Rooney dies aged 93<br>S2 : Ariel Sharon dies aged 85  |
| 2     | Not Equal        | Share some details              | S1 : Putin opens Paralympics as protest staged<br>S2 : Putin opens Winter Paralympics                                      |
| 3     | Roughly Equal    | Important information missing   | S1 : India Ink: Image of the Day: July 2<br>S2 : India Ink: Image of the Day: March 4                                      |
| 4     | Mostly Equal     | Unimportant information missing | S1 : U.S. retailers agree to Bangladesh plant safety pact<br>S2 : 70 retailers agree to new Bangladesh factory safety pact |
| 5     | Completely Equal | Means same thing                | S1 : CIA chief visits Israel for Syria talks<br>S2 : CIA chief in Israel to discuss situation in Syria                     |

**Table 1:** STS Score Level for Similarity

The objective of the work is to represent the context of the sentence embedding from the word embedding of the sentence. To achieve this most of the recent research and also previous years works on paraphrase detection were based on deep learning or dimensionality reduction for semantic representation. This in turn was followed by a classification or regression to get the similarity score (Agirrea et al., 2015). Most of the distributional semantic representation based on dimensionality reduction algorithms (Han et al., 2013; Kashyap et al., 2015) and word embedding models were based on deep learning (Kenter and de Rijke, 2015; Wu et al., 2014; Socher et al., 2011).

The knowledge of WordNet and Latent Semantic Analysis (LSA) was integrated in-order to develop features for STS model SemEval 2013. This was done using distributional semantics (based on word's co-occurrence in different context) and semantic relation between the words in sentences (Han et al., 2013; Kashyap et al., 2015). Web corpus from the Stanford WebBase<sup>1</sup> project utilized to build the distributional semantic word representation and then the model was enhanced by integrating POS with WordNet. Same system was then extended to the Multilingual Semantic Textual Similarity and Cross Level Semantic Similarity in SemEval 2014 with few external resources (Google translate<sup>2</sup>, Wordnik<sup>3</sup>, and bing<sup>4</sup>) and showed greater accuracy (Kashyap et al., 2015).

<sup>1</sup>[www-diglib.stanford.edu/testbed/doc2/WebBase/](http://www-diglib.stanford.edu/testbed/doc2/WebBase/).

<sup>2</sup><https://translate.google.co.in/>.

<sup>3</sup><http://developer.wordnik.com/>.

<sup>4</sup><https://www.bing.com/>.

In order to represent the sentence pair, high quality word embedding was obtained using Word2Vec and Glove. Further feature vectors of length 60 computed using feature functions and evaluated on Microsoft Research Paraphrase Corpus (MSRP) (Kenter and de Rijke, 2015). As dealt with short text, similarity on long texts were found by computing non-linear semantic word representations on it. Thereafter it was fed to the Deep Semantic Embedding (DSE) to map long text into semantic space, where the semantic information was utilized to compute the similarity score (Wu et al., 2014).

Unfolding Recursive Auto encoder (U-RAE) along with dynamic pooling layer for fixed size representation was introduced for measuring the similarity between sentence pairs. Here it represents sentence as the parsed tree and words as word embedding. The pooled representation of sentences are then fed to the soft-max classifiers. The performance of this approach was evaluated using MSRP corpus and it attained the state of art accuracy (Socher et al., 2011).

In the above mentioned systems few tried to achieve the objective by using lexical information alone with high feature engineering, which seemed to have high manual effort and external resources. Other systems achieved greater accuracy by having context of the sentence either with the help of much external resources or with complex structure and computation. Finding mean or sum of the word embedding, are poor way to represent the context of the sentence. Our proposed approach simplifies the objective by relying only on word embedding and

matrix factorization. This approach is able to represent the context of the sentence with fixed size, which serves to be the essential and complex part of the objective.

### 3 Mathematical Representation

This section details how the vector representation of the word gives context information of individual lexicon in semantic space with respect to their co-occurring lexicons (3.1). It also shows the methodology for fixed size representation of the sentence embedding (3.2). It then deals with the feature functions (3.3) that is fed to the regression analyser(3.4).

#### 3.1 Distributional to Distributed Representation

The phrase, "Distributional Semantics" means, representing a word with respect to the context that occurs across the corpus. Typically it was derived from dimensionality reduction algorithms (Singular Value Decomposition and other matrix factorization methods) applied on word - word context matrix (Turian et al., 2010). The represented vector in high dimension is sparse and dimension of the representation depends on the vocabulary of the word. This led to the research on word embedding representation.

Word embedding (Distributed Representation) is a low dimensional vector, which represents the word with respect to the context it occurs(Turian et al., 2010). Recent works have focused and shown proven results on distributed representation in-order to attain greater accuracy(Socher et al., 2011; Kennter and de Rijke, 2015). This is because, the model represents word as dense-low dimensional vector through non-linearity learning and negative sample learning for syntax - semantic information (Mikolov et al., 2013). Mathematically,

$$P(w_t|c) = \text{softmax}(\text{score}(w_t, c)) \quad (1)$$

$$= \frac{\exp \{ \text{score}(w_t, c) \}}{\sum_{w'} \exp \{ \text{score}(w', c) \}} \quad (2)$$

$w_t$  is the vector representation for the word  $t$  in the vocabulary and  $\text{score}(w_t, c)$  computes the like-mindedness of word  $w_t$  with the context  $c$ , where  $c$  represents the remaining words co-occurring with  $w_t$ .  $w_t$  is the word embedding with  $d$  dimension length, which is used to find the context embedding.

#### 3.2 Word Embedding to Context Embedding

As discussed in previous section, the objective is to find the fixed size vector representation of the context from the sentence. Sentences may vary in length but their representation need to be in same length for further similarity measure. Here this is achieved by concatenating word embedding (context matrix or word embedding matrix) of the words in the sentence followed by the Non - Negative Matrix Factorization (NMF) (Lee and Seung, 1999). Given non-negative matrix  $V$ , NMF will factorize it into the basis matrix  $W$  and mixture matrix  $H$ , which is also a non-negative matrix. Mathematically,

$$V \approx WH^T \quad (3)$$

Where,  $V$  is  $m \times n$  matrix,  $W$  is  $m \times r$  basis matrix and  $H$  is  $n \times r$  mixture matrix. Linear combination of basis vector (column vector) of  $W$  with weights of  $H$  gives the approximated context matrix (word embedding matrix)  $V$ . While factorizing, formerly random values are assigned to  $W$  and  $H$  then the optimization function is applied on it to compute appropriate  $W$  and  $H$ .

$$\min_f_r(W, H) \equiv \|V - WH^T\|_F^2 \quad (4)$$

$$\text{s.t. } W, H \geq 0$$

Where,  $r$  is the reduced dimension and  $F$  is the Frobenius norm. Here  $r$  fixed as 1 to have  $d \times 1$  context embedding, where  $d$  is the dimension of the word embedding.

Each column vector in  $V$  is represented by a basis vector  $W$  weighted by the elements of  $H$ . This basis vector considered as context embedding vector, which is linearly combined with elements in the  $H$  to recompute the word embedding vectors with respect to its context. The non-negativity constraints makes interpretability straight forward than the other factorization methods. The basis vector in context space is not constrained to be a orthogonal, which is not affordable by finding singular vectors or eigen vectors. (Xu et al., 2003)

#### 3.3 Feature Function and Decision Algorithm

Feature function measures the distance, dissimilarity and correlation between the context embedding pairs. Distance is measured to know, how close the

two context embeddings are in the context space, dissimilarity gives independence measure of context embeddings and correlation is carried over to know the dependency between context embeddings. Euclidean distance, BrayCurtis dissimilarity, City Block Distance, Chebyshev distance and Pearson correlation are considered in the feature function (Cha, 2007). For instance consider  $P$  and  $Q$  are the context embedding vectors of the two sentences and  $d$  is the dimension of the vector, then the measured functions given in the Table 2.

| Measured Feature Functions |   |
|----------------------------|---|
| Euclidean Distance:        | $\sqrt{\sum_{i=1}^d  P_i - Q_i ^2}$   |
| Bray Curtis Dissimilarity: | $\frac{\sum_{i=1}^d  P_i - Q_i }{\sum_{i=1}^d (P_i + Q_i)}$   |
| City Block Distance:       | $\sum_{i=1}^d  P_i - Q_i $  |
| Chebyshev Distance:        | $\min_i  P_i - Q_i $  |
| Pearson Correlation:       | $\sum_{i=1}^d \frac{(P_i - \bar{P})(Q_i - \bar{Q})}{\sqrt{\sum_{i=1}^d (P_i - \bar{P})^2} \sqrt{\sum_{i=1}^d (Q_i - \bar{Q})^2}}$ |

Table 2: Measured Features

Attributes from the feature function is fed to the Support Vector Regression (SVR) to build the supervised similarity measure model. SVR is extended version of Support Vector Machine in-order to deal with regression problems (Welling, 2004). The advantages of the SVR here is, it doesn't make any assumption about data distribution, empirical risk minimization and has the ability to include non-linearity learning by changing the kernels.

## 4 Experiment

The Model diagram of the conducted experiment is given in Figure 1.

Statistics about the data-set are given in Table 3. Given data-set includes wide varieties of sentences in varying length and representation. This work is focused on building a unified model irrespective of domain. The training corpus for similarity mea-

sure involves shuffled sentence pairs from all the domains (i.e. single model for measuring similarity for Plagiarism, Answer-Answer, Post-editing, Headlines and Question-Question corpus).

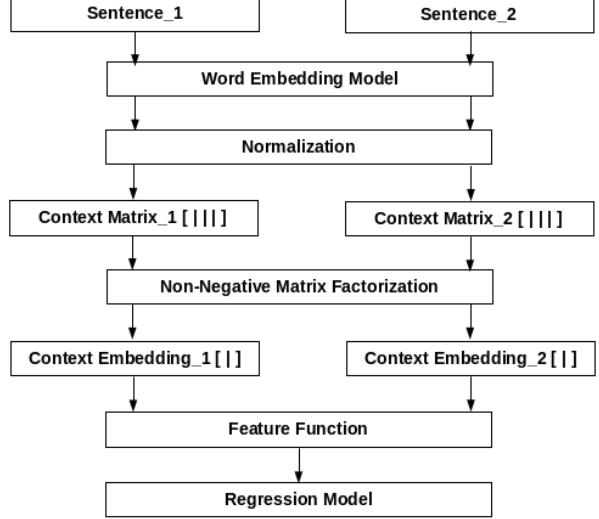

Figure 1: Model Diagram

To build the word embedding model, we use a snapshot of the articles in the English Wikipedia<sup>5</sup> (articles) has been utilized. After removing XML tags, special characters and unwanted spaces the corpus (size:12 GB) is fed to the Continuous Bag of Words (CBOW) model for processing (Mikolov et al., 2013). Window size, minimum occurrence and vector dimension are assigned as 5, 4, 400 respectively to create word embedding model (size:2.6 GB) using the Gensim package.<sup>6</sup>

The sentence pairs were fed to the word embedding model to represent the words in a sentence as vector of dimension 400. Word vectors in a sentence are concatenated to form a matrix (Context Matrix). Before concatenation the vectors are normalized (unity-based normalization) between 0 and 1, which forms dense positive vectors that are appropriate for further factorization. This is given by,

$$W' = \frac{W - \min(W)}{\max(W) - \min(W)} \quad (5)$$

By equating the reduction rank to be one ( $r=1$ ) the

| Question-Question | 1555                 | 209              | 0.74705 | 0.57140 | -0.03174   |

**Table 3:** Data-set Statistics and System Performance in terms of correlation

NMF is carried out using the Nimfa package<sup>7</sup> on the context matrix to get the basis vector. This resultant basis vector of NMF is considered as the context embedding. This is because the linear combination of basis matrix along with mixture matrix will reconstruct context matrix. This can be visualized by generating words based on its context.

Once the context embedding pairs are found, they are fed to the feature function to measure the distance and correlation between them. These are used as attributes to train the SVR. SVR has been trained using Python Scikit-learn<sup>8</sup>. Radial Basis Function (RBF) kernel used for the non-linearity learning. The typical C = 1.0 and gamma = 1/length(training set) parameters are used in SVR.

While training, the performance of the system is measured by 10-cross validation. Correlation coefficient between gold-standard and predicted vector are computed to validate the significance of the system. The average correlation value obtained out of 10-cross validation during the training phase is 0.4178.

Our final system was trained on entire training corpus (9183 pairs) and then submitted to the STS shared task for evaluation. The official evaluation results are reported in Table 3. Our model performed poorly on the Question-Question data, but performed better on all the others. The model did best on the Plagiarism and Post-editing pairs. The average score of the system is 0.4090, which is almost equal to the training accuracy (0.4178).

## 5 Conclusion

A novel method for SemEval-2016 Monolingual Semantic Textual Similarity task has been described in this paper. Without depending on any resources or hand crafted features, it represents a simplified and unsupervised feature learning model for similarity

measure. Our method performs well on the 2016 evaluation data except for the Question - Question corpus, however there is still room for improvement. The future work will be focused on more research on and the justification of context embedding derivation.

## Abstract

We present a multi-feature system for computing the semantic similarity between two sentences. We introduce the use of soft alignment for computing text similarity, and also evaluate different methods to produce it. The main features used by our system are based on alignment and Explicit Semantic Analysis. Our system was above the median scores for 4 out of the 5 datasets at SemEval 2016 STS Task 1.

## 1 Introduction

Semantic textual similarity is the task of deciding if two sentences express a similar or identical meaning and requires a deep understanding of a sentence and its meaning in order to achieve high performance. Recent successful approaches to this problem have been based on the idea of creating monolingual alignments (Sultan et al., 2014a) indicating which words in each of the two sentences correspond to each other. This is quite successful in many cases where many words have the same lemma, however when synonymous and semantically similar terms are used, it is much harder to construct alignment. For this reason, we propose the use of *soft alignments*, where instead of producing a hard linking between individual words in the sentence, we instead produce a score indicating how likely one word in a sentence is to be aligned to another word in the other sentence. We examine several methods that can be used to learn these alignments including word embeddings (Mikolov et al., 2013; Pennington et al., 2014) and models based on deep learn-

ing that have been suggested for machine translation (Bahdanau et al., 2014; Cho et al., 2014). In addition, we look into recent models for sentence and document similarity that can leverage the large amount of loosely aligned text in particular those based on Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007) and recent extensions aimed at generating orthogonal representations (McCrae et al., 2013; Aggarwal et al., 2015). While these novel techniques alone can achieve high performance on the task, we note that simple metrics such as the number of overlapping terms can produce reasonable performance. For added robustness we combine features based on simple metrics with novel methods explored in this work as a multi-feature regression problem, which we solve by means of an M5 Decision tree (Wang and Witten, 1996; Quinlan, 1992). The rest of the paper is structured as follows: we present our system in Section 2. We then present both our internal evaluation results and the official Task 1 results in Section 3 and finally we conclude in Section 4.

## 2 Methods

For convenience we assume that semantic textual similarity consists of finding a function that maps two strings,  $\mathbf{a}$  and  $\mathbf{b}$ , of length  $n_a, n_b$ , to a single value  $y \in [0, 1]$ . We will use  $A$  to denote the set of words in  $\mathbf{a}$  and  $B$  for the words in  $\mathbf{b}$ . We assume we have a dataset  $D$  consisting of triples of the form  $(\mathbf{a}_i, \mathbf{b}_i, y_i)$ .

## 2.1 Baseline features

The basic level of our system is the construction of baseline features that can be quickly and easily evaluated to quickly find candidates that are likely to be highly similar, which may be useful in search applications. Our features were partially based on those of Häning et al. (2015), but simplified such that we do not require a part-of-speech tagger. The features we used are as follows:

**Longest Common Subsequence** The length in tokens of the longest common subsequence between the two sequences

**$n$ -gram Overlap** The number of  $n$ -grams that occur in both sentences divided by the length of the shorter sentence.

**Jaccard** The Jaccard Index of the sentences using a bag-of-words model ( $|A \cap B| / |A \cup B|$ ).

**Dice** The Dice Co-efficient of the sentences using a bag-of-words model ( $2|A \cap B| / (|A| + |B|)$ ).

**Containment** The containment of the sentences using a bag-of-words model ( $|A \cap B| / \min(|A|, |B|)$ ).

**Sentence Length Ratio** The length of the sentence using the following symmetrized ratio:  $\min(|\mathbf{a}|, |\mathbf{b}|) / \max(|\mathbf{a}|, |\mathbf{b}|)$ .

**Average Word Length Ratio** The average length of the words, using the symmetric ratio as above.

**Greedy String Tiling** As in Wise (1993), we used Arun Kumar Jayapal’s implementation<sup>1</sup>, where similarity is given as follows, where coverage is the number of tokens covered by the tiling.

$$\frac{2 \times \text{coverage}}{|A| + |B|}$$

**Source and Target Length** The length (in tokens) of each of the two strings

<sup>1</sup><https://github.com/arunjeyapal/GreedyStringTiling>

**Keypairs** For each word pair  $(a, b)$  where  $a \in A$  and  $b \in B$ , we calculated

$$\lambda_{a,b} = \sum_{(\mathbf{a}_i, \mathbf{b}_i, y_i) \in D, a \in \mathbf{a}_i, b \in \mathbf{b}_i} y_i - \bar{y}$$

Where  $\bar{y} = \frac{\sum_D y_i}{|D|}$ . We took only the word pairs with the 20 highest absolute values for  $\lambda_{a,b}$ . The feature consisted of the number of occurrences of these keypairs.

## 2.2 Hard alignment

As we believe that hard alignments are also useful, we included features from hard alignment, firstly using a model based on Sultan et al. (2014b)’s system. We simplified this method using only the Word Similarity Aligner (*wsAlign*) and Named Entity Aligner (*neAlign*) parts of Sultan’s method, we found that this agreed with Sultan’s implementation<sup>2</sup> to an F-Measure of 93.8% and our observations and internal results suggested that the differences in alignments did not correspond to obvious improvements in alignment accuracy.<sup>3</sup>

We also use the alignments given by Jacana aligner (Yao et al., 2013)<sup>4</sup> directly as further alignments in our system. Jacana is a discriminatively trained monolingual word aligner that uses Conditional Random Field (CRF) model to globally decode the best alignment. It uses features based on WordNet and part-of-speech tags.

## 2.3 Soft Alignment

### 2.3.1 WordSim

Semantic relatedness measures can be directly used to compute the soft alignments between the sentences. In this approach, we compare the pre-trained neural word embeddings to compute the relatedness between words across both the sentences, thus producing the soft alignment matrix. We use cosine similarity for this purpose. We use the neural embeddings<sup>5</sup> developed by Baroni et al. (2014).

<sup>2</sup><https://github.com/ma-sultan/monolingual-word-aligner>

<sup>3</sup>For example in the pair “Being against nukes does not mean not wanting to use nukes” and “Being against using nukes means not wanting to use nukes” the systems differed in the alignment of the word “use”

**Table 1:** Pearson’s Correlation achieved by configurations of our system during development on the SemEval 2014 dataset

For each word pair  $(a, b)$  where  $a \in A$  and  $b \in B$ , let’s consider  $\vec{a}$  and  $\vec{b}$  as neural word embeddings respectively for  $a$  and  $b$ . Thus, soft alignment can be defined formally as a matrix  $\mathbf{S}$  of size  $n_a \times n_b$ , where  $s_{ij} = \vec{a} \cdot \vec{b}$  giving similarity between the word vectors.

### 2.3.2 BiLSTM

Soft alignments based only on the word similarity do not consider the word context in the sentence. Therefore, with the help of bidirectional recurrent neural network (BiRNN), we produce context-dependent word representations. BiRNN consists of a forward recurrent neural network (RNN) and a separate backward RNN to read the sentence in forward and backward directions respectively. Figure 1 shows a BiRNN representation for encoding a sentence. Here,  $\vec{a}_i$  refers to the pre-trained neural word embedding, and  $\vec{h}_i$  refers to the BiRNN representation for  $i^{th}$  word in the sentence, produced by the concatenation of forward and backward RNN representations. The approach being followed here is the same used in order to produce variable length sentence representation for soft attention mechanism in neural machine translation (Bahdanau et al., 2014). However, here we just use the BiRNN representations of the words for producing the soft alignments. Such representations can be considered as context-dependent representation as they carry the sentence summary at the position of each word. After producing the BiRNN representations for both the sentences, we simply compute cosine similarities be-

tween these representations at each word position across both the sentences, to produce the soft alignment matrix. Similarly as above in section 2.3.1, soft alignment can be defined as a matrix  $\mathbf{S}$  of size  $n_a \times n_b$ , where  $s_{ij} = \vec{h}_i \cdot \vec{g}_j$  and  $\vec{h}$  and  $\vec{g}$  are the BiRNN based contextual word representations. We use long short-term memory (Hochreiter and Schmidhuber, 1997, LSTM) for our experiments using our own implementation. For learning the BiLSTM based representations, we use a collection of the sentences from the previous years Semantic Textual Similarity Task.

**Figure 1:** BiRNN representation for encoding a sentence

### 2.3.3 Features

In order to apply soft alignment in a machine learning setting, we wish to transform these alignments into a set of features. In particular, these features should be able to calculate a single value bounded in some range regardless of the relative size of the two target sentences. As we generate a non-square matrix of variable size, we hypothesize that good alignments should resemble hard alignments.

| System                 | plagiarism | answer-answer | postediting | headlines | question-question | All     |
|------------------------|------------|---------------|-------------|-----------|-------------------|---------|
| m5all3                 | 0.80332    | 0.40165       | 0.81606     | 0.75400   | 0.72228           | 0.69528 |
| m5dom1                 | 0.75539    | 0.41211       | 0.80086     | 0.76778   | 0.69782           | 0.68368 |
| m5dom2                 | 0.74351    | 0.38303       | 0.76549     | 0.76485   | 0.57263           | 0.64520 |
| Median                 | 0.78949    | 0.48018       | 0.81241     | 0.76439   | 0.57140           | 0.68923 |
| Best system on dataset | 0.84138    | 0.69235       | 0.86690     | 0.82749   | 0.74705           | 0.77807 |

**Table 2:** Official results from SemEval, giving Pearson’s correlation on each dataset

For hard alignments, we used the number of rows (i.e., tokens) that had at least one alignment, thus for the soft alignment we used the row max of the alignment as follows:

$$m_\phi = \frac{\sum_{i=1 \dots n_a} \frac{\max_{j=1 \dots n_b} |\alpha_{ij}|^\phi}{\sum_{j=1 \dots n_b} \alpha_{ij}^\phi}}{n_a}$$

For our experiments we calculated four features with the following values of  $\phi = 0.1, 0.5, 1, 2$ .

In addition, we experimented with other sparsity features proposed by Hurley and Rickard (2009) and included the  $H_G$  metric and a modified version of the  $-l^p$  metric we call col- $-l^p$  as they gave good correlations with the sentence scores.

$$\begin{aligned} H_G &= -\sum_{i=1, \dots, n_a; j=1, \dots, n_b} \log \alpha_{ij}^2 \\ -l^p &= (\sum_{i=1, \dots, n_a; j=1, \dots, n_b} \alpha_{ij}^p)^{\frac{1}{p}} \\ \text{col-}l^p &= \frac{\sum_{i=1, \dots, n_a} (\sum_{j=1, \dots, n_b} \alpha_{ij}^p)^{\frac{1}{p}}}{n_a} \end{aligned}$$

We used  $p = 2, 10$  to give two features for col- $-l^p$ .

Finally, we noted that in many cases the most important alignments were those between low frequency words, therefore we transformed our alignments by multiplying them with the inverse document frequency of the words, e.g.,

$$\alpha'_{ij} = \frac{\alpha_{ij}}{df(a_i)df(b_j)}$$

## 2.4 ESA Similarity

Gabrilovich and Markovitch (2007) introduced the ESA model that represents the semantics of a word

with a distributional vector over the Wikipedia concepts. We use a snapshot of English Wikipedia from 1<sup>st</sup> October, 2013 which contains 13.9 million articles (concepts). We built an index of all Wikipedia articles using Lucene. We retrieve distributional vector of a sentence by searching over a Lucene index. Thus, a Lucene ranking score represents the magnitude of a vector dimension that corresponds to a retrieved Wikipedia article. We used Lucene’s built-in scoring function to obtain the top  $K = 1000$  articles and then to obtain the semantic relatedness between two sentences, we compute cosine similarity between their distributional vectors.

## 2.5 Classifying with M5 Trees

Finally, having baseline features, extracted features from the hard and soft alignments, and the ESA similarity, we combine all of our features into a single vector and thus transform the problem into that of a traditional regression task. We experimented with various classifiers using the Weka toolkit (Hall et al., 2009) and found that in nearly all experiments, the strongest performance was obtained using the M5 Decision Tree method (Wang and Witten, 1996; Quinlan, 1992) and so we adopted this for all our experiments.

## 3 Evaluation

### 3.1 Internal Evaluation

We conducted a series of evaluations using data from previous SemEval challenges (Agirre et al., 2014) as a baseline as shown in Table 1. These results present the following configurations using 10-fold cross-validation:

**Sultan Only (-DF)** Using baseline features, which are also used in all experiments, and Sultan et

|   |   |
|---|---|
| al.'s (2014a) aligner. Without accounting for term document frequency (see Section 2.3.3) | <b>m5dom1</b> This run uses Sultan, WordSim as aligners including ESA, and trains a decision tree per test dataset on the nearest training datasets using the domain classifier.  |
| <b>Sultan Only</b> As above only with document frequency included as a feature            | <b>m5dom2</b> This run uses all the aligners including ESA, and trains a decision tree per test dataset on the nearest training dataset using the domain classifier.  |
| <b>Sultan + Jacana</b> Including the Jacana aligner (Section 2.2)                         |   |
| <b>Sultan + WordSim</b> Including the WordSim features (Section 2.3.3)                    |   |
| <b>Sultan + WordSim + WordPairs</b> Including key-pairs features (Section 2.3.3)          |   |
| <b>All aligners</b> Using Sultan, Jacana, WordSim and BiLSTM aligners                     | We notice that our system has above-median performance in most datasets however, we have significant difficulties in the <i>answer-answer</i> , this is because of the length and complexity of the sentences. We also see that while the domain classifier was helpful in a few cases, notably the headlines, it did not in general seem to improve the results. Finally, we find that the combination of all classifiers was helpful. |
| <b>All aligners + ESA</b> Also including the ESA method (Section 2.4)                     |   |

In addition, we noticed that different datasets tended to have a different distribution of scores. As such we tried evaluating in two modes *macro-training* where we trained the decision tree on all datasets simultaneously and *microtraining* where a decision tree was trained for each dataset and used only for this dataset. As the microtraining results are much stronger, for the task, we developed a lightweight domain classifier that found the nearest training dataset to the test dataset and used the classifier trained on the most appropriate dataset in our evaluation runs. This classifier used the size of the intersection of the set of 100 most frequent words in each dataset and we obtained 100% accuracy for this classifier in identifying datasets by 10-fold cross-validation, i.e., we choose the classifier trained on the training set  $T$  which maximizes the following similarity to the test set  $T'$ :

$$|\text{top100words}(T) \cap \text{top100words}(T')|$$

### 3.2 SemEval results

We submitted three runs to the SemEval task and the results are reported in Table 2, the configurations were as follows:

**m5all3** This run uses all the aligners (Sultan, Jacana, WordSim) including ESA, and trains a single decision tree on all datasets simultaneously, without using the domain classifier.

## 4 Conclusion

We propose a combination of different approaches and our internal results suggest that combining multiple approaches can improve overall system performance. However, we notice that for some datasets performance is still very low and we hypothesise that in this case a new approach is needed. We notice that adapting to the domain proved extremely effective in the cross-fold setting but not in the general case, however our proposed method was very simplistic and further improvement in the quality of the result may be achieved by a more sophisticated algorithm.

## Acknowledgments

This research was supported in by funding from the Science Foundation Ireland under Grant Number SFI/12/RC/2289 (Insight).

# NORMAS at SemEval-2016 Task 1: SEMSIM: A Multi-Feature Approach to Semantic Text Similarity

Adebayo Kolawole John and Luigi Di Caro and Guido Boella

University of Torino

Corso Svizzera 185

Torino, 10149, Italy

kolawolejohn.adebayo@unibo.it, (dicaro, guido)@di.unito.it

## Abstract

This paper presents the submission of our team (NORMAS) to the SemEval 2016 semantic textual similarity (STS) shared task. We submitted three system runs, each using a set of 36 features extracted from the training set. The runs explore the use of the following three machine learning algorithms: Support Vector Regression, Elastic Net and Random Forest. Each run was trained using sentence pairs from the STS 2012 training data. Features extracted include lexical, syntactic and semantic features. This paper describes the features we designed for assessing the semantic similarity between sentence pairs, the models we build using these features and the performance obtained by the resulting systems on the 2016 evaluation data.

## 1 Introduction

Computationally assessing the semantic similarity of natural language data has gained the attention of researchers in the field of computational linguistics. Machines that are able to quantify the semantics of natural language have numerous important applications including: Document Similarity (Elsayed et al., 2008; Huang, 2008), Word Similarity (Resnik, 1995; Dagan, 2000; Bollegala et al., 2007; Pedersen et al., 2004), Text Summarization (Barzilay and El-hadad, 1999; Gong and Liu, 2001), Information Retrieval (Salton and Buckley, 1988; Manning et al., 2008), Plagiarism detection (Si et al., 1997), Paraphrase detection (Fernando and Stevenson, 2008) and especially Machine Translation (Brown et al., 1990).

The semantic textual similarity (STS) (Agirre et al., 2012) task measures the level of semantic equivalence between two approximately sentence sized snippets of texts on a graded scale from 0 (unrelated) to 5 (completely equivalent). This paper describes our participation in the SemEval 2016 STS shared task (Agirre et al., 2016). Our system explores 36 lexical and semantic features (e.g., string matching, WordNet similarity, word overlap) in combination with three very distinct learning algorithms (Support Vector Regression, Elastic Net and Random forest).

The remainder of this paper is organized as follows: *Section 2* describes our feature set in detail and our approach to feature selection. *Section 3* describes our machine learning models with section 4 presenting our results on the shared task evaluation data.

## 2 Feature Generation

We used a mixture of lexical, syntactic and semantic features extracted from text. Below, we describe each of the features provided to our model.

### 2.1 Lexical Features

**String matching:** String matching techniques compare words in two texts character by character and can be used to approximately capture morphological differences in the terms. Bär et al. (2012), one of the best performing systems in 2012, used variants of string matching algorithms. Our system made use of features computed using the following string matching methods:

1. **Longest common Substring:** This obtains the longest sequences of words appearing in both

sentences (Gusfield, 1997).

2. **Levenshtein Distance:** This measures the number of basic edit-operations (insertions, deletions, and substitutions) required to change one text into the other.
3. **Jaccard Similarity:** This measures the number of words shared by two sentences in ratio with the total number of words in the sentences i.e. given sentences A and B, the ratio is defined as:

$$Jac = \frac{A \cap B}{A \cup B} \quad (1)$$

**Word Ordering:** We use the union of all tokens in a pair of sentences to build a vocabulary of non-repeating terms. For each sentence, the position mapping of each word in the vocabulary is used to build a vector. To obtain the position mapping, a unique index number is assigned to each vocabulary term. To obtain the word order vector for a sentence, each term in the vocabulary is compared against terms in the sentence. If a vocabulary term is found in the sentence, the index number of that term in the vocabulary is added to the vector. Otherwise, similarity of the vocabulary term and each term in the sentence is calculated using a WordNet based word similarity algorithm. The index number of the sentence term with highest similarity score above a threshold is added. If the first two conditions does not hold, 0 is added to the vector. Consider two sentences S1 and S2,

**S1:** A panda bear

**S2:** A baby panda

Then the vocabulary is a list that contains the union of tokens in S1 and S2 as shown below:

**Vocabulary** = A, baby, bear, panda

**Vocabulary-Index** = A:1, baby:2, bear:3, panda:4

and the sentences are transformed to the vectors below:

**S1** = 1,0,3,4

**S2** = 1,2,4,4

In the example, the vocabulary term *bear* does not exist in S2. However, *bear* is closer to *panda* than all the terms in S2. The similarity score between them also exceeds the threshold. The index number of *panda* is thus assigned in place of *bear*. In

S1, the vocabulary term *baby* is not similar to any term, thus 0 is assigned. The word ordering feature is then computed as the cosine of the vectors after the WordNet based similarity transformation.

**Word Overlap:** We use the word n-gram overlap features of Šarić et al. (2012). The n-grams overlap is defined as the harmonic mean of the degree of mappings between the first and second sentence and vice versa, requiring an exact string match of n-grams in the two sentences.

$$Ng(A,B) = \left( 2 \left( \frac{|A|}{A \cap B} + \frac{|B|}{A \cap B} \right)^{-1} \right) \quad (2)$$

Where A and B are the set of n-grams in the two sentences. We computed three separate features using equation 2 for each of the following character n-grams: unigram, bigrams and trigrams. We also use weighted word overlap which uses information content (Resnik, 1995).

$$wwo(A,B) = \frac{\sum_{w \in A \cap B} ic(w)}{\sum_{w' \in B} ic(w')} \quad (3)$$

$$ic(w) = \left( \ln \frac{\sum_{w' \in C} freq(w')}{freq(w)} \right) \quad (4)$$

Where C is the set of words and *freq(w)* is the occurrence count obtained from the Brown corpus. Our weighted word overlap feature is computed as the harmonic mean of the functions *wwo(A,B)* and *wwo(B,A)*.

**Entity Overlap:** When two sentences have Named Entities (NEs) in common, a semblance of similarity is reflected. We extracted NEs from each sentence using the Stanford NER tagger (Finkel et al., 2005; Manning et al., 2014). The entity overlap feature is obtained as follows:

$$EOV = \frac{|A \tilde{\cap} B|}{|A \cup B|} \quad (5)$$

Where A and B represent the set of named entities in the first and second sentences, respectively. The intersection,  $\tilde{\cap}$ , allows partial matches since the NEs are considered equivalent if either there is an exact match or if one NE is a substring of the other. For example, '*President Obama*' is not the same as '*Barack Obama*', but '*Obama*' is considered a match for either of these.

## 2.2 Syntactic Features

**POS Overlap:** We used the Stanford POS-tagger to tag the words in each sentence with their POS categories. We group the words by the following coarse grained POS categories: nouns, verbs, adjectives and adverbs. We then compare the overlap between these classes of part of speech in each sentence, e.g., we compare the nouns in sentence 1 to the nouns in sentence 2 and vice versa across all 4 coarse grained POS categories. The POS overlap features are defined as the Jaccard similarity of the two sentences across just the words in a particular POS category:

$$POV_{pos} = \frac{|A_{pos} \cap B_{pos}|}{|A_{pos} \cup B_{pos}|} \quad (6)$$

Where  $A_{pos}$  and  $B_{pos}$  are the set of terms in POS class  $pos$  of sentences 1 and 2, respectively. This results in 4 unique POS overlap features.

**Dependency Parsing:** It is apt to assume that shared named entities can point to similarity in sentences. This assumption is more valid if sentences share the same *subject* and *object*. For example, if a named entity that is a *subject* in sentence 1 is also the *subject* in sentence 2 and vice versa the object. As an example, consider the two sentences below:

S1: Obama is the president of the United States

S2: Obama is the leader of the United States

In the first sentence, *Obama* is the subject (n-subj) of *President* while *State* modifies (nmod) the *President*. Also in the second sentence *Obama* is the subject of *leader* while *State* modifies the word *leader*.

We used the well-known *Stanford Parser* (Manning et al., 2014; De Marneffe et al., 2006) to extract the *subject-verb-object* triples from each sentence. In particular, the Neural Network-based dependency parser (Chen and Manning, 2014) was employed. We compare the *subject* and *object* of both sentences. If any of the objects or subjects in a sentence is a NE, we simply compare with the corresponding one from the other sentence by pure string matching. When the same word takes either the role of *subject* or *object* in the two sentences, we assign a flat score of 0.5. If both the *subject* and *object* in the two sentences correspond to the same NEs as in the example above, we assign a score of 1.0. Otherwise, we assign a score of 0.0.

## 2.3 Semantic Features

We extracted some semantic features using both information induced from corpus data as well as knowledge from existing semantic resources as described below:

**Word Embedding Similarity:** Word2Vec<sup>1</sup> (Mikolov et al., 2013b; Mikolov et al., 2013a) is an algorithm for inducing vector space representations of words, commonly known as word embeddings, that capture semantic relatedness and similarity. The method exploits the Distributional Hypothesis (Turney et al., 2010) and works best when trained on large corpora. We used the Gensim<sup>2</sup> implementation of the algorithm with specific parameter fine-tuning.<sup>3</sup> Gensim implements a variant of the algorithm known as *Skip-Gram*, which trains word representations using a model that when given a word will predict what words are likely to occur within a fixed window around it.<sup>4</sup> Once the word embeddings have been trained, the similarity of two words is computed as the cosine of the two embedding vectors.<sup>5</sup> Our word embeddings are trained on a combination of the Wikipedia dump of English language articles and the STS 2016 training data.<sup>6</sup>

For sentence level similarity scores, we compare each word in the first sentence to each word in the second sentence, obtaining a similarity score with the word2vec model. For each pair being compared, if the similarity score is less than < 0.25 then that similarity value is dropped. The final similarity is computed by summing the pair similarity values greater than 0.25 and dividing by the total count of these similarity scores. The aggregation function is

<sup>1</sup>Word2vec is available at <https://code.google.com/p/word2vec/>

<sup>2</sup>Gensim is a python library for an array of NLP tasks. It is available at <https://radimrehurek.com/gensim/>

<sup>3</sup>Parameters used: Context Window: 5, Neural Network layer size: 200, Minimum word count: 5.

<sup>4</sup>Skip-gram training generally performs better than an alternative Word2Vec model known as Continuous-Bag-of-Words (CBOW) that uses an alternative objective that tries to predict a word by conditioning on all of the words that surround it within a window.

<sup>5</sup>model.similarity(word1, word2) returns a similarity value from -1 to 1 between word1 and word2. Also model[word1] returns a numpy vector of word1

<sup>6</sup>The wikipedia dump was downloaded on July 30, 2015. It is accessible at <https://dumps.wikimedia.org/enwiki/>

given below:

$$\text{Sim} = \frac{\sum_{i,j}^{m,n} |S(w_i, w_j) > x|}{tCount} \quad (7)$$

Where  $S(w_i, w_j)$  is the similarity score for two words,  $tCount$  is the total number of the set of similarity scores that exceeds the threshold and  $\text{Sim}$  is the aggregating function combining all pairwise similarities.

**WordNet similarity:** The idea of pairing and aggregating similarity of words from two sentences being compared is not new and has been used both in textual entailment (Agichtein et al., 2008) and semantic textual similarity (Bär et al., 2012). To derive similarity from WordNet, we used both the path length between each word as well as the depth function. Usually, longer path length between two concepts signifies lower similarity. However, as pointed out by Li et al. (2006), this obviates the distance knowledge that can be easily observed from the hierarchical organization of some *semantic nets*. As a solution, the depth function was introduced, with the intuition that words at upper layer of a *semantic nets* contains general semantics and less similarity while those at lower layers are more similar. Thus, similarity should be a function of both the depth and the path length distances between concepts. If  $f1(h)$  is a function of the depth and  $f2(l)$  is a function of the length, then the similarity between two word is given by:

$$S(w_1, w_2) = f1(h).f2(l) \quad (8)$$

The length function is a monotonically decreasing function with respect to the path length  $l$  between two concepts. This is captured by introducing a constant alpha.

$$f2(l) = e^{-\alpha l} \quad (9)$$

Likewise, the depth function is monotonically increasing with respect to the depth  $h$  of concept in the hierarchy.

$$f1(h) = \frac{e^{\beta h} - e^{-\beta h}}{e^{\beta h} + e^{-\beta h}} \quad (10)$$

The similarity between two concepts is then calculated by:

$$S(w_1, w_2) = e^{-\alpha l} \cdot \frac{e^{\beta h} - e^{-\beta h}}{e^{\beta h} + e^{-\beta h}} \quad (11)$$

Li et al. (2006) empirically discovered that for optimal performance in WordNet, alpha should be set to 0.2 and Beta set to 0.45. To aggregate the similarities, we used the formula in equation 7 with a threshold of 0.25.

**Vector Space based Similarity:** We used the feature extraction module of the *scikit-learn* to extract the *TFIDF* weighted feature vectors for the two sentences and then calculated the cosine similarity between them:

$$\cos(A, B) = \frac{\sum_{t=1}^n TFIDF(w_{t,A})TFIDF(w_{t,B})}{\sqrt{\sum_{t=1}^n w_{t,A}^2 \sum_{t=1}^n w_{t,B}^2}} \quad (12)$$

Where  $A$  and  $B$  are the two texts being compared for similarity. The term frequency *TF* and inverse document frequency *IDF* are computed solely from the compared sentence pairs.

**Compositional Distributional Approach:** A limitation of Distributional Hypothesis (Harris, 1954; Firth, 1957) is that it captures the meaning of words in isolation. However, the true meaning of a sentence must take into account the interplay between the words it contains (Mitchell and Lapata, 2008; Mitchell and Lapata, 2009; Grefenstette et al., 2014). To account for this, we perform vector composition of the words in each sentence, using both additive and multiplicative composition (Mitchell and Lapata, 2010; Baroni, 2013). We obtained the vectors from the Word2Vec model described earlier. For the additive model, the vectors of all the words in a sentence are summed together to get a single vector for that sentence. Likewise, in the multiplicative model, vectors of all words in a sentence are multiplied component-wise to obtain a single vector for the sentence. To obtain similarity scores for each composition method, i.e., additive and multiplicative, we take the cosine of the vector space representation of the two sentences being compared.

### 3 System Description

For each sentence pair, our system generates 36 lexical, syntactic and semantic features. We experiment with using three distinct learning algorithms to map our feature representation onto an STS similarity score for the pair. The three learning algorithms correspond to the three runs we submitted to the shared task: **Normas-RFI**, was trained with *Random Forest*

| Dataset     | Run1  | Run2         | Run3        | Mean | Baseline-Median | Baseline-Best |
|-------------|-------|--------------|-------------|------|-----------------|---------------|
| Answer      | .160  | <b>.365</b>  | .276        | .267 | .480            | .692          |
| Question    | .467  | .613         | <b>.653</b> | .577 | .571            | .747          |
| Postediting | .720* | <b>.802*</b> | .797*       | .773 | .812            | .866          |
| Plagiarism  | .621  | <b>.746</b>  | .724        | .697 | .789            | .841          |
| Headlines   | .588  | .688         | <b>.722</b> | .666 | .764            | .827          |
| Runs Mean   | .508  | .640         | .630        | .596 |                 |               |

**Table 1:** Summary of Pearson Correlation Evaluation Of The Submitted System

(Breiman, 2001; Liaw and Wiener, 2002); *Normas-SV2*, uses *Support Vector Regression* (Chang and Lin, 2011; Basak et al., 2007); *Normas-ECV3*, is based on *Elastic Net* (Zou and Hastie, 2005). As training data, we used 2234 sentence pairs from the 2012 training data. Parameter fine-tuning<sup>7</sup> for each of the algorithms was done using *OnWN* dataset of the STS 2013 evaluation data as the development test set. We used the scikit-learn<sup>8</sup> implementation of the three algorithms.

#### 4 Evaluation and Discussion

We conducted two experiments, *Pre-Submission* and *Post-Submission* experiments. Table 1 summarizes the result of the Runs submitted across the datasets for the first experiment (*Pre-Submission*). The scores in **bold** shows the best scores per dataset. The scores with asterisk (\*) appended shows the best scores under each Run. We used the preliminary result of the 2016 STS task released by the organizers as the baseline for evaluation. The preliminary result includes the median scores (*Baseline-Median*) and best scores (*Baseline-Best*) of the participating systems on each dataset. The *Baseline Best* is the score of the top performing system for each dataset of the Semeval 2016 task(Agirre et al., 2016).

It can be seen from *Table 1* that our best scores were from #Run2 and #Run3. The Random Forest algorithm performed poorly compared to the other two Runs on all of the datasets. All three Runs performed best on the Post-Editing dataset. This conforms to the pattern observed from the Baseline

scores. Analysis of this dataset revealed that the sentences are longer and share more words.

Our worst performance across board is on the Answer-Answer dataset. Inspecting the data reveals that the sentences are both short and tend to share words that have little or no impact on their overall meaning. Our models may have been misguided by these spurious matching words.

Overall, our best systems, #Run2 and #Run3, have results very close to the *Baseline-Best* on three datasets and outclassed *Baseline-Median* on Question-question dataset. Our system performance may have been handicapped by the limited amount of data we used for training. Recall that we trained our system on only 2234 sentences of the 2012 training data. The tiny size of the dataset was necessitated by the complexity of computing some of the semantic features. Specifically, the WordNet similarity features used. Also, analysis of our training data shows that the sentences are of few words (short) and with high term overlap. Perhaps, our system could have performed better with more training data, especially if we had used a dataset with long sentences and also included more training data from previous STS evaluation tasks.

After the official evaluation, we reproduced our experiment using a larger training set. The new training data contains 9902 sentences drawn from the 2012-2014 evaluation datasets. Using more training data resulted in a notable improvement in performance. *Table 2* reports the results obtained by our (*post-submission*) systems. The *Percentage Gain* column shows the improvement in performance when the *Mean* result in the second experiment is compared to the one submitted initially (*pre-submission*).

The best improvement observed is from the *Answer-Answer* dataset with **38.0 %** improvement

<sup>7</sup>For SVR, we used the LibSvm scikit implementation with RBF kernel. We set C=1.0, epsilon=0.2 and cache size=200. For Elastic Net we used alpha=0.5. Random Forest, we used 100 trees, max\_depth=None and max\_leaf\_nodes=None. Grid search was used for hyperparameter optimization.

<sup>8</sup><http://scikit-learn.org/>

| Dataset     | Run1        | Run2         | Run3        | Mean | Percent Gain | Baseline-Median | Baseline-Best |
|-------------|-------------|--------------|-------------|------|--------------|-----------------|---------------|
| Answer      | .380        | <b>.542</b>  | .371        | .431 | 38.0         | .480            | .692          |
| Question    | .698        | .714         | <b>.723</b> | .711 | 18.8         | .571            | .747          |
| Postediting | .819*       | <b>.852*</b> | .809*       | .826 | 6.80         | .812            | .866          |
| Plagiarism  | .797        | <b>.821</b>  | .784        | .800 | 12.8         | .789            | .841          |
| Headlines   | <b>.805</b> | .789         | .780        | .791 | 15.8         | .764            | .827          |
| Runs Mean   | .699        | .743         | .693        | .711 | 16.1         | .683            | .794          |

**Table 2:** Post-Submission Experiment With More Training Data (9902 sentence pairs)

across all Runs. The result from our top performing Runs across all datasets clearly surpass the *Baseline-Median* results. The top scores for each dataset were also very close to the *Baseline-Best* results. Our overall Mean of **0.711** surpasses the overall Mean of the *Baseline-Median* (0.683) and is far better than the 0.596 obtained by our submitted systems.

## 5 Conclusion

This paper has described our system submission to the SemEval 2016 STS shared task. We participated in the STS-Core (*Monolingual subtask*). We submitted three Runs using the same feature set but with models built by different machine learning algorithms. We obtained the best performance from the *Support Vector Regression* and *Elastic Net* based models and observed relatively poor performance from *Random Forests*.

The systems we submitted to the shared task obtained results that are very close to the best performing shared task system in 3 datasets and above the median mark on another dataset .

After the shared task, we reproduced our experiment on a bigger training dataset. We obtained a significant improvement (16.1%) when compared to the first experiment.

In future work, we plan to investigate the significance of all features so as to identify noisy or less important ones as well as to attempt to identify the optimal combination of features. Another improvement might be to build an *ensemble* combining individual systems built using variations in any one of the following: learning algorithm, feature set, or training data sampling (e.g., combining our best two systems).

## Abstract

This paper describes the *SOPA-N* system used by the LIPN-IIMAS team in SemEval 2016 Semantic Textual Similarity (Task 1). We based our work on the *SOPA 2015* system. The *SOPA-2015* system used 16 similarity features (including Wordnet, Information Retrieval and Syntactic Dependencies) within a Random Forest learning model. We expanded this system with an Align and Differentiate based strategy, word embeddings and penalization, which showed 6.8% of improvement on the development set. However, we found that on the evaluation data for the 2016 STS shared task, the 2015 system outperformed our newer systems.

## 1 Introduction

The *SOPA* system combines a regression model with multi-level similarity measures, from very simple ones (like edit distance) to more sophisticated ones (like IR-based or Wordnet similarity) (Buscaldi et al., 2013). Our goal this year was to add an align-and-differentiate penalizing strategy based on (Han et al., 2015) to our 2015 system (*SOPA*) (Buscaldi

et al., 2015). The previous version consists on 16 similarity features which are regressed using a Random Forest learning algorithm. The rationale of the penalization was to account for cases when apparent distributional alignments are closer than their semantically equivalent (for instance, colors: while *black* and *white* are distributional close because are colors, but they are not semantically equivalent). We present two versions of the enhanced system *SOPA 100* and *1000* which refers to the number of estimation trees used by the Random Forest algorithm.

We find that augmenting our 2015 model with an align and differentiate module boosts performance on the 2015 evaluation data. However, on the STS 2016 test data it only outperformed our previous approach on the plagiarism dataset. A closer error analysis showed that the gap between *SOPA 100* and the gold standard (GS) scores are systematically positive, meaning that our new system overestimated the semantic similarity between phrases. Another interesting finding from the error analysis was that in those sentences where *SOPA 100* outperform *SOPA*, it was also more accurate, given the fact that the *SOPA 100* standard deviation from the gold standard annotation was smaller than the one of

*SOPA*.

Ablation tests for every feature were performed as well. Within our 2015 system, Sultan’s alignment based similarity feature, Sultan et al. (2015)’s feature 18 , seems to be pulling down scores both for the headlines and question-question domains of 2016 dataset, despite the fact that 2015 train and test sets were used to train our 2016 system. Further analysis might be necessary in order to fully answer why *SOPA* 100 runs seemed to improve our scores for evaluation data from 2015, but they didn’t for 2016 datasets.

## 2 SOPA

The SOPA system was built upon the idea on combining simple measures with a regression model to obtain a global, graded measure of textual similarity. Past experiences on this system have shown that the Random Forest (Breiman, 2001) outperforms other regression algorithms (like  $\nu$ -Support Vector Regression or Multi-Layer Perceptron). Table 1 shows individual text similarity measures used as features for the global system, which have been described in more detail in (Buscaldi et al., 2013) and (Buscaldi et al., 2015).

### 2.1 Align-and-differentiate

This year we included a strategy that consists in two main steps:

1. Align words of both phrases
2. Differentiate or penalize those alignments that distributionally appear closer than they really are.

In the first step, the first word of phrase  $A$  is compared against each word of phrase  $B$ , and the pair which has the best similarity score is considered as an alignment pair and the words are removed from candidates. Then the process is repeated for the second word of phrase  $A$  and so on until all words are used.

The second step consists in inspecting each candidate alignment and penalizing those alignments that do not represent interchangeable concepts (synonyms). First, if an alignment score does not surpass a threshold, the alignment pair is discarded and those words are considered out-of-context. Second,

|     | Measure                                      |

| 19* | Sultan alignment with word2vec* (right-left) |
| 20* | Sultan alignment with WordNet (right-left)   |
| 21* | Word2vec simple alignment (left-right)       |
| 22* | Word2vec simple alignment (right-left)       |
| 23* | Average of word2vec alignments               |

**Table 1:** Similarity Measures (\* new features for 2016.)

the words of each pair is searched in Wordnet and: if those words are antonyms the alignment is penalized; if both words are hyponyms of a Disjoint Similar Concept (DSC) (Han et al., 2015), the alignment is penalized as well.

We also included an alignment-shift-penalization. It is computed using Spearman correlation over the position in the phrase of the aligned words. The idea behind is to reduce the similarity score on those phrase alignments in which aligned pairs consist in words with a very different position in phrase  $A$  with respect phrase  $B$ .

### 2.2 Alignments

Two different alignment strategies were tried. A pure distributional based alignment in which words are aligned using *word2vec* (Mikolov et al., 2013) to measure the cosine similarity between the two words and aligned pairs are determined using the best local alignment. In this approach, a left-right alignment and a right-left alignment are combined in order to,

in some way, alleviate the appearance of local maxima.

The second is a hybrid strategy that combines a syntactic based alignment produced by Sultan with a distributional alignment. This is, it uses the pairs given by Sultan aligner (Sultan et al., 2014) and those not aligned words of both phrases are submitted to a second alignment process (distributional) that in some sense complements the syntactic alignment.

### 3 Experimental setting

We used the following configurations for *SOPA* 100 and *SOPA* 1,000 runs, they were applied to the features 17-23:

- Words identification and tokenization was done using a simple space-based regular expression.
- Similarity in WordNet was obtained using the *path\_similarity* metric available in NLTK package (Loper and Bird, 2002).
- For the penalization by shift-external-alignment, the Spearman correlation between the positions of aligned words is computed and, if the correlation is above a threshold of 0.25, it is multiplied by the alignment score.
- When checking the aligned pairs of words in WordNet: if one word of the pair is listed as an antonym of the other, a penalty of 1.0 is applied.; if words are not antonyms, we search the lowest common hypernym for both synsets, then we walk the path from this hypernym to the root and if in this walk we visit one of the nodes considered DSC then a penalty of 0.5 is applied.
- We used cosine as the measure of distance among vectors. The vectors are extracted form the standard Google pretrained *word2vec* models with 300 dimensions.<sup>1</sup>
- We used the list of English stop-words available in the NLTK package to filter stop-words from sentences.

---

<sup>1</sup><https://code.google.com/archive/p/word2vec/>

- We discarded alignments that are below an align-threshold of 0.3.

- Each unaligned word was considered out-of-context (OOC) and for each of those, a penalization of 1.0 was applied.

The code of our implementation and experimentation is openly available.<sup>2</sup>

### 4 Results

These year runs were:

**SOPA** The *SOPA* 2015 system (16 scores) trained with a random forest regressor set to 100 estimators (Buscaldi et al., 2015).

**SOPA 100** This was the *SOPA* similarities plus the align-and-differentiate scores trained with a random forest regressor set to 100 estimators.

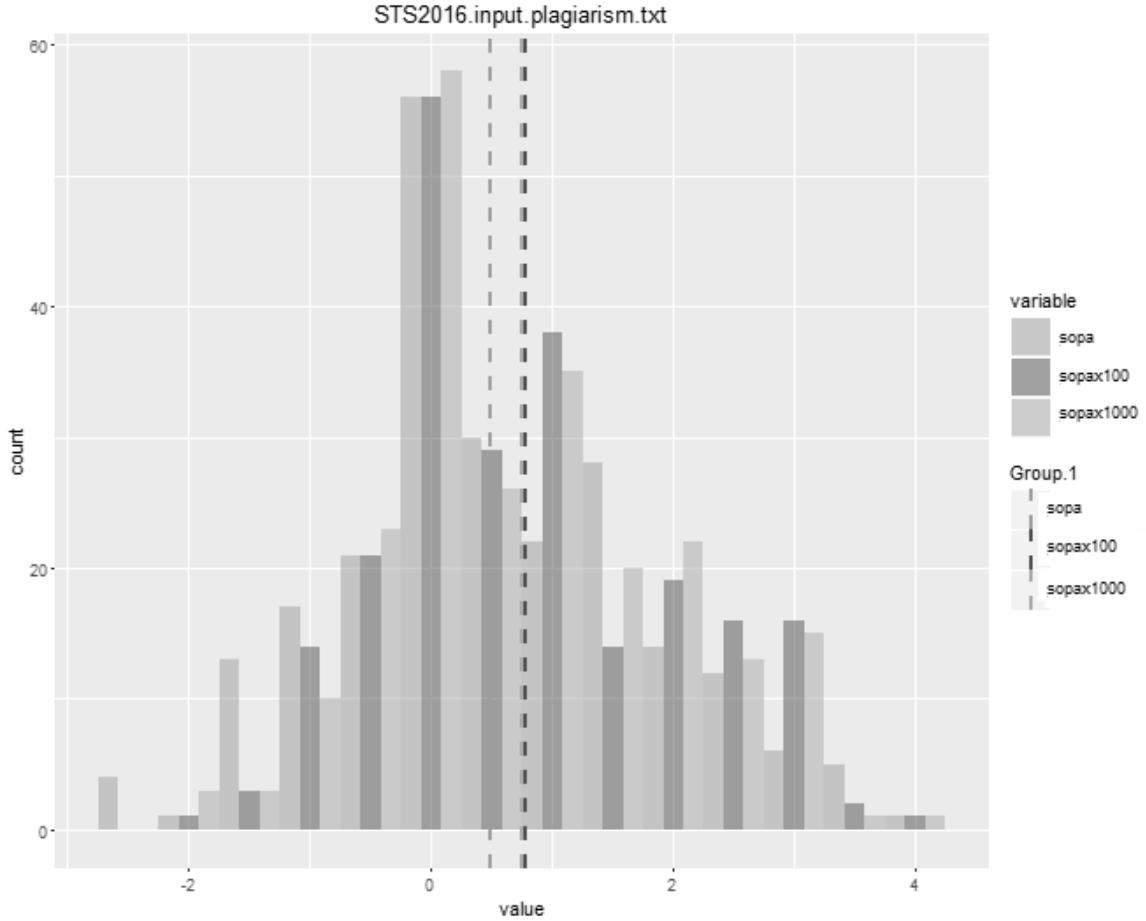

**SOPA 1000** This was the *SOPA* similarities plus the align-and-differentiate features trained with a random forest regressor set to 1,000 estimators.

Table 2 shows the performance of each of these systems on the 2016 STS evaluation data. As it can be appreciated the *SOPA* outperforms the other runs in most domains and in the overall evaluation. The extracted scores using the align-and-differentiate strategy were not helpful for these datasets. This was contrary to our development experience in which the these scores contributed to improve the performance of the 2015 *SOPA* system (see Table 3 with 2015 test dataset).

The change of behavior from the developing to the testing stage was unexpected. With this in mind we proceed to do further experimentation. First we re-run the *SOPA* 100 and *SOPA* 1,000 setting but only using the align-and-differentiate scores. Table 4 present these results, as expected this time the performance is quite poor. Effectively, the performances of the score were too poor, so that they bring down the full performance. These experiments confirms what we learn from Table 2. In order to gain a better insight on the scores we run an ablation experiment. In this case we suppress each the score and measure the loss in performance. Table 5 presents

---

<sup>2</sup><https://github.com/rcln/SemEval>

**Figure 1:** Distribution of the difference with plagiarism

these losses. The table marks with a star those score which have a negative loss, meaning that without them the performance will increase. However, we do not observe a general pattern. Similarity scores for some domains made them particularly worse, but not for others. The *headlines*, *plagiarism* and *question-question* has a larger amount of features that were not very useful. We identify 8 scores with a negative overall loss, however further experimentation without these features did not give a better performance for the *SOPA* 100 and *SOPA* 1,000 settings.

Figure 2 shows the differences of the runs with the gold standard. The first thing to notice from this graph is that all systems tend to overestimate the score, this is they give a larger score than the gold standard. We also notice that the standard deviation is close to one for most of the runs. However, these graphs do not tell the whole story, for instance in the case of the *plagiarism* domain the distribution of the

difference is far from normal, Figure 1 shows the histogram of score differences, illustrating a slight positive skew in the predictions.

## 5 Conclusions and perspectives

In this paper we introduced the *SOPA-N* system used to calculate semantic similarity between sentence pairs for the Semeval STS 2016 Challenge. *SOPA-N* is based in a 23 similarity feature set and

**Table 3:** Development results (STS 2015)

a Random Forest learning algorithm. New features for this year challenge included word embeddings based on Sultan et al. (2015)'s alignment and an Align-And-Differentiate strategy inspired by Han et al. (2015). These improvements allowed us to outperform our previous approach only for the *plagiarism* test corpus. Even if *SOPA-N* was more accurate for those sentences where its score gap between the gold standard was better than *SOPA*, further error analysis is needed.

**Table 4:** Re-run of 100 system with only align-and-differentiate scores

We hypothesize that the addition of align based features was not appropriate for this year data. Particularly we plan to analyze alignment errors and expand the context to better guide the alignment. Also, future research will focus in a deeper characterization of 2016 test in terms of spelling correctness, typography profile POS-tag categories, semantic and discursive level in order to find correlation between these characteristics and the GS gap of our system.

## Abstract

In this paper we consider several approaches to predicting semantic textual similarity using word embeddings, as well as methods for forming embeddings for larger units of text. We compare these methods to several baselines, and find that none of them outperform the baselines. We then consider both a supervised and unsupervised approach to combining these methods which achieve modest improvements over the baselines.

## 1 Introduction

Word embeddings (Mikolov et al., 2013) have recently led to improvements in a wide range of tasks in natural language processing. A number of approaches to forming embeddings for sentences, paragraphs, and documents have also recently been proposed (e.g., Le and Mikolov, 2014; Kiros et al., 2015). These methods seem particularly well suited to the task of predicting semantic textual similarity (STS), and indeed have been shown to work very well on similar tasks (Kiros et al., 2015).

This paper describes the system of UNBNLP at SemEval-2016 Task 1. We first implement several baseline approaches to STS based on cosine similarity of count-based vectors representing sentences, with a variety of approaches to term weighting. We then consider approaches drawing off of word2vec (Mikolov et al., 2013), paragraph vectors (Le and Mikolov, 2014), and skip-thoughts (Kiros et al., 2015). We find that none of these approaches improve over any of our baselines.

We then consider combining information from these individual methods to measuring STS. We consider an unsupervised approach based on the average of the predicted similarities for a number of these individual approaches. We further consider a supervised approach in which we train ridge regression with features corresponding to the similarities from these individual methods. Each of these methods for combining information achieves modest improvements over the baselines.

## 2 Measuring short text similarity

We present several methods for measuring STS in Section 2.1. We then present approaches to combining these methods in Section 2.2.

### 2.1 Individual methods

#### 2.1.1 Baselines

We present three baseline methods. In all of these baselines, each sentence in a pair of sentences is represented as a vector, where each dimension corresponds to a word type (i.e., a word form).

In the first approach, referred to as BASELINE-BIN, the dimensions hold binary values indicating whether the corresponding type occurs in the sentence. In the second approach, BASELINE-FREQ, the dimensions hold the frequency of the corresponding type in the sentence. For the third approach, BASELINE-TF-IDF, each dimension holds the tf-idf weight for the corresponding type in the sentence. Idf values were calculated over a 2015 dump of English Wikipedia from 1 September 2015, which was pre-processed using wp2txt<sup>1</sup> to remove markup.

<sup>1</sup><https://github.com/yohasebe/wp2txt>

For all baseline methods, the similarity between two sentences is calculated as the cosine between the vectors representing them. In these baseline methods, the documents are tokenized using an approach suggested by Speriosu et al. (2011) — the text is first split based on whitespace; for each token, if it contains at least one alphanumeric character, then all leading and trailing non-alphanumeric characters are stripped. Stopwords are removed based on a stopword list,<sup>2</sup> and case folding is applied.

### 2.1.2 Word2vec

We considered two methods based on word embeddings from word2vec (Mikolov et al., 2013). For each sentence, we formed a vector corresponding to the element-wise summation, and product, of the word embeddings for each token in that sentence. We then measure the similarity of two sentences as the cosine between their vector representations. We refer to these methods as WORD2VEC-SUM and WORD2VEC-PROD, respectively.

For this method, we used pre-trained word2vec vectors provided by Google.<sup>3</sup> These vectors have 300 dimensions, and were trained on a corpus of documents from Google News that contained approximately 100 billion tokens.

For this method, sentences were tokenized by splitting on whitespace, and then removing non-alphanumeric characters. The text was also case-folded.

### 2.1.3 Paragraph vectors

Paragraph Vectors (Le and Mikolov, 2014) is an extension of word2vec (Mikolov et al., 2013) to text of arbitrary length. In our implementation, we used the Distributed Memory Model of Paragraph Vectors (PV-DM) to represent each sentence as a vector. The similarity between two sentences was then computed as the cosine of their vector representations. We refer to this approach as PARAGRAPH VECTORS.

The gensim<sup>4</sup> implementation of the PV-DM model was trained on a roughly 540 million token sample of English Wikipedia. To tokenize the

Wikipedia corpus, the text was first split based on whitespace; then, all non-alphanumeric characters, except for +, -, \$ and %, were removed. The remaining tokens were case-folded. Tokens that did not have a Unicode encoding, or that occurred less than 5 times in the corpus were removed. During training, every paragraph in the corpus was treated as a separate paragraph in the model.<sup>5</sup>

The dimensionality of the word and paragraph representations was set to 400. A window size of 8 was used. The negative sampling parameter was set to 20. The subsampling parameter was set to  $10^{-5}$ . After training the model, the vector representing each sentence was inferred.

### 2.1.4 Skip-thoughts

Skip-thoughts (Kiros et al., 2015) can be viewed as an extension of the word2vec skipgram model for obtaining vector representations of sentences. Skip-thoughts is primarily an encoder–decoder model composed of gated recurrent units (GRUs). A GRU (Cho et al., 2014) is a recurrent neural network used for sequence modeling (Chung et al., 2014). It is similar to long short-term memory (Hochreiter and Schmidhuber, 1997), but with a simplified gating architecture that does not include separate internal memory cells. The encoder receives a sequence of tokens from a sentence, and the decoder attempts to predict the sentence before the input sentence, and the sentence after it. Once the model has been trained, the vector representation of a sentence can be extracted from the learned encoder by inputting the sequence of tokens that makes up the sentence.

We used the pre-trained combine-skip model provided by Kiros et al. (2015) to build the vector representation of sentences. This produces a 4800 dimensional vector for each sentence by concatenating the vector representations from the uni-skip model and the bi-skip model. The uni-skip model is a unidirectional encoder that encodes the input tokens of a sentence in their original order, and outputs a 2400 dimensional vector. The bi-skip model is a bidirectional model that encodes the input tokens of a sentence in their original order, and in their reversed order, outputting a 1200 dimensional vector for each direction. The similarity between two sentences is

| PARAGRAPH-VECTORS       | 0.41123        | 0.69169        | 0.60488        | 0.75547        | -0.02245          | 0.50206        |
| SKIP-THOUGHTS           | 0.27148        | 0.23199        | 0.49643        | 0.48636        | 0.17749           | 0.33446        |
| SKIP-THOUGHTS-REG       | 0.28626        | 0.51019        | 0.66708        | 0.69947        | 0.40459           | 0.51299        |
| AVERAGE (Run 2)         | <b>0.58520</b> | 0.69006        | 0.78923        | <b>0.82540</b> | 0.58605           | 0.69635        |
| REGRESSION (Run 3)      | 0.55254        | 0.71353        | 0.79769        | 0.81291        | 0.62037           | <b>0.69940</b> |

**Table 1:** Pearson correlation for each method, on each dataset, as well as the weighted average correlation over all datasets (“All”). The best method on each dataset, and over all datasets, is shown in boldface.

then computed by taking the cosine similarity of their vector representations. This method is referred to as SKIP-THOUGHTS.

We further considered a supervised approach based on skip-thought vectors. We again formed a vector representing each sentence using the pre-trained model provided by Kiros et al. Then, following Kiros et al., we represented each pair of sentences as a vector consisting of the concatenation of the componentwise product, and absolute difference, of the vectors representing the sentences. That is, if  $\vec{u}$  and  $\vec{v}$  are the  $d$ -dimensional skip-thought vectors representing two sentences, we represent this sentence pair as a  $2d$ -dimensional vector consisting of the concatenation of  $\vec{u} \circ \vec{v}$  and  $|\vec{u} - \vec{v}|$ . We trained ridge regression using gold-standard STS data from 2012, 2013 and 2015, and then used this model to predict similarity for the test sentence pairs. We refer to this model as SKIP-THOUGHTS-REG. We implemented this model after submitting our official runs.

## 2.2 Method combinations

We used two different methods — one unsupervised, and one supervised — to combine the individual methods in an effort to develop a stronger system.

For the unsupervised method, AVERAGE, we computed the average of BASELINE-BIN, BASELINE-TF-IDF, WORD2VEC-PROD, PARAGRAPH-VECTORS, and SKIP-THOUGHTS. We did not consider BASELINE-FREQ here because it is quite similar to BASELINE-BIN, which performed better on development data.

For the supervised approach to combining individual methods, we trained ridge regression over

the similarities produced by the following methods: BASELINE-BIN, BASELINE-TF-IDF, PARAGRAPH-VECTORS, and SKIP-THOUGHTS. The ridge regression was trained using the gold standard data provided for STS tasks in 2012, 2013, and 2015; this model was then used to predict similarities for sentence pairs in the test data. We refer to this method as REGRESSION.

## 3 Results

Results for each method, on each dataset, are shown in Table 1. We first consider the baseline approaches. On development data from previous STS tasks, BASELINE-TF-IDF gave higher correlations than baselines based on word presence (BASELINE-BIN) or word frequency (BASELINE-FREQ). Moreover, this was a challenging baseline to beat, and was among the best methods we considered on the development data. It was therefore submitted as one of our official runs. However, on the test data, BASELINE-TF-IDF had the lowest average correlation of the three baseline approaches considered.

In terms of the methods based on word2vec, representing a sentence as the componentwise product of the vectors for the words in that sentence (WORD2VEC-PROD) performed much better than the approach based on vector addition (WORD2VEC-SUM). PARAGRAPH-VECTORS outperformed both word2vec approaches. However, none of these word embedding-based methods performed as well as any of the baselines.

Naively measuring similarity as the cosine between skip-thought vectors for the sentences in a pair (SKIP-THOUGHTS) led to relatively poor perfor-

mance. Training ridge regression based on features derived from skip-thought vectors (SKIP-THOUGHTS-REG, described in Section 2.1.4) led to substantial improvements, although again this approach did not beat any of the baselines.

AVERAGE and REGRESSION — both submitted as official runs — combine several of the individual methods together, and both achieve correlations that are, overall, better than those of any of the baselines. However, the improvements are relatively modest. Although there is some variation across the datasets, AVERAGE and REGRESSION perform very similarly overall. AVERAGE, however, has an advantage, in that it is an unsupervised approach.

## 4 Conclusions

In this paper we first considered several baseline approaches to STS. We then considered approaches based on word2vec, paragraph vectors, and skip-thoughts. We found that none of these approaches improved over any of the baselines. We further considered combining these approaches via averaging, and a supervised approach based on regression, and achieved modest improvements over the baselines.

## Abstract

A growing body of research has recently been conducted on semantic textual similarity using a variety of neural network models. While recent research focuses on word-based representation for phrases, sentences and even paragraphs, this study considers an alternative approach based on character n-grams. We generate embeddings for character n-grams using a continuous-bag-of-n-grams neural network model. Three different sentence representations based on n-gram embeddings are considered. Results are reported for experiments with bigram, trigram and 4-gram embeddings on the STS Core dataset for SemEval-2016 Task 1.

## 1 Introduction

This paper presents an approach for finding the degree of semantic similarity between sentence pairs. Semantic textual similarity (STS) is of relevance to many NLP applications. Recent tasks in recognizing textual entailment, sentence completion and paraphrase identification are closely related. The approach described here makes use of a neural network (NN) algorithm (word2vec) that is typically used to generate word embeddings (Mikolov et al., 2013a). Rather than generating vector representations for words however, we propose a character n-gram-to-vector approach. A sentence is then represented as a vector generated through a combination of character n-gram embeddings.

The use of character level vectors has been proposed in a number of recent studies. Subword language models that use the combination of characters, syllables and frequent words have been

explored by Mikolov et al. (2012). Character-level language modeling has been performed for modeling OOV words, where using words as the atomic units of the model would not be sufficient to assign a probability score. In Ling et al. (2015), word representations are composed of vectors of characters, called character to word (C2W). The C2W vectors are used successfully for language modeling and POS tagging without any handcrafted features. The resulting model is competitive on English POS tagging with the Stanford POS tagger word look-up tables and also produces a notable improvement in results for morphologically rich languages such as Turkish. Kim et al. (2015) apply a simple convolutional neural network model, which uses character level inputs for word representations. Again, this method outperforms the models that use word/morpheme level features in morphologically rich languages, while also having competitive results in English. Huang et al. (2013) introduce a word hashing technique using character n-grams to scale up training of deep NN models for large-scale web search applications.

Our motivation for exploring character n-grams derives in part from previous work we have conducted on paraphrase identification (PI). The PI task is that of deciding whether two sentences have the same meaning. We have shown that sentence representations based on bags or sets of character n-gram features can perform well at this task (Eyecioglu and Keller, 2015). It is hypothesized that n-grams are useful for capturing lexical similarity and perform a role similar to lemmatization whilst preserving differences. Thus, sentence representations based on collections of n-grams as features may offer some advantages over representations based on words as features.

The current study aims to extend this earlier work by working with n-gram embeddings. (Mikolov et al., 2013a) introduced two new NN architectures that were applied to learning word embeddings: continuous-bag-of-words (CBOW) and skip grams (SG). These NN models have been shown to perform well in many NLP areas such as STS and PI (Zarrella et al., 2015; Yin and Schütze, 2015; He et al., 2015). Recent research has taken steps to extend these word vectors to sentences, paragraphs and documents (Le and Mikolov, 2014).

We introduce an alternative approach to obtaining sentence level embedding vectors that make use of character n-grams rather than words. We adopt a model architecture that is analogous to CBOW, which we call *continuous-bag-of-n-grams* and notate as CBOOnG throughout the paper. In keeping with our earlier work on paraphrase identification (Eyecioglu and Keller, 2015), pre-processing is kept to a minimum and no use is made of any manually constructed semantic or syntactic processing tools or resources.

Operationally, STS is similar to paraphrase identification. The two tasks differ in that STS sentence pairs are assigned a degree of semantic equivalence instead of a binary paraphrase label. STS shared tasks have produced a sizable amount of research on sentence similarity (Agirre et al., 2012, 2013, 2014, 2015).

## 2 The Task

SemEval-2016 Task 1: Semantic Textual Similarity (Agirre et al., 2016) requires systems to determine the degree of semantic similarity between pairs of sentences. Similarity scores are on a scale from 0 (completely dissimilar) to 5 (semantically equivalent). We participated in the monolingual STS Core subtask. This subtask includes English language evaluation data from multiple sources organized into 5 distinct evaluation datasets: Plagiarism Detection, Q&A Question-Question, Q&A Answer-Answer, Post-Edited Machine Translations and Headlines. The evaluation data have a gold standard similarity score based on human judgements collected using Crowdsourcing. The Pearson correlation between similarity scores assigned by the systems and the human judgements is used to assess task performance.

## 3 Approach

The sentences within the STS pairs are split into character n-grams. No preprocessing is applied besides lowercasing of the text and removing punctuation.

Our training procedure was unsupervised, using only a large unlabelled dataset drawn from Wikipedia. These data are used to train a CBOOnG model. We explore using three different methods for constructing sentence level vector representations from the character embeddings. STS scores for the sentence pairs are computed as the cosine similarity of the resulting sentence level embedding vectors. Three different cosine similarity scores, one from each representation, are obtained.

## 4 Wikipedia Dataset

We used a dump of English Wikipedia articles<sup>1</sup> that includes 3,831,719 articles and 8,179,596 unique words. Wikipedia provides a large and accessible collection of text consisting of well-formed sentences that is suitable for training purposes. We obtained a plain text representation of the documents by removing the data dump xml tags using the script provided in the Gensim package (Rehurek and Sojka, 2010). Matching the minimal pre-processing performed on the STS pairs, training data are only lowercased and cleared of punctuation. The Wikipedia dataset is split into adjacent n-grams and spaces between words replaced with the “-” symbol. For example, the following sequence of trigrams would be produced from the text *amazon gift*.

*-am ama maz azo zon on- n-g -gi gif ift ft-*

### 4.1 Constructing a CBOOnG Model

Our CBOOnG is constructed and trained identically to a CBOW model (Mikolov et al., 2013a) but substituting character n-grams in place of words. The quality of such a model is affected by a number of hyper-parameters such as the size of the character n-gram vectors (embeddings), the size of the training window, and the cut-off point for less frequent n-grams. Although experiments by Mikolov et al. (2013b) describe how to choose the appropriate features for a word similarity task, the same fea-

---

<sup>1</sup> Downloaded at 07/07/2015 from  
<https://dumps.wikimedia.org/enwiki/>

tures might not be ideal here. Moreover, our model brings an additional new modeling parameter that defines the size of the character n-grams.

Embedding models scale linearly with the number of unique unfiltered tokens in the training data. Each token has a corresponding fixed size embedding vector. Mikolov et al. (2013a) explored using embedding vector sizes ranging from 20 to 600. In general, the results showed that increasing the dimensionality of vectors and the size of training data, improved the accuracy on semantic-syntactic word relationship task using otherwise identical features.

For our experiments, we make use of 400 dimension embedding vectors. Our CBOOnG model was trained using surrounding n-grams within a window size of 5. Character n-grams that occur fewer than 5 times are filtered. Our model is trained using the Gensim package (Rehurek and Sojka, 2010) and its support for CBOW (*word-level*) models but over data tokenized into character n-grams.

## 4.2 Compositions of Vector Representations

The construction of embedding vectors for phrases and sentences directly from word embeddings is still an active area of research. As noted in Section 2, there have been various efforts to build good embedding representations of text beyond those tied to individual words. We believe the diversity of methods for constructing textual embedding representations beyond the word level is due to the fact the appropriateness of the various representations is very task dependent.

One simple approach is to construct textual embedding representations using either point-wise addition multiplication of the embedding vectors representing individual words and phrases. The resulting representations have been shown to work well for phrase similarity and PI tasks (Blacoe and Lapata, 2012).

We make use of a similar composition algorithm for our sentence level embeddings, but using character n-gram rather than word embeddings. We describe three different methods for combining n-gram embeddings. The first is formed by addition of the embeddings of the n-gram *tokens* in a sentence, effectively weighting the embeddings by their frequency. The second and third are based on n-gram *types*, and formed by concatenation and weighted addition, respectively.

## 4.3 Sentence Representations

For the STS task, the core experimental unit is a pair of sentences. A target sentence,  $S$ , consisting of some sequence of  $n$  tokens (i.e. character n-grams)  $(t_{S_1}, t_{S_2}, \dots, t_{S_n})$  is paired with another sentence,  $S'$  that consists of some sequence  $m$  of tokens  $(t_{S'_1}, t_{S'_2}, \dots, t_{S'_m})$ . Note that the numbers of tokens for each sentence do not necessarily need to be equal. In the following, a vector embedding associated with a token  $t$  is notated by  $v_t$ . We consider three different vector based sentence representations built from n-gram embeddings.

For a given sentence  $S$ , the first representation is produced through element-wise addition of the vectors associated with each token in  $S$ . The result of this operation is a vector  $V_S^1$  having the specified vector size of the token embeddings, as is defined in advance to building the models (i.e. 400 in this case).

For the second approach,  $S$  is represented as a matrix of size  $400 \times d$ , where  $d$  is the size of the model vocabulary (i.e. the number of unique n-grams used in training). Combining the  $d$  vectors in order forms a vector representation:

$$V_S^2 = [v_{t_1}^S, v_{t_2}^S, \dots, v_{t_d}^S]$$

where  $v_{t_i}^S$  is the embedding associated with the  $i^{\text{th}}$  term  $t_i$  in the model vocabulary if  $t_i$  occurs in  $S$ , and is the null vector if the  $i^{\text{th}}$  term does not occur in  $S$ .

Finally, for the third representation, element-wise addition of all of the embeddings in  $V_S^2$  is computed. We obtain a new vector of  $V_S^3$  the dimension of the embedding vector size, which is specified as 400:

$$V_S^3 = [v_{t_1}^S + v_{t_2}^S + \dots + v_{t_d}^S]$$

We note that the difference between Run1 and Run3 is that for Run1, the contributions of the n-gram embeddings are weighted for frequency.

## 5 Experiments

To obtain semantic similarity scores for each pair of sentences  $S$  and  $S'$ , the cosines of the corresponding vector representations are computed.

$$\begin{aligned} \text{Run1: } & \text{Sim1}(S, S') = \text{cosine}(V_S^1, V_{S'}^1) \\ \text{Run2: } & \text{Sim2}(S, S') = \text{cosine}(V_S^2, V_{S'}^2) \\ \text{Run3: } & \text{Sim3}(S, S') = \text{cosine}(V_S^3, V_{S'}^3) \end{aligned}$$

Previous work on the use of character n-grams for PI has shown that trigrams perform well. The three runs chosen for submission to SemEval 2016’s STS task use sentence representations constructed from trigram embeddings. Wikipedia articles were pruned using the Gensim package with default parameters. A total of 108,452 articles are used to construct a character-trigram model for the experiments. The statistical properties of the Wikipedia-trained model using character trigrams are shown in Table 1 below.

| Properties          | Count         |
|---------------------|---------------|
| Total trigrams      | 1,068,456,094 |
| Unique trigrams     | 91,686        |
| Unique trigrams > 5 | 47,951        |

**Table 1:** Statistical properties of Wikipedia dataset used in our experiment.

Further experiments were conducted for sentence representations based on bigrams and 4-grams. Although these were not submitted for the task, the results are also reported in the following section.

## 6 Results

The Pearson Correlation results from our three different runs obtained using trigram embeddings are presented in Table 2. These results represent the ASOBEK submission to SemEval-2016 Task 1. It is noted that Run2 and Run3 generally appear to outperform Run1, with Run2 performing best overall. The best individual result is obtained on the Post-editing dataset. This result is ranked above the median for results reported on this sub-task. The correlation scores evidence variable performance across the individual datasets. Most notable is that the results from each of the runs applied on the Question-Question dataset are much lower relative to the other categories. In spite of this, the overall performance is 0.6178 with Run2.

| Datasets (Trigrams) | Run1   | Run2          | Run3          |
|---------------------|--------|---------------|---------------|
| <i>Overall</i>      | 0.5956 | <b>0.6178</b> | 0.6143        |
| Answer-Answer       | 0.4269 | <b>0.5228</b> | 0.4792        |
| Headlines           | 0.6790 | 0.6374        | <b>0.6865</b> |
| Plagiarism          | 0.7572 | <b>0.7852</b> | 0.7778        |
| Post-editing        | 0.8195 | <b>0.8425</b> | 0.8409        |
| Question-Question   | 0.2618 | <b>0.2635</b> | 0.2480        |

**Table 2:** Pearson Correlation Results using character trigrams. Experiments were also conducted for bigrams and 4-grams. Results are shown in Table 3. Highlighted scores indicate cases where performance exceeds that obtained using trigram embeddings.

As for trigrams, better results are generally obtained for Run2 and Run3. For 4-grams, the overall performance of Run3 actually exceeds that based on trigrams. Across all of the systems, results on the Question-Question dataset depress the overall performance significantly. This is especially evident for Run2 of the 4-gram dataset, where there is little correlation evident between system scores and human judgements. In contrast, using bigrams Run2 produces our best result for this dataset. Examination of the data indicates that this may be due to the particular form of the questions. For example, character n-grams generated from the following pair will contain many tokens that are not informative in discriminating meaning:

*What should I look for in a jump rope?*

*What should I look for in a running shoe?*

| Datasets (Bigrams) | Run1   | Run2          | Run3          |
|--------------------|--------|---------------|---------------|
| <i>Overall</i>     | 0.5340 | 0.5996        | 0.5784        |
| Answer-Answer      | 0.3869 | 0.4547        | 0.4520        |

**Table 3:** Pearson Correlation Results using character bigrams and 4-grams

## 7 Conclusions

A method for STS based on embeddings of character n-grams generated by a CBOnG model was introduced. This is the only study that we are aware of that utilizes embeddings of character n-grams to build representations of sentences. The study presents preliminary results showing that the approach can successfully help identify semantic similarity of sentence pairs.

Using our method, we observe significant variations in performance across the STS Core datasets. In particular, performance is generally poor for the

Question-Question dataset. This suggests that it may improve performance to weight the contributions of the embeddings according to the informativeness of the associated n-grams. We intend to consider this in future experiments.

## Abstract

This paper describes the SimiHawk system submission from UMass Lowell for the core Semantic Textual Similarity task at SemEval-2016. We built four systems: a small feature-based system that leverages word alignment and machine translation quality evaluation metrics, two end-to-end LSTM-based systems, and an ensemble system. The LSTM-based systems used either a simple LSTM architecture or a Tree-LSTM structure. We found that of the three base systems, the feature-based model obtained the best results, outperforming each LSTM-based model’s correlation by .06. Ultimately, the ensemble system was able to outperform the base systems substantially, obtaining a weighted Pearson correlation of 0.738, and placing 7th out of 115 participating systems. We find that the ensemble system’s success comes largely from its ability to form a consensus and eliminate complementary noise from its base systems’ predictions.

## 1 Introduction

The task of semantic textual similarity (STS) has been developed over the past several SemEval competitions with the idea of capturing the degree of similarity in the meaning conveyed by two snippets of text (usually two sentences). In that respect, the STS task can be seen as similar to such tasks as paraphrase detection (Xu et al., 2015), recognizing textual entailment (RTE) (Negrí et al., 2012), and semantic relatedness (Marelli et al., 2014a). The

STS task captures different gradations of similarity, rather than a binary decision, and it is symmetric, rather than directed, as is the case with RTE (Agirre et al., 2012). It also aims to capture a more general notion of semantic similarity that does not focus solely on the semantic relatedness derived through compositional processes. In this paper, we describe the SimiHawk system submission for the core Semantic Textual Similarity (STS) task at the SemEval-2016 competition.

The STS task series (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirrea et al., 2015) has aggregated a sizable dataset of sentence pairs annotated with numeric similarity scores. The presence of this dataset allows for a shift from earlier work that mostly used unsupervised learning (Corley and Mihalcea, 2005; Mihalcea et al., 2006; Li et al., 2006), to the supervised approaches that leverage the labeled data (Sultan et al., 2015; Han et al., 2015; Häning et al., 2015). The availability of labeled data from different genres also allows for a clearer evaluation and a better comparison across different approaches.

Specifically, the task of semantic similarity is defined as follows: given an input of two sentences, output a real number in the range [0,5] where 0 means lowest and 5 means highest similarity. The top-performing system from last year’s task (Sultan et al., 2015) relied heavily on a hand-engineered word alignment tool (Sultan et al., 2014) (achieving 5th place with the aligner alone), combined with dense word embeddings (Baroni et al., 2014) to create a two-feature regression model. Other top-performing systems (Han et al., 2015; Häning et al.,

\*These three authors contributed equally to this work.

2015) follow this trend of exploiting word alignment and embedding similarity across textual pairs.

Recent work (Bowman et al., 2014; Bowman et al., 2015b; Tai et al., 2015) has shown the effectiveness of deep learning end-to-end architectures using recurrent and recursive neural networks on tasks similar to semantic similarity, such as semantic relatedness (Tai et al., 2015), natural language inference (Bowman et al., 2015a), and textual entailment (Marelli et al., 2014b), providing state-of-the-art performance. Since all of these tasks evaluate the relationship between the semantics of two input sentences, it stands to reason that systems with such architecture may perform well on the more general task of semantic similarity.

In our submission, we are interested in comparing an approach using hand-engineered features against the deep RNN-based architectures with Long Short-Term Memory (LSTM) cells. We therefore implemented a feature-based system over a small number of heavily engineered features, and two LSTM-based systems: one that uses a simple LSTM architecture and one that uses a Tree-LSTM architecture that mirrors the syntactic dependencies of the input in the LSTM model.

In the following section, we describe each system in detail. We then report and analyze the outcome of this bake-off. Not surprisingly, the ensemble system performs the best, obtaining a weighted Pearson correlation of 0.738. Of the three base systems, the feature-based model obtained the best results, outperforming the LSTM-based models by .06.

## 2 System Description

### 2.1 Feature-Based

Because of the impressive success of feature-based methods in previous STS shared tasks, we wanted to understand whether deep learning approaches were even necessary. The winning system for the 2015 shared task computed two features:

1. **alignment ratio** As part of their 1st place system, (Sultan et al., 2015) constructed a custom, open tool to align the words within a sentence pair<sup>1</sup>. The alignment ratio feature  $r$  is computed as:

---

<sup>1</sup><https://github.com/ma-sultan/monolingual-word-aligner>

$$r = \frac{a(s_1) + a(s_2)}{t(s_1) + t(s_2)} \quad (1)$$

where  $s_1$  and  $s_2$  are sentences 1 and 2 respectively,  $a()$  is the number of aligned content words in a sentence, and  $t()$  is the total number of content words in a sentence.

2. **cosine of word2vec centroids** Since word2vec came out in 2013 (Mikolov et al., 2013), word embeddings have gained massive popularity. Though a naive form of compositionality, simple vector addition has been shown as a surprisingly effective way to represent phrases. Using the official word2vec skip-gram Google News embeddings<sup>2</sup>, we compute the word2vec cosine feature  $w$  as follows:

$$w = \cos\left(\frac{\Sigma w_1^i}{N_1}, \frac{\Sigma w_2^i}{N_2}\right) \quad (2)$$

where  $\Sigma w_s^i$  is the sum of the embeddings of each word in sentence  $s$  and  $N_s$  is the sentence length.

We used this system as a starting point, but we added two additional feature classes. The two feature classes we added were:

1. **cosine of one-hot bag-of-words** Similar to word2vec centroids, we also computed a feature  $b$  as the cosine of binary bag-of-words encodings of each sentence:

$$b = \cos(\Sigma e_1^i, \Sigma e_2^j) \quad (3)$$

where for a vocabulary (consisting of the union of the two sentences' sets of tokens) of size  $V$ , the one-hot vector  $e_s^i$  is a vector of size  $V$  consisting of  $V - 1$  zero entries and a 1 at word  $i$ 's entry in the vocabulary. Note that subscripts 1 and 2 signify one-hot vectors representing tokens from sentences 1 and 2, respectively.

2. **Machine Translation evaluation metrics** In 2012, an ensemble of various MT metrics was created to attain (at the time) state-of-the-art results in Paraphrase Identification (Madnani et

---

<sup>2</sup><https://code.google.com/archive/p/word2vec>

al., 2012). We created features for each of the following metrics to compute the similarity between sentences 1 and 2:

- BLEU (Papineni et al., 2002)<sup>3</sup>
- NIST (Doddington, 2002)<sup>4</sup>
- METEOR (Lavie and Agarwal, 2005)<sup>5</sup>
- BADGER (Parker, 2008)<sup>6</sup>
- TER (Snover et al., 2006)<sup>7</sup>
- TERp (Snover et al., 2009)<sup>8</sup>

We combine these four feature classes using a fully-connected neural network with 2 layers of size 40. Similar to (Tai et al., 2015) (specifically equations (14) and (15)), the network produces a probability distribution over scores and is trained using categorical cross-entropy loss. To build the network, we use the Keras library (Chollet, 2015), a Python neural network library written on top of Theano (Bergstra et al., 2010; Bastien et al., 2012).

## 2.2 Deep End-to-End LSTM-Based Systems

Deep end-to-end systems are very enticing because they learn the representation for a given input, as opposed to manually constructing a feature space. We built two LSTM-based systems for this task. Although in principle these systems can be considered end-to-end, both systems make use of pre-trained word embeddings as input. We describe the two systems below, assuming a familiarity with regular LSTM cell structure. We begin by discussing Tree-LSTM because it recently achieved state-of-the-art performance on the semantic relatedness task (Tai et al., 2015).

### 2.2.1 Tree-LSTM

The architecture of Tree-LSTM is a generalization of LSTMs to tree-structured network topologies. The tree-structured LSTM composes its current state from an input vector, as well as the hidden

<sup>6</sup><http://babblequest.org/badger>

<sup>7</sup><http://www.cs.umd.edu/~snover/tercom/tercom-0.7.25.tgz>

<sup>8</sup><https://github.com/snover/terp>

states of an arbitrary number of child units. As previously mentioned, the Tree-LSTM architecture has been used for the semantic relatedness task. For this task, the specific tree structure the authors use is a dependency tree, obtained via the Stanford Neural Network Dependency Parser (Chen and Manning, 2014). For the semantic relatedness task, the system takes as input two pieces of text, and outputs a real number in the range [1,5]. Therefore, one only needs to modify the original Tree-LSTM system to output a number in the range [0,5] in order to apply it to the task of semantic similarity.

The specific architecture we use is referred to by the original authors as Child-Sum Tree-LSTM (Tai et al., 2015). Using the authors' original notation, and using  $C(j)$  to denote the set of children of node  $j$ , the hidden state at a given node is computed as follows:

$$\tilde{h}_j = \sum_{k \in C(j)} h_k \quad (4)$$

$$i_j = \sigma(W^i x_j + U^i \tilde{h}_j + b^i) \quad (5)$$

$$f_{jk} = \sigma(W^f x_j + U^f h_k + b^f) \quad (6)$$

$$o_j = \sigma(W^o x_j + U^o \tilde{h}_j + b^o) \quad (7)$$

$$u_j = \tanh(W^u x_j + U^u \tilde{h}_j + b^u) \quad (8)$$

$$c_j = i_j \odot u_j + \sum_{k \in C(j)} f_{jk} \odot u_k \quad (9)$$

$$h_j = o_j \odot \tanh(c_j) \quad (10)$$

where  $x_j$  is the input of node  $j$  (typically a word embedding vector),  $\sigma$  is the logistic sigmoid function, and  $\odot$  is element-wise multiplication. Note here we refer to nodes instead of timesteps, since the tree structure induced by the dependency parse alters the standard temporal flow of a normal LSTM. Consequently, the hidden state from the root node is then used as a representation for a given text input.

Given two input texts, the authors use a Tree-LSTM to generate a representation for each input, which we call  $h_L$  and  $h_R$ . These are then used to compute a final score,  $\hat{y}$ , as follows:

$$h_\times = h_L \odot h_R \quad (11)$$

$$h_+ = |h_L - h_R| \quad (12)$$

$$h_s = \sigma(W^\times h_\times + W^+ h_+ + b^h) \quad (13)$$

$$\hat{p}_\theta = \text{softmax}(W^p h_s + b^p) \quad (14)$$

$$\hat{y} = r^T \hat{p}_\theta \quad (15)$$

Note how (14) creates a distribution over integer scores, and (15) converts the distribution into a real number in range  $[a,b]$  by setting  $r$  equal to a vector of integer values  $[a \dots b]$ . For our system, we simply set  $r$  equal to the vector  $[0 \ 1 \ 2 \ 3 \ 4 \ 5]$ , as opposed to the original values of  $[1 \ 2 \ 3 \ 4 \ 5]$  for the semantic relatedness task. The inclusion of zero will better facilitate the output of scores less than one. This is because distributions that have their mass highly concentrated in the first index will have little remaining mass in the other indices that can then multiply by the non-zero integers.

For our implementation we used the code from the original authors<sup>9</sup>, which uses Glove embeddings (Pennington et al., 2014) as input vectors  $x_j$ , hidden states ( $h_i$ ) of size 200, and a similarity module of size 50 ( $h_s$  (13)). For training, we use a regularization strength of 0.0004, a minibatch size of 25, and a learning rate of 0.05. The model trained for 10 epochs. We also decided to disregard the use of a validation set, since our intermediate results showed that, if anything, the use of a validation set hurt performance.

## 2.2.2 LSTM

Despite the potential of the Tree-LSTM model for this task, (Bowman et al., 2015b) shows that even for text that is highly syntactically dependent, a standard LSTM architecture can perform as well as a Tree-LSTM architecture given enough training data. The authors also show that an LSTM can perform better on shorter sentences. Moreover, (Vinyals et al., 2015) successfully applied a sequence-to-sequence LSTM model with attention to the syntactic parsing task, achieving state-of-the-art results. Motivated by these results, we also produced a model that uses standard LSTM architecture.

The architecture of the LSTM model is represented in Figure 1. The model is very similar to the Tree-LSTM, but instead of using tree-structured LSTMs, it uses standard LSTM cells. The hidden states of the LSTMs are combined by concatenation

of element-wise multiplication, summation and cosine similarity, and the resulting vector serves as the input to the fully-connected layer. As in (Tai et al., 2015), the network produces a probability distribution over scores, which is in turn transformed into a real number over the specified range.

We used the Keras library to implement this model, creating LSTMs with hidden states of size 300, and fully-connected layers of size 50. For training, we use a regularization strength of 0.0004, mini-batch size of 25, and dropout of 0.1. The model was trained for 15 epochs. We also trimmed sentences to have a maximum length of 50 tokens. The LSTM system uses Glove embeddings (Pennington et al., 2014) as its pretrained word vectors. We chose to use Glove instead of word2vec because Glove had fewer out-of-vocabulary tokens for the dataset.

## 2.3 Ensemble

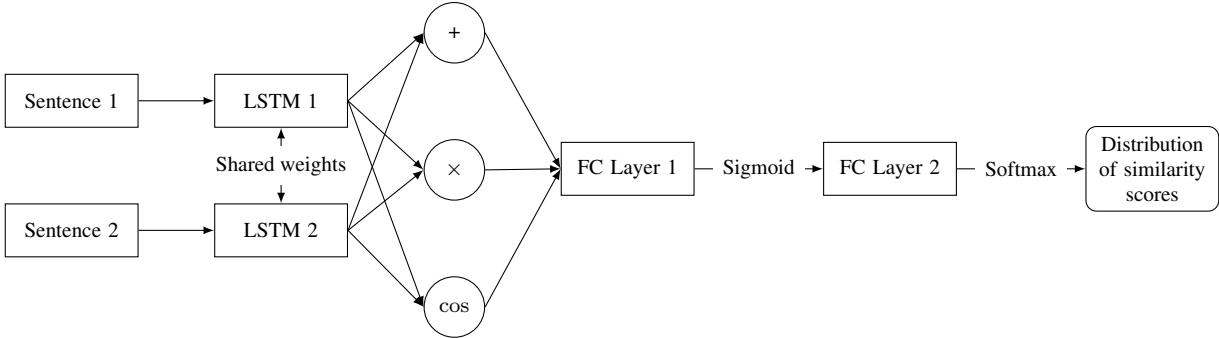

In order to hedge our bets, we created a ensemble system, using Feature-Based, Tree-LSTM, and LSTM systems as base systems. The ensemble model can be seen as a feature-based, stacking system because it uses the predictions of the three base systems as the features for a supervised model. Thus, the most basic stacking system has three features, one for each base system.

In order to train the stacking model, we need base predictions that are not ‘dirty’: the data used to train base systems to generate predictions (which in turn train our stacking system) must have an empty intersection with the data we use to make predictions. To overcome this, each base system performed 5-fold cross-validation on the training data. By doing this, we create predictions for each training example from ‘clean’ data. Next, we used the predictions on the held-out folds as the features to train the stacking model. We made sure to shuffle the training data prior to creating the folds to ensure that each fold would be statistically similar in terms of which domains are represented as well as the distributions over gold standard scores. To generate test scores for the stacking system, we allowed the base systems to train on all the training data and then make predictions on the test data, which become the test features for the stacking system.

We hypothesize that in certain scenarios, the stacking system should favor the scores from certain

| -align ratio           | 0.6952        |
| -sentence length       | 0.7116        |

**Table 2:** Feature ablation study for ensemble system. ‘-’ denotes withholding a feature.

base systems. For example, (Bowman et al., 2015b) has shown that LSTM models can have difficulty on long sequences. Therefore, we performed a feature ablation study where we combined the three baseline predictions with several hand-picked features: length of sentence 1, length of sentence 2 (these two combined are called sentence length), alignment ratio (1), string edit distance, embedding similarity (2), average sentence length between the pair, and average pronoun count. We included average pronoun count because we found certain domains contain a larger frequency of pronouns. The ablation experiment was performed on 2015 evaluation data, and the results are shown in Table 2. It is visible in the table that the only feature absence that generated any significant drop-off is alignment ratio. Therefore, we decided to include alignment ratio as the fourth and final feature in our stacking system. For the stacking implementation, we use the same neu-

ral network as the feature-based system. However, we decided to use a three-layer network based on experimental results.

### 3 Results

All systems were trained using the training/evaluation data from previous years’ tasks (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirrea et al., 2015). After filtering for duplicate examples, our training set contains a total of 13,061 examples.

Results of our systems on the 2016 gold standard are shown in Table 1. We report the performance, specifically Pearson correlation, across five different domains: Answer-Answer, Headlines, Plagiarism, Postediting, and Question-Question. We also report the weighted mean across all five domains. The last row of Table 1 also records the number of gold standard examples for each domain.

According to the official results, the overall performance of our ensemble system was .738, exceeding the performance of the base systems, although it is not the highest performing system for every domain. Specifically for the question-question domain, the feature-based system seems to outperform it substantially. The overall ranking of the ensemble system is 7 out of 115 submitted systems, while feature-based ranks 37, LSTM ranks 73, and TreeLSTM ranks 77.

| System        | Fold 1 | Fold 2 | Fold 3 | Fold 4 | Fold 5 | mean  |
|---------------|--------|--------|--------|--------|--------|-------|
| LSTM          | 0.802  | 0.806  | 0.805  | 0.795  | 0.790  | 0.800 |
| Feature-based | 0.790  | 0.800  | 0.813  | 0.823  | 0.799  | 0.805 |
| TreeLSTM      | 0.772  | 0.797  | 0.793  | 0.806  | 0.794  | 0.792 |

**Table 4:** Pairwise correlation scores amongst systems’ predictions and gold labels (Reference) on the answer-answer domain.

We also report five-fold cross-validation results for our three base systems (Table 3). These experiments used the training data, drawn from several domains. We shuffled the data for our cross-validation experiments so that each fold has a similar distribution of domain examples as well as scores. These results show that when the data is shuffled, and domains and scores are equally distributed, the overall correlation is much higher.

## 4 Discussion

The ensemble system’s success can be attributed to its ability to form a consensus among the base systems and eliminate noise in the predictions. As we can see in Table 4, which shows the correlation between systems for the answer-answer domain, although the three base systems have low pairwise correlations (.456, .413, .608), they all have high correlations with the ensemble system (.769, .751, .802). We can also see that the ensemble system has its largest correlation with the highest-scoring base system for answer-answer, TreeLSTM. Since each base system had pairwise low correlation, they were capturing different views of the data, and the ensemble system was able to take the important parts of each view, while canceling out the noise. This allowed the ensemble system to outperform the base systems in answer-answer by .12, on average.

To further illustrate this point, take for example the following input pair: “There’s not a lot you can do about that.” and “There’s not that much that you can do with a sourdough starter.” with a gold label of 2. The baseline systems predict the following scores: 3.96 from the feature-based system, 0.31 from the LSTM system, and 1.39 from the TreeL-

STM system. The TreeLSTM system provides the closest prediction, while the feature-based system provides the worst prediction, over-predicting the gold label by almost 2. However, the ensemble system is able to effectively leverage this higher prediction, producing a prediction of 1.76, which is the most accurate prediction out of all four systems.

In our experiments, we found that in three domains (answer-answer, headlines, question-question), the ensemble system had the highest correlation with TreeLSTM. It is likely that TreeLSTM’s low score on question-question (.553), combined with a high correlation with the ensemble (.900), were what brought the ensemble system’s score down enough for the feature-based system to outperform it. On the other two occasions (plagiarism and postediting), the base system with the highest correlation with ensemble system was the feature-based system. In both of these scenarios, the two systems produced very similar scores, within .01 of one another for both occasions.

Although the feature-based system was the highest scoring base system on 4 out of 5 domains, there is only one occasion where its correlation with another base system exceeds .79 (plagiarism with LSTM). This suggests that the shallow methods for feature extraction are not able to represent some important information that the deep LSTM-based models are able to capture. As a result, the ensemble system was able to outperform all three base systems in most cases, suggesting that none of the base systems were able to capture the whole picture individually.

# SERGIOJIMENEZ at SemEval-2016 Task-1: Effectively Combining Paraphrase Database, String Matching, WordNet and Word Embedding for Semantic Textual Similarity

Sergio Jimenez  
Bogotá D.C., Colombia  
sergio.jimenez.vargas@gmail.com

## Abstract

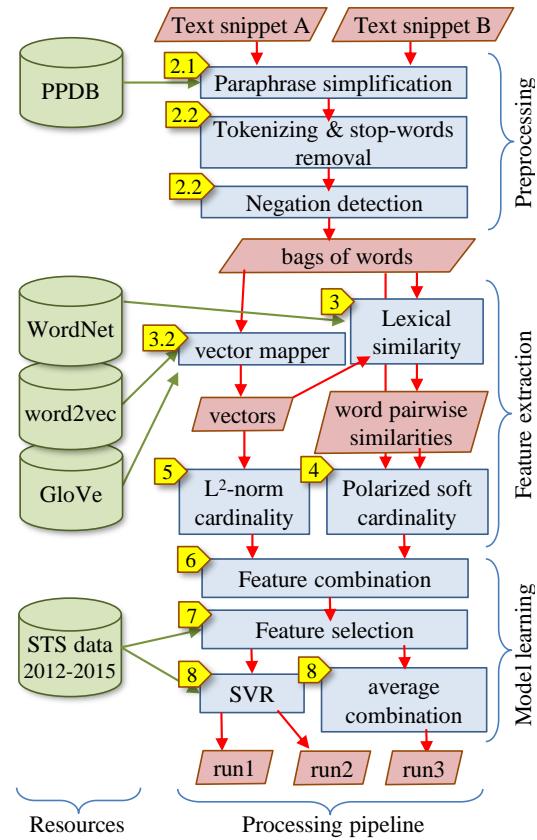

In this paper, a system for semantic textual similarity, which participated in Task-1 in SemEval 2016 (monolingual and cross-lingual sub-tasks) is described. The system contains a preprocessing step that simplifies text using PPDB 2.0 and detects negations. Also, six lexical similarity functions were constructed using string matching, word embedding and synonyms-antonyms relations in WordNet. These lexical similarity functions are projected to sentence level using a new method called Polarized Soft Cardinality that supports negative similarities between words to model opposites. We also introduce a novel L<sup>2</sup>-norm “cardinality” for vector space representations. The system extracts a set of 660 features from each pair of text snippets using the proposed cardinality measures. From this set, a subset of 12 features was selected in a supervised manner. These features are combined by SVR and, alternatively, by using the arithmetic mean to produce similarity predictions. Our team ranked second in the cross-lingual sub-task and got close to the best official results in the monolingual sub-task.

## 1 Introduction

Semantic Textual Similarity (STS) is a fundamental task in the field of natural language processing that has been addressed in SemEval competitions uninterrupted since 2012 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). The task is to compare two text fragments and produce a similarity score that is assessed according to human judgment. This year (Agirre et al., 2016), a

new cross-lingual sub-task in English and Spanish is proposed in addition to the traditional monolingual English task. In SemEval 2015, the most popular approach among the best systems was the use of words alignments between sentences combining resources such as WordNet (Miller, George A., 1995), neural word embedding (Mikolov, Tomas et al., 2013) and the Paraphrase Database (Pavlick et al., 2015).

Figure 1: STS system architecture

This paper describes our system submission to STS 2016 that uses a cardinality-based approach (instead of word alignments) for combining the resources mentioned above. Several teams have used soft cardinality successfully in previous STS competitions from 2012 to 2014 (Jimenez et al., 2012; Jimenez et al., 2013a; Jimenez et al., 2013b; Jimenez et al., 2014; Lynam et al., 2014). For the proposed system, we extended the model of soft cardinality to allow the use of negative values in the lexical similarity component to model opposites due to antonymy and negation.

Figure 1 shows the overall architecture of the proposed system. Yellow labels in the upper left corner of each process component (blue squares) indicate the sections of this document where the module is discussed. In this figure, the processing pipeline is represented vertically in three stages: pre-processing, feature extraction and model learning. Red parallelograms represent the inputs and outputs of each process, from the pair of snippets of text for evaluation, through different intermediate representations (bag-of-words, vectors, etc.) and end on the predictions of similarity scores. The left side contains the used external resources linked to the process that makes use of each one.

## 2 Preprocessing

### 2.1 Paraphrase Simplification

The Paraphrase Database (PPDB) is a list of pairs of words, short phrases or syntactic rules where each pair is semantically equivalent in some degree (Pavlick et al., 2015). In PPDB, each paraphrases pair  $\{e_1, e_2\}$  is obtained from translation models making use of the observation that if  $e_1$  and  $e_2$  are frequently translated to a same word or phrase in a foreign language, then there is a high probability of  $e_1$  and  $e_2$  being paraphrases of each other. In PPDB 2.0 each pair is labeled with  $-\log(P(e_1|e_2))$  and  $-\log(P(e_2|e_1))$  obtained from the translation models, where  $P(e_2|e_1)$  is the inferred probability that the word or phrase  $e_1$  is a good paraphrase for  $e_2$ , and the contrary for  $P(e_1|e_2)$ . The motivation for using this resource is that text pairs that can be paraphrased to simplified versions should be easier to analyze by downstream modules. For example, consider the paraphrase pair  $e_1 = \text{"interdisciplinary"}$

and  $e_2 = \text{"cross-disciplinary"}$  labeled in PPDB with  $-\log(P(e_2|e_1)) = 4.28$  and  $-\log(P(e_1|e_2)) = 0.82$ . Now, consider a pair of sentences for STS evaluation where these paraphrases occur: “The study was *interdisciplinary*.” and “Our research is *cross-disciplinary*.” Given that  $e_1$  is higher scoring paraphrase for  $e_2$  than the contrary (i.e.  $-\log(P(e_2|e_1)) > -\log(P(e_1|e_2))$ ),  $e_2$  can be replaced by  $e_1$  in the second sentence: “Our research is *interdisciplinary*”. As a result, the pair of sentences now contains more frequent words and shares more words thereby facilitating subsequent STS analysis.

Let  $A$  and  $B$  be a pair of texts snippets for STS evaluation and  $e_1$  and  $e_2$  a pair of paraphrases from PPDB. Thus,  $\{e_1, e_2\}$  occurs in  $\{A, B\}$  if  $e_1 \subset A \wedge e_2 \subset B$  or  $e_2 \subset A \wedge e_1 \subset B$ , being aware of the special cases when  $e_1 \subset e_2$  or  $e_2 \subset e_1$  (whole words matching is used in those cases). The operator “ $\subset$ ” means that the left argument is a sub-string of the right one. The input pairs of sentences for the STS task where preprocessed by looking for occurrences of paraphrases from PPDB and replacing the least probable paraphrase by the most probable paraphrase. For that, we used the top-ranked lexical paraphrases and phrasal paraphrases from the M-size version of the PPDB 2.0<sup>1</sup> (syntactic rules were not used). We determined the number of top-ranking lexical and phrasal paraphrases to use experimentally by using the overall STS system described in this paper trained and tested with STS datasets from previous years. Consistent increases in the performance measured by mean correlation was observed as the number of used paraphrases increased. The average relative improvement stabilized around 2% using 150,000 lexical paraphrases and 3,000,000 phrasal paraphrases. Using these thresholds for the paraphrase database we assessed the 14 thousand sentence pairs in training data and found 3,294 occurrences of lexical paraphrases and 1,778 phrasal paraphrases.

### 2.2 Tokenizing, Stop-words Removal and Negation Detection

The preprocessing continues by tokenizing sentences, removing stop-words and labeling negated

---

<sup>1</sup><http://paraphrase.org/#/download>

words. For this stage, we use the tokenizer and stop-words list from NLTK<sup>2</sup> augmented with the following words: *should, now, 's, 't, 've, something, would* and *also*. Once stop-words are removed from the text, each word preceded by a negation token is labeled as a negated word. The negation tokens we use are: *not, n't, nor, null, neither, barely, scarcely, hardly, no, none, nobody, nowhere, nothing, never* and *without*. The negation tagged tokens are used by subsequent modules for modeling oppositeness between negated and non-negated forms (e.g. “not running” and “running”).

### 3 Lexical Similarity

The analysis of short texts based on soft cardinality relies only on a similarity function between lexical units (Jimenez et al., 2010). Therefore, the first component of the proposed STS system is composed of four lexical similarity functions that compare a pair of words and yield a numerical value in [-1,1] interval. Returning values of 1 means that the two words can be considered identical, 0 for unrelated words, negative values for representing opposition, and other values for representing intermediate degrees of similarity and opposition. In this section, the four lexical similarity functions we use are described.

#### 3.1 Lexical String Matching Boosted with Synonyms and Antonyms

The NLP community has widely recognized that the use of lemmas or stems, instead of words, is desirable in many applications of automatic text processing. Therefore, before comparing any pair of words we reduced them to their stems using the Porter’s algorithm (Porter, 1980). Let  $x$  and  $y$  be two stemmed words represented each as a sequence of characters. The first proposed lexical function replaces this basic word representation by the set of tri-grams and tetra-grams of characters on each word. This representation was used successfully for addressing the STS task with purely string-based approaches (Jimenez et al., 2012). For example, the word *country* is stemmed to  $x = countri$ . Next, its [3:4]-grams representation is  $x = \{cou, oun, unt, ntr, tri, coun, ount, untr, ntri\}$ . Once  $x$  and  $y$  are represented as

described, they are compared with the following expression:

$$S_1(x, y) = \frac{|x \cap y|}{\sqrt{|x| \times |y|}}$$

The second lexical similarity function is the well-known Jaro-Winkler (Winkler, 1990) expression:

$$d(x, y) = \frac{1}{3} \left( \frac{m}{\text{len}(x)} + \frac{m}{\text{len}(y)} + \frac{m - t}{m} \right)$$

$$S_2 = \begin{cases} d(x, y) & \text{if } d(x, y) < b_t \\ d(x, y) + (lp \times (1 - d(x, y))) & \text{otherwise} \end{cases}$$

Where,  $\text{len}(x)$  is the number of characters in word  $x$ ,  $m$  is the number of matching characters between  $x$  and  $y$ ,  $t$  is the number of transpositions between  $x$  and  $y$ ,  $lp$  is the length of the common prefix,  $p = 0.1$ , and  $b_t = 0.7$  is the “boost threshold”. The number of matching characters  $m$  is the number of common characters between  $x$  and  $y$  whose occurrences are not farther than  $\left\lfloor \frac{\max[\text{len}(x), \text{len}(y)]}{2} \right\rfloor - 1$  positions. The number  $t$  of transpositions is the number of matching characters that occur in different sequence order on each string. Clearly,  $m \leq \text{len}(x)$ ,  $m \leq \text{len}(y)$ , and  $t \leq m$ , therefore  $d(x, y)$  is defined only in [0, 1] interval (if  $m = 0$ , then  $d(x, y)$  is set to 0). Similarly to  $S_1$ ,  $S_2$  was used to compare stems instead of words.

Both  $S_1$  and  $S_2$  returns 1 when  $x$  and  $y$  are identical, 0 when  $x$  and  $y$  do not have common characters, and intermediate values for other cases. To a certain extent, this stem string similarity reflects semantic similarity between words. To improve this property, a wrapper function  $\hat{S}$  was built over  $S_1$  and  $S_2$  to include information from the synonym and antonym relationships in WordNet and the negation feature extracted at preprocessing stage (see subsection 2.2). If  $x$  and  $y$  are synonyms in WordNet, then the wrapper function  $\hat{S}$  overwrites the results of  $S_1$  and  $S_2$  to 1 (identical meaning). For the case when  $x$  and  $y$  are antonyms, the wrapper function should return a negative value to represent the opposition between words  $x$  and  $y$  (opposite meaning). Unlike synonymy and identity, the relation between antonymy and numerical oppositeness is rather unclear because most antonym pairs also are semantically similar (e.g. *small-large*) (Mohammad et al.,

---

<sup>2</sup><http://www.nltk.org/>

2008). The natural choice for this negative values is -1 (Yih et al., 2012)(Yih et al., 2012). However, instead of setting -1 to represent oppositions between two words, we decided to set this value as a parameter to be determined experimentally. For that, we used the overall STS system described in this paper with the STS datasets from previous years. The value that optimized the mean correlation was -0.2 in a search range from -1 to 1. The negation feature of the words is used to add negation logic to  $\hat{S}$ . For example, if  $x$  and  $y$  are synonyms but  $x$  is negated, then they are considered antonyms. Some examples are:  $\hat{S}(car, auto) = 1$ ,  $\hat{S}(\neg car, \neg auto) = 1$ ,  $\hat{S}(\neg car, auto) = -0.2$ ,  $\hat{S}(love, hate) = -0.2$ ,  $\hat{S}(\neg love, \neg hate) = -0.2$  and  $\hat{S}(\neg love, hate) = 1$  ( $\neg$  signify “negated word”). In the remaining cases, when  $x$  and  $y$  are neither synonyms nor antonyms, the wrapper function returns  $S_i(x, y)$  except for the case when either  $x$  or  $y$  is negated. In that later case, the wrapper function returns  $0.26 \times S_i(x, y)$ , which is a scaling factor for modeling negation determined experimentally in the same way as the opposite value of 0.2. A couple of examples are:  $\hat{S}_1(skater, skateboard) = 0.489$ ,  $\hat{S}_1(\neg skater, skateboard) = 0.489 \times 0.26 = 0.127$ . Henceforth, functions  $S_1$  and  $S_2$  are assumed to be overwritten by the described wrapper function.

### 3.2 Word Embedding

Two additional lexical similarity functions were built using word embedding representations. Let  $\vec{x}$  and  $\vec{y}$  be the vectorial representations of words  $x$  and  $y$  in  $\mathbb{R}^n$ . The used lexical similarity function between a pair of words is the cosine between these vectorial representations:

$$S_3(x, y) = \frac{\vec{x} \cdot \vec{y}}{\|\vec{x}\| \times \|\vec{y}\|}$$

Function  $S_3$  is computed using the publicly available pre-trained Google News corpus word embedding<sup>3</sup> from the *word2vec* tool (Mikolov, Tomas et al., 2013). We also include a similar function  $S_4$  that is defined identically to  $S_3$  but uses pre-trained Twitter corpus word embedding<sup>4</sup> from the *GloVe*

<sup>3</sup>GoogleNews-vectors-negative300.bin downloaded from <https://code.google.com/archive/p/word2vec/>

<sup>4</sup>glove.twitter.27B.50d.txt downloaded from <http://nlp.stanford.edu/projects/glove/>

tool (Pennington, Jeffrey et al., 2014). These cosine based similarities produce scores in the range from -1 to 1.

## 4 Polarized Soft Cardinality

Lexical similarity can be leveraged to address sentence similarity by aggregating lexical similarity scores. One successful mechanism for doing this is soft cardinality (Jimenez et al., 2010), which is a generalization of the classic set cardinality that considers similarities between elements. Thus, the soft cardinality of a bag of words  $A = \{a_1, a_2, \dots, a_n\}$  (i.e. a sentence) and a similarity function between words  $S(a_i, a_j)$  is defined by this expression:

$$|A|_S = \sum_{i=1}^n \left( \frac{1}{\sum_{j=1}^n S(a_i, a_j)^p} \right)$$

Where  $p$  is the softness-control parameter, which is positive and its default value is  $p = 1$ . Soft cardinality is a generalization of classic cardinality because as  $p$  increases,  $|A|_S$  gets closer to  $|A|$ . The soft cardinality of the union of two bags of words  $|A \cup B|_S$  is simply the soft cardinality of the concatenation of the bags. The soft cardinality of the intersection of two bag is defined as  $|A \cap B|_S = |A|_S + |B|_S - |A \cup B|_S$ . This model is restricted only to positive lexical similarity functions because negative values could lead to division-by-zero if  $\sum_{j=1}^n S(a_i, a_j)^p = 0$  for any  $a_i$ .

Given that the lexical similarity functions  $S_1$  to  $S_4$  (described in Section 3) can return negative values for words with opposite semantics, a new soft cardinality model that supports such negative similarities between elements was proposed for this competition. The new *polarized soft cardinality* model is:

$$\begin{aligned} |A|_S &= \sum_{i=1}^n \left( \frac{2 - \frac{1}{1 - \sum_{j=1}^n \text{neg}(S(a_i, a_j), p)}}{\sum_{j=1}^n \text{pos}(S(a_i, a_j), p)} \right) \\ \text{neg}(s, p) &= \begin{cases} (-s)^p & \text{if } s < 0 \\ 0 & \text{otherwise} \end{cases} \\ \text{pos}(s, p) &= \begin{cases} s^p & \text{if } s \geq 0 \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

Functions  $\text{neg}(s, p)$  and  $\text{pos}(s, p)$  filter respectively negative and positive values of  $s$ , then raise

them to  $p$  power ignoring the sign. Note that, if  $S(a_i, a_j)$  is strictly positive, then this model is equivalent to soft cardinality. This new model inserts dummy or “ghost” elements in  $A$  if there are opposite elements in  $A$ . For example, consider  $A = \text{auto, love, hate}$  and  $S(\text{auto}, \text{love}) = S(\text{auto}, \text{hate}) = S(\text{love}, \text{hate}) = 0$ . Clearly,  $|A|_S = 3$ . However, if  $S(\text{love}, \text{hate}) = -1$ , then  $|A|_S = 4$ . This increment in soft cardinality reflects the presence of a dummy element due to the fact that *love* and *hate* are opposites.

Using the lexical similarity functions presented in Section 3, four soft cardinality functions can be built:  $|*|_{S_1}$ ,  $|*|_{S_2}$ ,  $|*|_{S_3}$  and  $|*|_{S_4}$ . Each of those has the following softness control parameter values:  $p_{S_1} = 1.05$ ,  $p_{S_2} = 0.85$ ,  $p_{S_3} = 0.5$  and  $p_{S_4} = 0.65$ , which were obtained experimentally using STS data from previous SemEval campaigns. These soft cardinality functions are used to extract numerical features from each pair of sentences to be evaluated (see Section 6).

## 5 L<sup>2</sup>-norm Cardinality

Given two sentences  $A$  and  $B$  represented as bag of words, the proposed *L<sup>2</sup>-norm cardinality* is a measure of the amount of information in  $A$ ,  $B$ ,  $A \cap B$  and  $A \cup B$ . L<sup>2</sup>-norm cardinality is analogous to soft cardinality but uses vectorial representations of the words and vector operations in its formulation. Instead of exploiting pairwise similarities between words as soft cardinality does, L<sup>2</sup>-norm cardinality uses vectorial representations of the words in the “bag” to assess its cardinality. Let  $A = \{\vec{a}_1, \vec{a}_2, \dots, \vec{a}_p\}$  and  $B = \{\vec{b}_1, \vec{b}_2, \dots, \vec{b}_q\}$  be a bag of vector-represented words in  $\mathbb{R}^n$ , where  $p$  and  $q$  are the number of words in  $A$  and  $B$  respectively. Firstly,  $A$  and  $B$  obtain a representation in  $\mathbb{R}^n$  by adding up the vectors in their respective bags, i.e.  $\mathbf{A} = \sum_{i=1}^p \vec{a}_i$  and  $\mathbf{B} = \sum_{i=1}^q \vec{b}_i$ . L<sup>2</sup>-norm cardinality is defined by the following expressions:

$$\begin{aligned}|A|_n &= \|\mathbf{A}\|^2 \\ |B|_n &= \|\mathbf{B}\|^2 \\ |A \cap B|_n &= \mathbf{A} \cdot \mathbf{B} \\ |A \cup B|_n &= |A|_n + |B|_n - |A \cap B|_n\end{aligned}$$

Two L<sup>2</sup>-norm cardinality functions can be built

reusing the same word embedding used in  $S_3$  and  $S_4$ . Thus,  $|*|_{300}$  is obtained using the pre-trained word2vec vectors and  $|*|_{50}$  is obtained from the pre-trained GloVe vectors. L<sup>2</sup>-norm cardinalities  $|*|_{300}$  and  $|*|_{50}$  are added to the set of the four previously proposed soft cardinality functions to be used for extracting numerical features from sentence pairs.

## 6 Feature Extraction

The six cardinality functions proposed in Section 4 and Section 5 can be used to build a variety of similarity assessment measures for STS.. For example, for sentences  $A$  and  $B$ , the expression  $\text{sim}(A, B) = \frac{|A \cap B|_{S_1}}{|A \cup B|_{S_1}}$  is a possible STS measure based on Jaccard’s coefficient. However, the space of possible similarity functions that can be built from cardinalities  $|A|_{S_1}$ ,  $|B|_{S_1}$ ,  $|A \cup B|_{S_1}$  and  $|A \cap B|_{S_1}$  is huge. We explore a limited portion of this space by generating similarity function expressions from a set of 11 factors (see Table 1). Parameter  $c$  in Table 1 represents the sub-index for identifying the possible cardinality function,  $c \in \{S_1, S_2, S_3, S_4, 300, 50\}$ . The set of expressions used for combining these factors is heuristic but motivated by the formulations of existing cardinality-based similarity measures (e.g. Jaccard, Dice, matching, cosine among others). For each one of the six cardinality functions, these factors were combined into expressions that generate a total of  $11 \times 10 = 110$  features of the form  $\frac{f_i}{f_j}$ ;  $i \neq j$ .

## 7 Feature Selection

The feature selection process consists in selecting the  $k$ -best features from the set of 110 features for each cardinality function. We used the method *SelectKBest*<sup>5</sup> from the *Scikit-learn* machine learning kit (Pedregosa, Fabian et al., 2011). The data used for this selection process was the concatenation of 20 STS datasets labeled with gold standard from the past SemEval campaigns from the years 2012 to 2015 (14,437 sentence pairs with gold standard annotations). The process was performed using 10-fold cross-validation repeating the selection ten times with different randomly selected fold partitions. The  $k$  features that were selected the most

<sup>5</sup>[http://scikit-learn.org/stable/modules/generated/sklearn.feature\\_selection.SelectKBest.html](http://scikit-learn.org/stable/modules/generated/sklearn.feature_selection.SelectKBest.html)

| Factor   | Expression <sup>†</sup>                    | Name                 |
|----------|--|----------------------|
| $f_1$    | $ A \cap B _c$                             | intersection         |
| $f_2$    | $ A \cup B _c$                             | union                |
| $f_3$    | $ A \Delta B _c$                           | symmetric diff.      |
| $f_4$    | $\min[ A _c,  B _c]$                       | minimum              |
| $f_5$    | $\max[ A _c,  B _c]$                       | maximum              |
| $f_6$    | $0.5 \times ( A _c +  B _c)$               | mean                 |
| $f_7$    | $\sqrt{ A _c \times  B _c}$                | geometric mean       |
| $f_8$    | $\sqrt{0.5 \times ( A _c^2 +  B _c^2)}$    | quadratic mean       |
| $f_9$    | $\sqrt[3]{0.5 \times ( A _c^3 +  B _c^3)}$ | cubic mean           |

| $f_{11}$ | 1.0  | 1.0                  |

<sup>†</sup>  $c \in \{S_1, S_2, S_3, S_4, 300, 50\}$

**Table 1:** Factors for rational similarity functions based on cardinality functions

times in the  $k$ -best selection after all runs were retained for the final model. Preliminary experiments suggest a good value for  $k$  is two, as determined using the overall STS system with the same data. Table 2 shows the selected features for each cardinality function and their results on the mean correlation performance measure as assessed under previous STS shared task evaluation settings. Although, none of the features outperformed the best official results, results of  $|*|_{S_1}$  and  $|*|_{300}$  cardinality functions are highly competitive. It is important to note that, in spite that the feature selection procedure is supervised, the selected features by themselves are inherently un-supervised.

## 8 Feature Combination

The 12 selected features showed in Table 2 were combined to produce predictions for our three participating runs. *Run1* and *run2* were SVR (support-vector regression) models with RBF kernel (Drucker, Harris et al., 1997) built with the 14,437 sentence pairs available for training. The difference between *run1* and *run2* is the values of the used SVR parameters  $C$  and  $\gamma$ . For *run1*, we used  $C = 0.6$  and  $\gamma = 0.004$ , which were obtained by optimizing the weighted average of Pearson correlations using each available STS dataset alternatively for testing and the remaining pairs for training. For *run2*, we used  $C = 53$  and  $\gamma = 0.012$ , which were obtained using all 14,437 sentence pairs as a single dataset

and 5-folds cross-validation in 5 randomly selected division folds.

Unlike *run1* and *run2*, *run3* was effectively unsupervised and operated by simply averaging the 12 feature values after multiplying by -1 the values of the features with negative correlations in Table 2.

## 9 Cross-lingual Sub-task

The predictions of the three runs submitted to the STS cross-lingual sub-task were produced using the same systems that produced predictions for the STS monolingual sub-task (English). For that, the texts in Spanish were translated into English using Google’s public translate service.<sup>6</sup>

## 10 Results

Table 3 shows results obtained with the same systems used to produce our runs 1, 2 and 3, but using datasets from STS competitions from 2012 to 2015. The results labeled as “held-out” were obtained by holding out each dataset for testing and using the remaining datasets for training including the three training datasets from 2012. The results labeled as “same-data” were obtained using the same training data available during each historical STS evaluation. All “held-out” systems outperformed consistently the best official results obtained by a single system for each year using the performance measure of weighted mean correlation. For the “same-data” systems, the *run1* outperformed historical official results from 2013 to 2015, while *run2* and *run3* made it only for 2013 and 2014. Table 4 shows results of the same systems (“held-out” testing setting) and the best official results obtained on each dataset of the 20 individual evaluation datasets from prior STS competitions. In this tougher comparison, the proposed systems obtained state-of-the-art results in 10 out of the 20 individual datasets, and competitive results for the majority of the remaining datasets. Finally, Table 5 and Table 6 show the results obtained by our systems on the 2016 datasets along with the best official results of the competition. When comparing our three runs, none of them was consistently better with the three runs typically obtaining similar results. Therefore, it is possible to conclude that the

contribution of SVR was not considerable, with an exception for the *answer-answer* dataset.

## 11 Conclusion

The proposed STS system combined effectively the most popular resources used by the top systems during the SemEval 2015 for STS shared task. Results show that the proposed system outperformed all past systems in a per-system based comparison, and obtained state-of-the-art results in half of the datasets from past STS competitions at SemEval.

# RTM at SemEval-2016 Task 1: Predicting Semantic Similarity with Referential Translation Machines and Related Statistics

Ergun Biçici

ergunbicici@yahoo.com  
bicici.github.com

## Abstract

We use referential translation machines (RTMs) for predicting the semantic similarity of text in both STS Core and Cross-lingual STS. RTMs pioneer a language independent approach to all similarity tasks and remove the need to access any task or domain specific information or resource. RTMs become 14th out of 26 submissions in Cross-lingual STS. We also present rankings of various prediction tasks using the performance of RTM in terms of MRAER, a normalized relative absolute error metric.

## 1 Semantic Agreement

We participated in Semantic Textual Similarity task at SemEval-2016 (Bethard et al., 2016) with RTMs. RTMs identify translation acts between any two data sets with respect to interpretants, data close to the task instances, effectively judging monolingual and bilingual similarity. We use RTMs for predicting the semantic similarity of text. Interpretants are used to derive features measuring the closeness of the test sentences to the training data, the difficulty of translating them, and the presence of the acts of translation, which may ubiquitously be observed in communication.

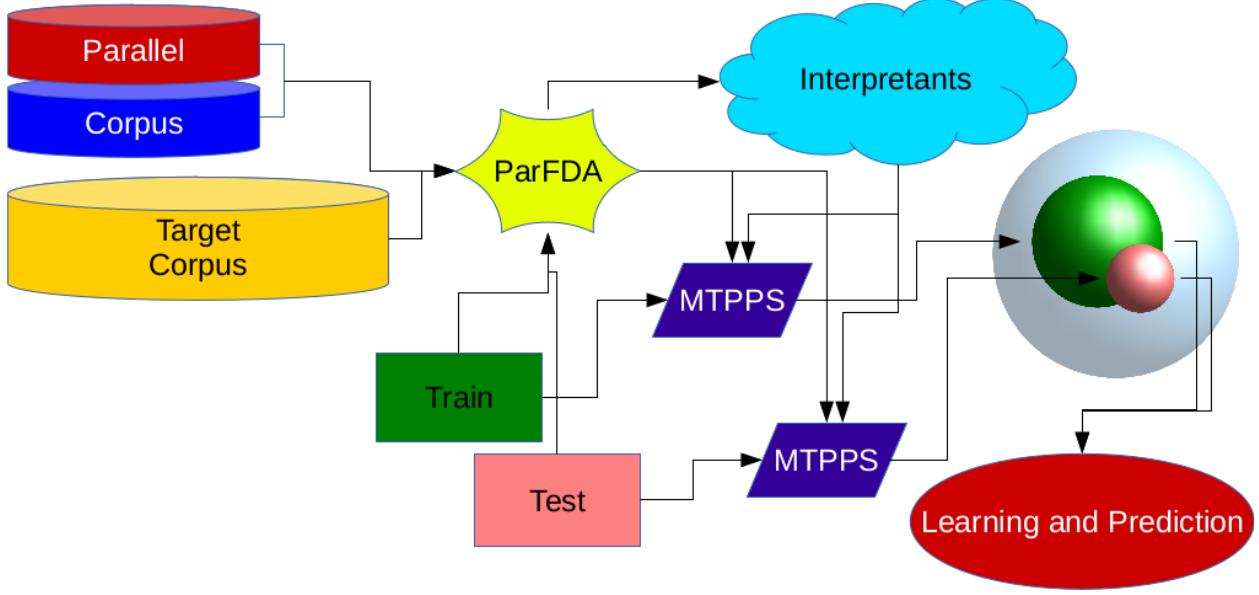

Semantic Web’s dream is to allow machines to share, exploit, and understand knowledge on the web. As more and more shared conceptualizations of domains emerge, we get closer to this goal. Semantic textual similarity (STS) task (Agirre et al., 2016) at SemEval-2016 (Bethard et al., 2016) is about quantifying the degree of similarity between

two given sentences  $S_1$  and  $S_2$  in the same language (English) in STS Core (STS English) or in different languages (English or Spanish) in Cross-lingual STS (STS Spanish), with a real number in [0, 5].  $S_1$  and  $S_2$  may be constructed using different models and with different conceptualizations of the world or different ontologies and different vocabulary. Even if two instances are categorized as same, they may have different implications for commonsense reasoning (both albatros and penguin are a bird) (Biçici, 2002).

The existence of a single ontology that can cover all the required conceptual information for reaching semantic understanding is questionable because it would presume an agreement among all ontology experts. Yet, semantic agreement using heterogeneous ontologies may not be possible as well since in the most extreme case, they would not use the same tokens. Therefore, semantic textual similarity is harder than the Chinese room thought experiment (Internet Encyclopedia of Philosophy, 2016) since we are not given any instructions about how to answer queries. Our goal is to quantify the level of semantic agreement between  $S_1$  and  $S_2$  and RTMs use interpretants, data close to the task instances for building prediction models for semantic similarity.

## 2 Referential Translation Machine

Each RTM model is a data translation prediction model between the instances in the training set and the test set and translation acts are indicators of the data transformation and translation based on accurate and language independent results in both monolingual (Biçici and Way, 2015) and bilingual set-

**Figure 1:** RTM depiction: ParFDA selects interpretants close to the training and test data using parallel corpus in bilingual settings and monolingual corpus in the target language or just the monolingual target corpus in monolingual settings; an MTPPS use interpretants and training data to generate training features and another use interpretants and test data to generate test features in the same feature space; learning and prediction takes place taking these features as input.

**Table 1:** Number of instances in the STS test set. Only some of the instances are actually evaluated (eval. row).

tings (Biçici et al., 2015b). Our encouraging results in the semantic similarity tasks increase our understanding of the acts of translation we ubiquitously use when communicating and how they can be used to predict semantic similarity. RTMs are powerful enough to be applicable in different domains and tasks with good performance.

Figure 1 depicts RTMs and explains the model building process. Given a training set  $\text{train}$ , a test set  $\text{test}$ , and some corpus  $\mathcal{C}$ , preferably in the same domain, the RTM steps are:

1.  $\text{select}(\text{train}, \text{test}, \mathcal{C}) \rightarrow \mathcal{I}$
2.  $\text{MTPP}(\mathcal{I}, \text{train}) \rightarrow \mathcal{F}_{\text{train}}$
3.  $\text{MTPP}(\mathcal{I}, \text{test}) \rightarrow \mathcal{F}_{\text{test}}$
4.  $\text{learn}(M, \mathcal{F}_{\text{train}}) \rightarrow \mathcal{M}$
5.  $\text{predict}(\mathcal{M}, \mathcal{F}_{\text{test}}) \rightarrow \hat{y}$

RTMs use ParFDA (Biçici et al., 2015a) for instance selection and machine translation performance prediction system (MTPPS) (Biçici and Way, 2015) for generating features.

We use support vector regression (SVR) for building the predictor in combination with feature selection (FS) and partial least squares (PLS). Assuming that  $\hat{\mathbf{y}}, \mathbf{y} \in \mathbb{R}^n$  are the prediction and the target respectively, evaluation metrics we use are defined in Equation (1) where metrics are Pearson's correlation ( $r$ ), mean absolute error (MAE), relative absolute error (RAE), relative Pearson's correlation ( $r_R$ ), MAER (mean absolute error relative), and MRAER (mean relative absolute error relative).

We use MAER and MRAER for easier replication and comparability. MAER is the mean absolute error relative to the magnitude of the target and MRAER is the mean absolute error relative to the absolute error of a predictor always predicting the target mean assuming that target mean is known (Biçici and Way, 2015).  $\lfloor \cdot \rfloor_\epsilon$  caps its argument from below to  $\epsilon$  where  $\epsilon = \text{MAE}(\hat{\mathbf{y}}, \mathbf{y})/2$ , which represents half of the score step with which a decision about a change in measurement's value can be made.

**Table 3:** STS Spanish test results.

### 3 SemEval-16 STS Results

$$\begin{aligned}
 r &= \frac{\sum_{i=1}^n (\hat{y}_i - \bar{y})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (\hat{y}_i - \bar{y})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \\
 \text{MAE}(\hat{\mathbf{y}}, \mathbf{y}) &= \frac{\sum_{i=1}^n |\hat{y}_i - y_i|}{n} \\
 \text{RAE}(\hat{\mathbf{y}}, \mathbf{y}) &= \frac{\sum_{i=1}^n |\hat{y}_i - y_i|}{\sum_{i=1}^n |\bar{y} - y_i|} \\
 r_R &= \frac{\sum_{i=1}^n \left( \frac{\hat{y}_i - \bar{y}}{\lfloor |y_i| \rfloor_\epsilon} \right) \left( \frac{y_i - \bar{y}}{\lfloor |y_i| \rfloor_\epsilon} \right)}{\sqrt{\sum_{i=1}^n \left( \frac{\hat{y}_i - \bar{y}}{\lfloor |y_i| \rfloor_\epsilon} \right)^2} \sqrt{\sum_{i=1}^n \left( \frac{y_i - \bar{y}}{\lfloor |y_i| \rfloor_\epsilon} \right)^2}} \\
 \text{MAER}(\hat{\mathbf{y}}, \mathbf{y}) &= \frac{\sum_{i=1}^n \frac{|\hat{y}_i - y_i|}{\lfloor |y_i| \rfloor_\epsilon}}{n} \\
 \text{MRAER}(\hat{\mathbf{y}}, \mathbf{y}) &= \frac{\sum_{i=1}^n \frac{|\hat{y}_i - y_i|}{\lfloor |\bar{y} - y_i| \rfloor_\epsilon}}{n}
 \end{aligned} \tag{1}$$

We compare different tasks in Table 9 with evaluation results that are calculated relative to the magnitude of each target score instance.  $r$  multiplies distance of  $\hat{y}_i$  and  $y_i$  to their own means (Equation (1)). We obtain normalized correlation,  $r_R$ , using  $\epsilon = \sigma(\mathbf{y})/2$ .

SemEval-2016 STS contains sentence pairs from different domains: answer-answer, headlines, plagiarism, postediting, question-question for English and multisource and newswire for Spanish. Official evaluation metric in STS is the Pearson’s correlation score. Table 1 lists the number of instances in the test set where only some of the instances are actually evaluated.

We build individual RTM models for each subtask. Our team name is RTM. Interpretants are selected from the corpora distributed by the translation task of WMT16 (Bojar et al., 2016) and they consist of monolingual sentences used to build the LM and parallel sentence pair instances used by MTPPS to derive features and for word alignment features. We use monolingual corpora in English for STS English to select interpretants and also for STS Spanish shuffled dataset, which is the official format that was made available to the participants.

We used English-Spanish parallel corpus and English and Spanish monolingual corpora for our STS Spanish experiments in Section 4 after the challenge using the language identified version. We built RTM models using 200 thousand sentences for training data and 5 million sentences for the language model, which corresponds to the fixed training set size setting in (Biçici and Way, 2015). We identified numeric expressions using regular expressions as a pre-processing step, which replaces them with a label. For training RTM models for STS Spanish, we use STS English training data and STS Spanish data from SemEval-2015 after scaling the scores to range

| Task  | Setting   |     | $r$         | MAE           | RAE          | MAER          | MRAER |

**Table 5:** STS English test results for each domain from new experiments. Domain % numerics lists the percentage of tokens classified as numerics in each domain.

[0, 5].

Table 2 and Table 3 list the results on the test set. Ranks are out of 26 submissions in STS Spanish. We also observe that  $r$  over all of the test set, which does not compute the weighted average of  $r$  according to the number of instances in each domain can differ from the weighted  $r$  scores.

## 4 Experiments After the Challenge

In this section, we detail the training performance of our model based on major modeling differences with our previous RTM models on SemEval tasks (Biçici and Way, 2015). This year, we identified numeric expressions using regular expressions as a pre-processing step, which mainly identifies integers and real numbers that can have exponents. After sending the test results, we further worked on the numeric expression identification to expand the types of identified expressions. We also experimented with language identification for STS Spanish. Language identification is done using the manually corrected results starting from the output of automatic language identification tool mguesser.<sup>1</sup> After language identification, corpora were split into English and Spanish rather than the shuffled format that was made available to the participants. We compare the performance after identification of numeric expressions and identification of the language using SVR. Both STS Spanish models use previous years’ training data from both STS English and STS Spanish for training, which total to 13823 instances.

<sup>1</sup><http://www.mnogosearch.org>

Table 4 and Table 5 presents the results before and after identification of numerics on STS English. We observe that identification of numerics improve the performance on the test set (**bolded** results).

Table 6 presents the results on STS Spanish with the default shuffled setting and with the setting where we model the prediction as machine translation performance prediction from English to Spanish after identifying the language of each sentence in the training set. STS Spanish training dataset contains English sentences in majority and shuffled +numerics setting only use English corpora even though Spanish sentences are shuffled in the test set and eventually, shuffled +numerics setting obtains better results than language identified +numerics setting on the training set. Even so, we observe that identification of the language improve the performance on the test set (**bolded** results). Training results on setting language identified +numerics is lower, which may be due to the RTM model using language identified test corpus and the same training corpus as the shuffled +numerics setting.

Table 8 plots the performance on the test set where instances are sorted according to the magnitude of the target scores. For STS English, we observe decreasing AER and a valley of absolute errors, which may be due to SVR preferring predictions close to the mean of train score distribution.

## 5 RTMs Across Tasks and Years

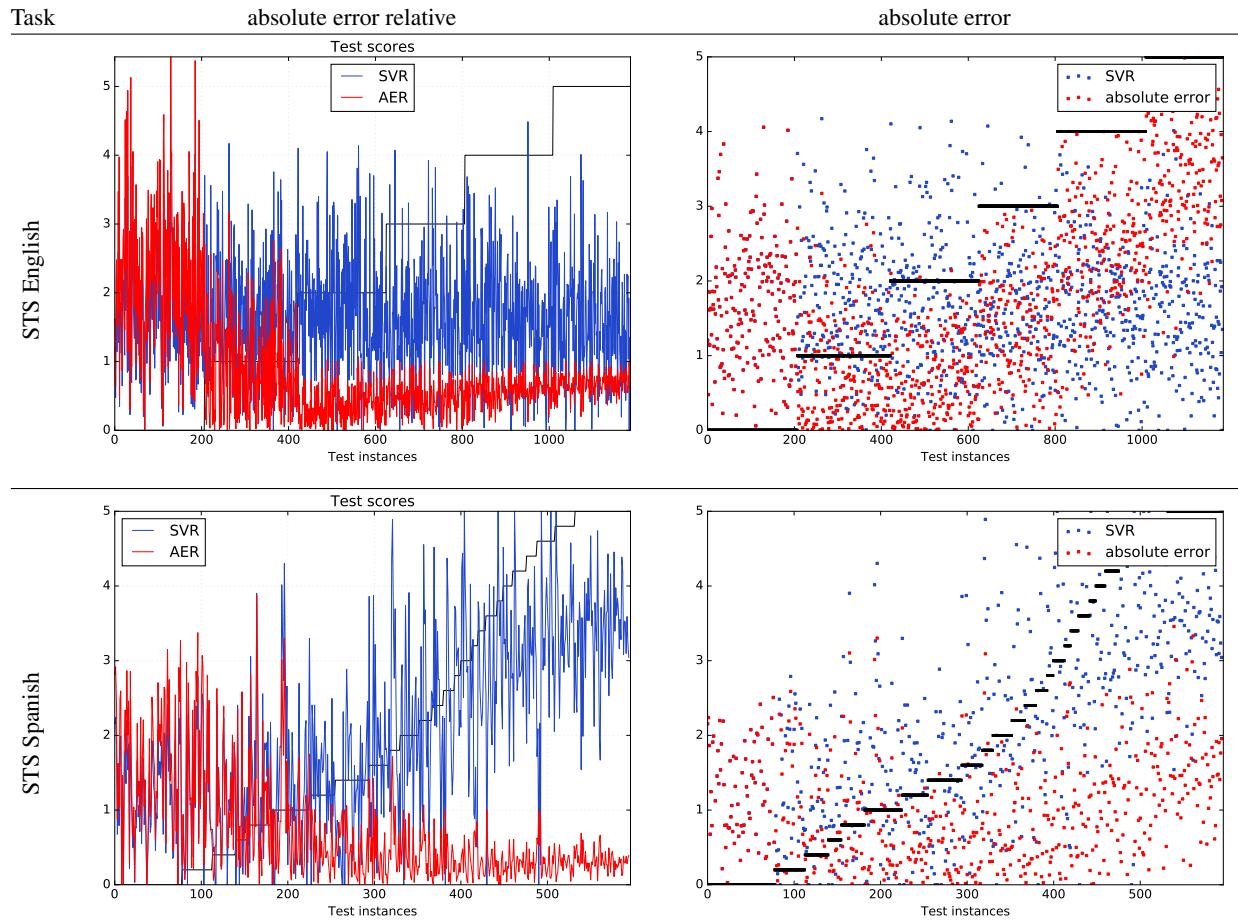

We compare the difficulty of various prediction tasks where RTMs participated (Biçici and Way, 2015) ac-

| Task  | Setting                       |     | $r$           | MAE           | RAE          | MAER          | MRAER        |
|-------|-------------------------------|-----|---------------|---------------|--------------|---------------|--------------|
| train | shuffled +numerics            | SVR | 0.72          | 0.8224        | 0.639        | 0.4864        | 0.718        |

**Table 7:** STS Spanish test results from new experiments.

**Table 8:** RTM SVR performance on the test set in STS 2016. Left figure in each row is the absolute error relative to the magnitude of the target (AER) and the right figure is the absolute error.

cording to MRAER in Table 9. MAER and MRAER considers both the predictor’s error and the fluctuations of the target scores at the instance level, which is at the sentence level in STS 2016. The best results are obtained for the CLSS 2014 paragraph-to-

sentence subtask, which may be due to the larger contextual information that paragraphs can provide for the RTM models. We observe that the performance in STS improved in 2016 compared to STS in previous years. Table 9 can be used to eval-

ate the difficulty of various tasks and domains based on RTM. We separated the results having MRAER greater than 1 as in these tasks and subtasks RTM does not perform significantly better than the mean predictor, and fluctuations render these as tasks that may require more work. Our findings are negative towards re-use of those datasets and results obtained without further work. STS Spanish is able to achieve MRAER less than 1 in 2016. We also note that RTMs achieve the top result in both CLSS 2014 (Jurgens et al., 2014) and in all QET tasks in Table 9, including the QET 2015 German-English METEOR task (Bojar et al., 2015).

## 6 Contributions

Referential translation machines pioneer a clean and intuitive computational model for automatically measuring semantic similarity by measuring the acts of translation involved. We show that identification of numeric expressions in STS English and identification of the language in STS Spanish improve the performance on the test set. RTM test performance on various tasks sorted according to MRAER can identify which tasks and subtasks and the datasets provided are mature enough for further results.

## Abstract

This paper describes our system submission to the SemEval 2016 English Semantic Textual Similarity (STS) shared task. The proposed system is based on the compositional text similarity model, which aggregates pairwise word similarities for computing the semantic similarity between texts. In addition, our system combines word importance and word similarity to build an importance-similarity matrix. Three different word similarity measures are used in our three submitted runs. The evaluation results show that taking into account context dependent word importance information improves performance. However, the performance of the system varies drastically between different evaluation subsets. The best of our submitted runs achieves rank 60th with weighted mean Pearson correlation to human judgements of 0.6892.

## 1 Introduction

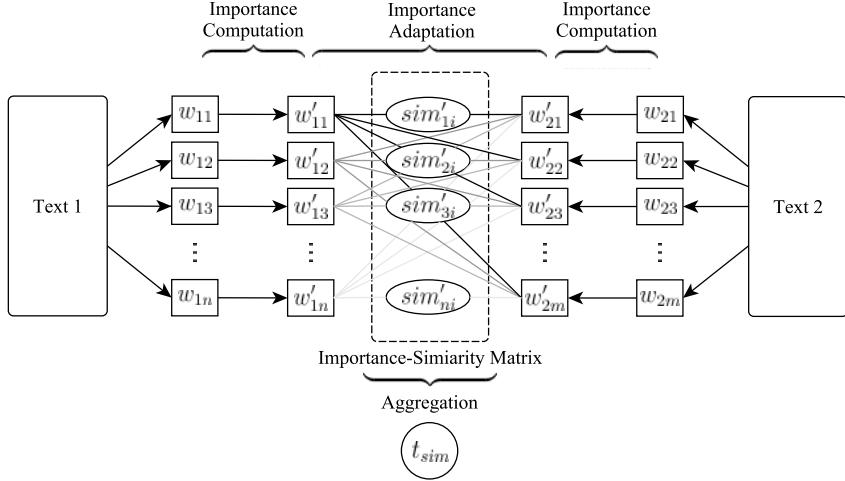

Semantic Textual Similarity (STS) measures the degree of equivalence in the underlying semantics of paired natural language texts. It is an extensively researched problem with applications widely used in many research areas including natural language processing, information retrieval, and text mining. The STS task has been held annually since 2012 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirrea et al., 2015) to encourage research into understanding sentence-level semantics. Systems for this task compute semantic similarity scores for paired text snippets. Performance is evaluated by

**Figure 1:** The general procedure of the compositional text similarity measures. They take three general steps: tokenize the input text, compute pairwise word similarities between all words, and aggregate the resulting scores to a sentence level textual similarity score.  $\{w_{11}, w_{12}, \dots, w_{1n}\}$  and  $\{w_{21}, w_{22}, \dots, w_{2m}\}$  are the tokenized words from Text 1 and Text 2, respectively. Each node in the middle represents a vector of pairwise similarity values computed by one word from Text 1 and all distinct words from Text 2.

the Pearson correlation between the system scores and human judgements.

This paper describes our system submission to the SemEval 2016 STS shared task (Agirre et al., 2016). The proposed system is based on the compositional text similarity model, which have been broadly researched in the literature by (Mihalcea et al., 2006; Li et al., 2006; Islam and Inkpen, 2006; Ho et al., 2010; Islam et al., 2012; Bär, 2013). The compositional text similarity model makes use of word-level

**Figure 2:** The procedure of the proposed importance-aware similarity measure. The general compositional procedure in Fig. 1 uses context independent similarity value. In addition, this measure takes into account context dependent word importance information. It first computes the word importance value  $w'$  using Eq. 3 and adapted into every entry  $sim'$  in the importance-similarity matrix using Eq. 4.

similarity values as the building blocks to compute sentence-level semantics. Computing textual similarity using this approach proceeds as follows: tokenize the input text, compute pairwise word similarities between all words, and aggregate the resulting scores to a sentence level textual similarity score. State-of-the-art word similarity measures can be used in this model to provide context independent word relatedness. However, words can be more or less important depending on the contexts in which they appear.

We extend traditional compositional models with an importance term for each word. Our three submitted runs use this extended model in combination with three different word similarity measures: Google Trigram Method (Islam et al., 2012), Skipgrams word embedding (Mikolov et al., 2013), and GloVe word embedding (Pennington et al., 2014). The evaluation results show that including matching importance information improves the performance of compositional models on most of the evaluation sets for STS 2015 and 2016. However, the relative performance of our systems varies dramatically when comparing against other systems submitted to the shared task. The best of our submitted runs achieves rank 60th with weighted mean Pearson correlation of 0.6892 with human judgements.

The rest of the paper is organized as follows: Section 2 describes the details of the submitted sys-

tems. Section 3 shows the experimental results for our three runs using evaluation data from SemEval 2015 and 2016. Section 4 summarizes our observations and concludes.

## 2 System Description

Our proposed approach takes advantage of the compositional model while also taking the importance of words into consideration. It first computes the matching importance, which characterizes the importance of a word in a particular text pair similarity computation. Instead of building the similarity matrix used by the traditional compositional approach (Fig. 1), we construct an alternative importance weighted similarity matrix. The importance weighted similarity values are then used when computing the overall textual similarity score.

### 2.1 Text Preprocessing

The input texts are tokenized using the Penn Treebank tokenization with additional rules from Google.<sup>1</sup> Punctuation and the 33 most common English words are filtered because these tokens contribute little to the semantic meaning of a text. Then, we lemmatized the remaining words taking into account their POS tags. The preprocessed input text

<sup>1</sup>Described in Section 2.2 on  
<https://catalog.ldc.upenn.edu/docs/LDC2006T13/readme.txt>

is represented by these lemmas. POS tagging and lemmatization use NLTK toolkit.<sup>2</sup>

## 2.2 Word Similarity Computation

Word similarities are the core building blocks in compositional text similarity measures. Our three different runs each explore using a different word similarity algorithm.

Google Trigram Method (Islam et al., 2012) is an unsupervised statistical similarity measure that can be applied to word pairs. This word similarity method characterizes the co-occurrence feature using the frequencies of trigrams starting and ending with a word pair. It is computed using the following formula:

$$\varphi'(w_1, w_2) = \frac{\frac{1}{2}(f_n(w_1, w_2) + f_n(w_2, w_1))}{\min(f(w_1), f(w_2))}, \quad (1)$$

$$\frac{f(w_1)}{f_{\max}} \cdot \frac{f(w_2)}{f_{\max}}$$

where  $f_n(w_1, w_2)$  indicates the total frequency of  $n$ -grams starting with  $w_1$  and ending with  $w_2$ .  $f(w)$  stands for the word (i.e. uni-gram) frequency of  $w$  and  $f_{\max}$  is the largest word frequency in the corpus. Then, the following normalization function is applied to Eq. 1 to bound the word similarity values in range  $[0, 1]$ :

$$sim(w_1, w_2) = \begin{cases} \frac{\log \varphi'(w_1, w_2)}{-2 \times \log \frac{\min(f(w_1), f(w_2))}{C_{\max}}} & \text{if } \log \varphi'(w_1, w_2) > 1 \\ \frac{\log 1.01}{-2 \times \log \frac{\min(f(w_1), f(w_2))}{f_{\max}}} & \text{if } \log \varphi'(w_1, w_2) \leq 1 \\ 0 & \text{if } f_n(w_1, w_2) + f_n(w_2, w_1) = 0. \end{cases} \quad (2)$$

We use the efficient implementation of this method described in Mei et al. (2015).

Skip-grams (Mikolov et al., 2013) is a neural network model for learning word embeddings. Word embeddings are trained using a model that attempts to discriminatively predict word co-occurrences within a fixed context window. The resulting word embedding vectors have been shown to be effective at capturing word-level semantic information. We use the pre-trained vectors that were learned on a part

---

<sup>2</sup><http://www.nltk.org/>

of Google News dataset (about 100 billion words).<sup>3</sup>

GloVe (Pennington et al., 2014) is an unsupervised learning algorithm for word embeddings. The method learns word embedding vectors using a model that predicts global word co-occurrence statistics extracted from a corpus. We use the pre-trained vectors built using the Wikipedia 2014 dump and the English Gigaword Fifth Edition.<sup>4</sup>

For Skip-gram and GloVe, we use cosine similarity to compute pairwise similarity value.

## 2.3 Matching Importance Computation

We define matching importance as a function that characterizes the importance of a word in a particular textual similarity computation. Given  $w$  in one text and  $w_1, w_2, \dots, w_n$  in the other text, the matching importance of  $w$  is computed by this expression:

$$imp(w) = \alpha \cdot \mu(S) + \beta \cdot \sigma(S) \quad (3)$$

$$s.t. \quad S = \{s \mid s = sim(w, w_i), 1 \leq i \leq n\},$$

where function  $\mu$  and  $\rho$  stands for the mean and standard deviation of a set of values. This expression is used in Islam et al. (2012) for selecting important matchings. The mean of similarities is an indicator of semantic relatedness, whereas the standard deviation indicates distinctiveness. We take the weighted sum of both features as the final importance score. In our system submissions, we set  $\alpha = \beta = 1$ .

## 2.4 Matching Importance Adaptation

To incorporate the importance information, we re-scale the pairwise word-level similarity scores by the minimum of the context dependent importance scores for the words being compared:

$$sim'(w_i, w_j) = sim(w_i, w_j) \cdot \min(imp(w_i), imp(w_j)). \quad (4)$$

## 2.5 Textual Similarity Computation

Given a preprocessed text pair, we count ( $\delta$ ) and remove the identical words in both texts. Let the

remaining words be  $T_1 = \{w_{11}, \dots, w_{1n}\}$  and  $T_2 = \{w_{21}, \dots, w_{2m}\}$ , we construct an importance weighted similarity matrix  $M_{n \times m}$ . Prior work suggests that only using the most important entries in the matrix may suppress interference during semantic analysis. (Mihalcea et al., 2006; Islam and Inkpen, 2008; Islam et al., 2012) Thus, we set up a threshold  $t_i$  to filter the less important matchings in the  $i$ th row of the matrix:

$$t_i = \mu(S') + \rho(S') \quad (5)$$

$$s.t. \quad S' = \{s \mid s = sim'(w_{1i}, w_{2j}), 1 \leq j \leq m\}.$$

The textual similarity between two sentences is computed as follows in Eq. 6:

$$t_{sim} = \frac{(\delta + \sum_{1 \leq i \leq n} \mu(S))(n + m + 2\delta)}{2(n + \delta)(m + \delta)} \quad (6)$$

$$s.t. \quad S = \{s \mid s = sim'(w_{1i}, w_{2j}), s \geq t_i, 1 \leq i \leq n, 1 \leq j \leq m\}.$$

$sim'$  is the importance weighted similarity from Eq. 4.  $n + \delta$  and  $m + \delta$  are the lengths of two pre-processed texts. The textual similarity score ranges within [0, 1].

### 3 Evaluation

We evaluated our three system submissions using the STS 2015 and 2016 evaluation datasets. The SemEval 2015 and 2016 datasets contain test sentence pairs distributed across nine domains. Each

pair was assigned a similarity scores in the range [0, 5] by multiple human annotators. The performance of our three system submissions is shown in Table 2 and 3. Recall that our three systems only differ in the method they use for assessing lexical similarity: Google Trigram Method (*GTM*), Word2vec (*W2V*), and *GloVe*. Systems that make use of matching importance are tagged with *+IAC*. Otherwise, the system directly uses pairwise similarity values to compute the aggregate similarity score using Eq. 6. Note that systems with the proposed matching importance approach perform consistently better than the original compositional model in most of the domain subsets. This shows that adding an importance feature can effectively improve the performance of the compositional model. However, comparing against the average system performance in each domain, the performance of our submitted systems vary dramatically in their relative performance to systems submitted by other participating teams. For example, our systems perform well on the postediting dataset and dramatically worse, even relative to other systems, on the question-question data. This suggests that the proposed system may have an implicit domain specific bias.

### 4 Conclusions and Future Work

In this paper, we present an Importance-Aware Compositional Approach to STS and its evaluation during the SemEval 2016 STS shared task. Experimental results show that the proposed approach performs consistently better than matched compositional similarity models that do not take importance into account. In future work, it would be useful to investigate a more robust weighting scheme for word importance, incorporating syntactic analysis of texts and using external knowledge-bases for word sense disambiguation.

### Acknowledgments

The research was funded in part by the Natural Sciences and Engineering Research Council of Canada (NSERC), and The Boeing Company.

**Table 2:** Evaluation result for SemEval 2015 STS dataset. Both the compositional model and the proposed model (systems with +IAC) are implemented with three word similarity measures: *GTM*, *W2V*, and *GloVe*. In most of the comparison experiments, the proposed model gets higher Pearson correlation than the original compositional model with the same setting. However, the performance of our submitted systems varies dramatically comparing with the average system performance in different domain subsets.
